The magnitude of the spots, and the scale on which their movements are performed, are not the least remarkable circumstances connected with the phenomena. At the distance of the sun, a line which subtends an angle of one second is equal to about 460 miles, and a circle of that diameter has an area of about 166,000 miles; and this is the smallest space which can be distinctly discerned on the sun's disc. But a spot was observed by Mayer having a diameter equal to 1-20th of the diameter of the sun, or upwards of 96″, and consequently (supposing it to be circular) covering an area of 1520 millions of square miles, — upwards of 30 times the whole surface of the earth.

Numerous hypotheses have been formed respecting

the solar spots. Scheiner supposed them to be planets revolving at no great distance from the sun's surface. Galileo and Hevelius conceived them to be a sort of *scoriæ* or *scum* formed at the surface of the sun, and floating in an ocean of liquid matter. Lahire supposed them to be protuberant parts of solid, opake, and irregular masses, floating in the fluid matter of the sun. Dr. Wilson, of Glasgow, accounted for the spots by supposing the sun to consist of a dark nucleus, covered to a certain depth by luminous matter, through which cavities or gulfs are made by volcanic or other actions, and permit the dark nucleus to be seen. Lalande suggests that the spots or opake bodies may be merely the summits of mountains, usually covered by the igneous fluid, but which, by the flux and reflux of the fluid, sometimes protrude beyond its surface, and thus become visible. (*Astronomie*, art. 3240.) The most probable view, however, is that taken by Sir William Herschel, who considers "the luminous strata of the atmosphere to be sustained far above the level of the solid body by a transparent elastic medium, carrying on its upper surface (or rather at some considerably lower level within its depth) a cloudy stratum, which, being strongly illuminated from above, reflects a considerable portion of the light to our eyes, and forms a penumbra, while the solid body shaded by the clouds reflects none. The temporary removal of both the strata, but more of the upper than the lower, he supposes effected by powerful upward currents of the atmosphere, arising, perhaps, from spiracles in the body, or from local agitations." (*Sir J. Herschel's Astronomy*, p. 209.)

Physical Constitution of the Sun. — Respecting the physical nature of the enormous mass of matter which controls the motions of all the bodies of the solar system, and supplies them with light and heat, we can only form conjectures, guided in a feeble degree by the phenomena of the spots. According to the hypothesis broached by Sir William Herschel, as stated in the above quotation, there are two regions of solar clouds; the inferior stratum being opake, and probably resembling our own atmosphere; while the upper stratum is the repository of light and heat, which emanate from it in all directions. This upper luminous stratum he supposed to have an altitude of between 1840 and 2765 miles above the surface of the sun. The lower stratum, by reflecting a considerable portion of the rays which fall upon it from the luminous clouds above, not only increases the quantity of light which the latter send forth into space, but serves as a canopy to screen the surface of the solid body of the sun from the scorching effects of the surrounding regions of light and heat; and he supposed its density might even be such as to maintain a temperature at the actual surface of no greater elevation than is consistent with the support of animal life. But whatever may be the state of the temperature at the actual surface, of which only casual glimpses are obtained through openings in the luminous clouds, it is difficult to conceive that the luminous matter can be otherwise than in a state of the most intense ignition. "That the temperature," says Sir John Herschel, "at the visible surface of the sun cannot be otherwise than very elevated, much more so than any artificial heat produced in our furnaces, or by chemical or galvanic processes, we have indications of several kinds. 1st, From the law of decrease of radiant heat and light, which being inversely as the squares of the distances, it follows that the heat received on a given area exposed at the distance of the earth, and on an equal area at the visible surface of the sun, must be in proportion to the area of the sky occupied by the sun's disc to the whole hemisphere, or as 1 to about 300,000. A far less intensity of solar radiation, collected in the focus of a burning-glass, suffices to dissipate gold and platina in vapour. 2dly, From the facility with which the calorific rays of the sun traverse glass, — a property which is found to belong to the heat of artificial fires in the direct proportion of their intensity. 3dly, From the fact that the most vivid flames disappear, and the most intensely ignited solids appear only as black spots upon the disc of the sun when held between it and the eye." (*Astronomy*, p. 210.)

These circumstances give great probability to the supposition that luminous matter which surrounds the body of the sun has a temperature far exceeding any which can be produced by artificial means; but the sciences of light and heat are not yet sufficiently advanced to enable us to arrive at any certain conclusions on the subject, or to form other than purely conjectural hypotheses respecting the nature and constitution of the sun. "The great mystery," continues Sir John Herschel, "is to conceive how so enormous a conflagration (if such it be) can be kept up. Every discovery in chemical science here leaves us completely at a loss, or rather seems to remove farther the prospect of probable explanation. If conjecture might be hazarded, we should look rather to the known possibility of an indefinite generation of heat by friction, or to its excitement by the electric discharge, than to any actual combustion of ponderable fuel, whether solid or gaseous, for the origin of the solar radiation." (P. 212.)

Considering the enormous and incessant emanation of light and heat from the sun, the question has often arisen whether the volume of the sun undergoes any diminution. If the high temperature is kept up either by electric currents, or by friction, as above suggested, no loss of volume would be sustained; but if, according to the hypothesis of Newton, light is produced by the actual emission of luminous particles, a diminution of volume would appear to be a necessary consequence. Observation, however, can afford us no information on this head; for, supposing an actual diminution to be going on at such a rate as to lessen the diameter by two feet in 24 hours (which, having regard to the sun's magnitude, may be considered as enormous), 3000 years would elapse before the diminution of the apparent diameter would amount to a single second. Buffon supposed the sun to be an immense furnace, alimented by comets precipitating themselves into it from time to time.

Atmosphere of the Sun. — The existence of a solar atmosphere was inferred by Bouguer from a comparison of the intensity of radiation at different points of the disc. By reason of the globular figure of the sun, a much larger portion of the surface towards the border is comprehended under a given visual angle than at the centre; and, as every point of the surface must be supposed to radiate equally in all directions, it follows that the intensity of light near the border should be greater than at the centre in proportion to the greater extent of surface comprised under the same angle. Bouguer's observations, however, led him to infer that the light from the centre of the disc had a greater intensity than that which proceeded from the borders, — a circumstance which would be explained on the supposition of its being absorbed in a greater proportion by having to traverse a greater extent of atmosphere. But the more delicate experiments of Arago have shown that all the points of the disc are equally luminous; so that the hypothesis of an atmosphere, however probable on other grounds, is not supported by such observations. The existence of a solar atmosphere is, however, indicated by the faint light observed round the sun's limb in a total eclipse; and, perhaps, still more unequivocally by the phenomenon of the zodiacal light. *See* ZODIACAL LIGHT.

Sun's Position and proper Motion in the Heavens. — The discoveries in sidereal astronomy which have been made in modern times, all tend to establish the hypothesis of a similarity of condition and a community of nature between the sun and the fixed stars. The prevalence of gravitation among these remote bodies, following the same law as is observed in the solar system, is no longer a matter of speculation; the proof being afforded by the elliptic orbits described by so many of the double stars about their common centre of gravity. With respect to the place which the sun occupies in the heavens, we have, says Sir J. Herschel (*Mem. Royal Astron. Society*, vol. xi.), almost ocular evidence that our system is excentrically situated within the nebula of the *Milky Way*, and nearer to its southern than to its northern portion. It was also an opinion of Sir William Herschel, that the sun, like many of the fixed stars, has a proper motion in space, in consequence of which it is at present advancing towards a point of the heavens within the constellation *Hercules*. That the sun does not remain absolutely at rest in space, but has a proper motion in *some* direction, may be regarded as not only highly probable, but almost certain; but many centuries of observation may be required to enable astronomers to detect its laws, or even to arrive at any definite conclusions respecting its direction or the remote centre about which it is performed. (*Sir J. Herschel's Astronomy*; Lalande, tom. iii.; Biot, *Astronomie Physique*; Laplace, *Système du Monde*; Delambre, *Astronomie*, &c.) *See* STAR.

SUNDAY, the first day of the week, is said to derive its name from the Saxons, who consecrated it to the sun in heathen times. The solemnization of this day dates from the earliest age of the Christian church, in memory of the death of Christ, and of the descent of the Holy Ghost, both of which events took place upon it. The Jewish Christians retained at the same time their Sabbath, the last day of the week; but this practice became obsolete early, at least in the Western church. The Sunday was at first distinguished merely by peculiar prayers and passages of the Scriptures. It does not appear to have been strictly observed as a day of cessation from labour before the reign of Constantine. By the decree of that emperor (A. D. 321) public business, and military exercises, were suspended. The council of Laodicea (A. D. 360) forbade labour in general terms; and the laws of Theodosius (circ. A. D. 420) sanctioned this interdiction by civil penalties. *See* SABBATH.

SUNDAY LETTER. *See* DOMINICAL LETTER.

SUNNIAH. (Arab. *a troop*, or *band*.) The name given to the sect commonly considered as orthodox among the Mussulmans by the followers of Ali. The

latter believe that the sovereign imâmship, or imaginary dignity which conveys supremacy over all the faithful, belongs of right to the descendants of Ali, son-in-law of Mohammed. The schism between these two sects has subsisted from the earliest times of Mohammedanism; when Ali, having become fourth caliph after the death of Othman, a rebellion was raised against him by Maaniah, founder of the Ommiad race of caliphs, about the year 1000 of the Christian era. The division took place between the two parties in the court of the caliph Moli l' Mah, which resulted in the Schiite party becoming pre-eminent in Persia, the Sunniahites in Turkey and most other Mohammedan countries.

SUO'VETAURILIA. (Lat. sus, *a swine*, ovis, *a sheep*, and taurus, *a bull*.) In Roman History, a quinquennial sacrifice, which consisted of the immolation of a sow, a sheep, and a bull; hence the name. *See* LUSTRATION.

SUPERCARGO. The person in a merchant ship appointed to superintend all the commercial transactions of the voyage is so called.

SUPERDO'MINANT. (Lat. super, *above*, and dominans, *governing*.) In Music. In the descending scale, the sixth of the key.

SU'PEREROGA'TION, WORKS OF. In Theology. It is a belief countenanced by many tenets of the church of Rome, that men may acquire merit in the eyes of God by good works beyond what are necessary for salvation. This notion is said by Protestants to have been first known about the 12th or 13th century, and to have been founded upon what the Roman Catholics call "counsels of perfection;" that is, rules which do not bind under the penalty of sin, but are only useful in carrying men to a higher degree of perfection than is requisite for Christians. This doctrine is condemned by the church of England in her 14th article.

SUPERFI'CIAL MEASURE. The measure of surfaces or areas; also called square measure. *See* MEASURE.

SUPERFI'CIES. The exterior face of any body. *See* SURFACE.

SUPE'RIOR. In Scottish Law, one who has made an original part of heritable property with reservation of rent and service. The grantee is termed *vassal*: the interest of the grantor is *dominium directum*, that of the grantee *dominium utile*; or, the former superiority, the latter property. The reunion of these two rights in the same person is termed *consolidation*.

SUPE'RLATIVE. In Grammar, the name vulgarly given to the third degree in comparison, formed in the Teutonic languages by the additional syllable "est."

SUPERSE'DEAS. In Law, a writ that lies to stay various ordinary proceedings; as to stay an execution after a writ of error has been allowed and bail put in; to set aside erroneous judicial processes; and, in certain cases, to discharge prisoners.

SUPERSTI'TION. (Lat. superstitio, from super, *above*, sto, *I stand*: the steps of the derivation are extremely obscure.) This word, like many others, has, in common language, both a subjective and objective sense; that is, we speak of superstition as a habit in the mind; and we also speak of a particular tenet, or a particular observance, as "a superstition." Every belief, 1. in the existence of particular facts or phenomena, produced by supernatural agency, which existence is not demonstrated by experience nor asserted in Revelation; 2. in causation not demonstrated by experience or asserted by Revelation, *i. e.* of the *direct* agency of supernatural power in producing results which can either be proved to proceed from secondary causes, or by reasonable analogy must be inferred so to proceed, — is, in common language, superstition. An instance of the first species is the belief in the existence of imaginary beings, ghosts, spectres, &c.; of the second, the belief that epileptic fits are produced by witchcraft, — that meteorological phenomena hitherto imperfectly explained, such as wind or lightning, are produced without the intervention of regular physical causes by the immediate act of the divinity, &c. The word is almost always used in a religious sense, like the Greek δεισιδαιμονια; that is, the belief which we regard as *superstitious* concerns the agency of the Deity, or inferior supernatural agents. For example, we do not generally term the belief in animal magnetism, tellurism, the divining rod, &c. superstitions; these are persuasions respecting certain occult powers of nature undemonstrated (that is, in the case of most believers) by experience; they are *superstitions* in the mode in which they are generated and affect the mind, but not in point of subject matter. On the other hand, there is much carelessness in the application of the word to religious tenets, where these flow necessarily from the belief in certain other truths as revealed: for example, no Christian esteems it superstition to believe that a dead man was, in a certain instance, restored to life, although nothing can be in itself more incredible; because it is asserted in writings which he considers as revealed, and the power of working miracles is expressly claimed in that revelation. But some Christians place faith in the declaration of their church, just as all Christians do in Scripture; and justify that faith by argument addressed to the reason. How, then, can they be accused of superstition in believing the truth of narratives, however incredible in themselves, which that church sanctions and approves; for example, many of the miraculous legends commonly received in the Romish church? Those who do not adhere to that church may stigmatize it as superstitious; but they can hardly call the belief which leads the Roman Catholic to address his prayer to Saints, or the Virgin, a superstition *in him*.

SUPERTONIC. (Lat. super, *above*, and tonus, *a tone*.) In Music, the second above the key note. From its being a comma higher in the major scale than in the relative minor, it is, in theory, considered a variable sound.

SUPINA'TION. The art of turning the palm of the hand upwards by rotating the radius upon the ulna.

SU'PINES. In Grammar, certain forms of the Latin verbs. The supine in *um* (of which the form is the same as the neuter of the past participle, as *amatum* in the verb *amo*) serves generally, in conjunction with another verb, to express an *intended* action; as "Lusum it Mæcenas," "Neque vos ultum injurias hortor;" in both which cases it would be expressed by the infinitive in modern languages; in the Greek, either by the infinitive, or more accurately by the infinitive used as a noun with a preposition. The existence of the other supine (in *u*) is doubted by some grammarians. The name is said to have been given to signify their character, neither passive nor active.

SU'PPLEMENT. In Geometry and Trigonometry, the supplement of an arc or angle is what must be added to it in order to make a semicircle, or 180°.

SUPPLEMENT. In Literature, an addition made to any work or treatise, in the view of rendering it more complete.

SUPPLY. In Parliamentary language, the sum granted to the sovereign by parliament for defraying the expenses of the current year. The known or probable amount of the different branches of the year's expenses is stated to the House of Commons in a committee of supply by the chancellor of the exchequer, and, after these have been voted by the committee, they are formally granted by an act of parliament, called the Appropriation Bill. The granting of the annual supplies is a peculiar privilege of the House of Commons, which never permits any alteration or amendment (except merely verbal) to be made by the House of Lords in the bills passed for this purpose.

SUPPLY. In Political Economy. *See* POLITICAL ECONOMY.

SUPPORT. In Architecture. *See* POINTS OF SUPPORT.

SUPPORTERS. In Heraldry, the figures placed on each side of a shield. The device of supporters probably originated from the practice of knights at tournaments having their armorial shields fixed or hung near the place of justing, and guarded by pages or other retainers standing on the side of them dressed in various fanciful accoutrements; although some consider it as entirely a modern invention, or ornamental addition by painters and limners, who found a vacant space on each side of the escutcheon which they filled up by imaginary figures. It does not appear that supporters were at first exclusively borne by individuals of a particular rank; and some private families are supposed to be still entitled to them by prescription. But, in modern English heraldry, the grant of supporters is limited to sovereigns and princes of the blood royal, peers of the realm, knights of the Bath, knights banneret, baronets of Nova Scotia (by their patents of creation), and to such persons as receive them by special license from the king. It is said by heraldic writers that females cannot assume supporters; but this prohibition seems to be habitually infringed in practice.

SUPPO'SED BASS. In Music, the bass of a chord when it is not the root of the common chord or harmonic triad. It is also sometimes called the inversion of the accompanying chord.

SUPPOSI'TION. (Lat. suppositum.) In Music, the use of two successive notes of equal value as to time, one of which being a discord supposes the other a concord. The harmony, though by rule falling on the accented part of the bar, and free from discords, requires their proper preparation and resolution; and they are called *passing notes*. Discords on the unaccented part of the measure are allowable by conjoint degrees, and it is then not required that the harmony should be so complete on the accented part. This transient use of discords followed by concords is what we, after the French, call *supposition*, whereof there are several kinds.

SUPPO'SITORY. A pill or bolus introduced into the rectum, where it gradually dissolves. Opium is sometimes usefully applied in this way to allay irritation of the bladder and neighbouring parts.

SUPPRESSION. A figure in Grammar is sometimes so called by which words are omitted in a sentence, which are nevertheless to be understood as necessary to a perfect construction: as, for instance, in most languages, the repetition of a noun is avoided where it is coupled with a pronoun in one branch of the proposition; *e.g.*

"this (horse) is my horse," or "this horse is mine" (horse). *See* ELLIPSIS.

SUPPURA'TION. The process by which pus or matter is formed in inflammatory tumours.

SUPRACRETACEOUS ROCKS. A Geological term applied to certain rocks or strata lying above the chalk; they have also been called *tertiary strata*. *See* GEOLOGY.

SUPRALAPSA'RIANS. Those who assert that the fall of Adam, with all its pernicious consequences, was predestinated from all eternity, and that our first parents had no liberty in the beginning. *See* CALVINIST.

SUPRANA'TURALISTS. A name given of late years to the middle party among the divines of Germany, to distinguish them from the *Rationalists*, who exclude all supernatural manifestations from religion; and from the Evangelical party, whose tenets are of a more strict description. Thus many of the supranaturalists appear to have given way to the system of accommodation (as it is termed) in religious matters, so far as to explain away the doctrine of original sin, and other tenets which we are accustomed to consider as fundamental: others approximate to what are regarded as orthodox Protestant opinions among ourselves.

SUPRE'MACY, OATH OF. An oath denying the supremacy of the pope in ecclesiastical or temporal affairs in England, which by many statutes was required to be taken, along with the oath of allegiance, by persons in order to qualify themselves for office, &c. By 10 G. 4. c. 7. s. 10. Roman Catholics are qualified for all offices (with the exception named in the act), on taking a declaration, which is substituted for the former oaths.

SURAES. A name given in Persia to buildings constructed for the accommodation of travellers. They are synonymous with *khans* or *caravanseras*, which see.

SU'RBASE. (Fr.) In Architecture, the upper base of a room, or rather the cornice of the dado.

SURD. In Arithmetic and Algebra, a magnitude which is inexpressible by rational numbers. Thus the square root of 2, the cube root of 3, &c. are numbers which cannot be expressed exactly in the ordinary notation, and are represented by prefixing the radical signs indicating the operation, viz. $\sqrt{2}$, $\sqrt[3]{3}$. Such quantities are otherwise called *irrational* or *incommensurable*.

SURFACE. A mathematical surface or superficies is defined by Euclid to be that which has only length and breadth. This definition excludes a *line*, which has length only; and a solid, which has length, breadth, and thickness. As a line is generated by the motion of a point, so a surface is generated by the motion of a line. If the generating line be a straight line, and move subject to the condition of having always two consecutive positions in the same plane, the surface generated is *developable*, and can be stretched out on a plane, as the surface of a cone, a cylinder, &c. But if the generating straight line is constrained to move so that no two of its consecutive positions are in the same plane, the surface cannot be developed on a plane. Such a surface is called by the French geometers *surface gauche*.

SURMOUNTED. In Architecture, a term used to denote an arch or dome which rises higher than a semicircle.

SURMOUNTED. In Heraldry, a term used when one figure is laid over another: *e.g.* a pile surmounted of a chevron.

SURNAME. In modern European usage, the family name of an individual; but often used for any distinguishing name. (*See* NAME.) According to Ducange, the use of surnames in France began about the year 987, when the barons adopted the practice of designating themselves by the names of their estates. And this has been the general, though by no means the uniform origin, of family names in the nobility of Europe; some having been derived from badges, cognizances, the nicknames applied to individuals, &c. Among the commonalty of this country, surnames are said not to have been general before the reign of Edward II. It will be found on examination that a great number of them originate in the still older custom of adding to the son's Christian name that of the father by way of distinction; many more from the names of trade; and many more from accidental distinctions, as of size or colour, probably applied in the first instance to the founder of the family.

SU'RPLICE. (Lat. superpelliceum, apparently from pellis, *skin*.) This ecclesiastical vestment is thought by Mr. Palmer (*Orig. Liturg.* ii. 320.) to have been at one time not different from the alb. It now has wider sleeves, a difference which is thought to have originated in some distinction between the dress of a superior and inferior order of clergy. It dates from the 12th century. The vehement objections entertained by the Puritans of the 16th century to its use are well known. *See* VESTMENTS.

SURRE'NDER. In Law. 1. A deed by which the tenant of a particular estate conveys his interest to tenant in remainder, a reversion immediately expectant on the determination of that estate. 2. A surrender of copyhold or customary estates is the yielding up of such estates by the tenant into the hands of the lord for purposes expressed in the surrender. By this means are accomplished conveyances of copyhold lands, the lord being in general bound to admit the party in whose favour the surrender is made. *See* COPYHOLD.

SU'RROGATE. (Lat. surrogatus.) In Law, one substituted for or appointed in the room of another. It is commonly used in the ecclesiastical courts as the description of an officer who acts as deputy for the bishop's chancellor.

SURSO'LID. In Arithmetic, the fifth power of a number. If 2 be the root, the sursolid is $2 \times 2 \times 2 \times 2 \times 2 = 32$.

SU'RTURBRAND. A species of peaty bituminous coal found in Iceland. It resembles Bovey coal.

SURVEYING. (Fr. survoir, *to overlook*.) In Practical Mathematics, the art of determining the boundaries and superficial extent of a portion of the earth's surface. The object of a survey may be either to ascertain the contents of a field or portion of land, or to determine the relative distances and bearings of the most prominent objects of a country for the purpose of constructing a map, or to determine the form and dimensions of a portion of the earth's surface with a view to deduce the magnitude and figure of the earth by comparing the geodetical distances between given points with their astronomical positions. In all cases the operation is conducted on the same principles; but while the first requires only the application of the merest elements of arithmetic and trigonometry, the last can only be accomplished with the aid of instruments of the most refined description, and processes of calculation deduced from mathematics of the highest order.

In measuring land all the lines and the surfaces whose contents are to be found are reduced to the same horizontal plane, on the principle that as plants shoot up vertically no greater number can be produced on the slant side of a hill than would grow on the area covered by its horizontal base. When the lines actually measured are not horizontal, they are therefore multiplied by the cosines of their respective inclinations to the horizon.

The English standard unit of land measure is the acre, which contains four roods; and a rood is subdivided into 40 poles or perches, each pole containing $30\frac{1}{4}$ square yards. (*See* MEASURE.) But though roods and poles are the legal subdivisions of the acre, and the terms continually occur in all descriptions of the contents of land, in practice a decimal division is followed, which is greatly more convenient for calculation. For the linear measurements a chain is employed consisting of 100 links, and its whole length is such that one *square chain* is equal to the tenth part of an acre. But the acre containing 4840 square yards, the square chain consequently contains 484 square yards, and the length of the chain is the square root of 484, that is, 22 yards; whence its 100th part, or one link, is 7·92 inches. In order to avoid decimal fractions, surveyors usually set down all the measures in links; and when the contents of a field are cast up in square links, it is only necessary to mark off the five last figures as decimals in order to have the contents in acres, the number of square links in an acre being $100 \times 100 \times 10 = 100{,}000$.

The measurement of angles being in general an operation much less liable to error than the measurement of linear distances, when the surface to be measured is of considerable extent the skilful surveyor will avoid making further use of the chain than is necessary for obtaining the data requisite for a trigonometrical computation. The most convenient instrument, and that which is almost universally employed in land surveying for the measurement of angles, is the theodolite, which, from the nature of its construction, gives the angles reduced to the plane of the horizon, and consequently renders a computation for that purpose unnecessary. (*See* THEODOLITE.) As auxiliary to the theodolite, and for the purposes of sketching and filling in the details of a map, the *plane table* and the *prismatic compass* (see the terms) are used; and in order to determine the bearings of the several objects observed from any station with reference to the cardinal points of the horizon, a compass and needle accompany the theodolite.

It frequently happens in surveying that triangles are to be measured whose sides contain very acute or obtuse angles. In such cases a small error in the angular measurement would lead to very erroneous results; and the practice usually adopted for finding the area is to measure the longest side of the triangle and the perpendicular let fall upon it from the opposite angle, the area being half the product of the side into the perpendicular. For the purpose of tracing the perpendicular, the simple cross-staff may be employed; but the instrument called the *optical square* (which is merely a small shallow circular box containing the two principal glasses of the sextant fixed at an angle of 45°) will effect the purpose with greater accuracy. The method of using it is obvious. If the observer moves forward or backward in the straight line A B until the object B seen by direct vision coincides with another object C seen by reflexion, then a straight

line drawn to C from the point at which he stands when the coincidence takes place will be perpendicular to A B. The box sextant might evidently be employed for the same purpose.

Since every plane figure may be regarded as composed of a certain number of triangles, the whole theory of land surveying resolves itself into the measurement of the areas of plane triangles. For computing the area of a triangle it is necessary to know the length of at least one side; and when this is known, together with any two of its other parts, the remaining parts and the area are computed by the rules of trigonometry. As usual, let the sides of a triangle be denoted by a, b, c, and the angles respectively opposite by A, B, C, and let $s = \frac{1}{2}(a + b + c)$; then the area is found by either of the three following formulæ: $\sqrt{\{s(s-a)(s-b)(s-c)\}}$, $\frac{1}{2}ab$ sin. C, $\frac{a^2 \text{ sin. B sin. C}}{2 \text{ sin. A}}$. (*See* TRIGONOMETRY.)

In surveying an estate, the usual practice is to measure round it with a chain, and observe the several angles with the theodolite; and if the boundaries are very irregular, a straight line is run between two points so as to cut off one or more of the bendings and the perpendiculars or *offsets* from the straight line to each bending measured with a rod or offset staff, the most convenient length of which is 10 links. By this means the spaces included between the actual boundaries and the assumed straight lines are computed; and the sides and angles of the interior polygon being known, its area may be formed without resolving it into triangles. *See* POLYGON.

Trigonometrical Survey. — When a survey is to be effected on a large scale, as for making a geometrical map of a country, or for measuring an arc of the terrestrial meridian, not only is minute accuracy required in all the practical parts of the operation, but it becomes necessary to have regard to the curvature of the earth's surface, the effects of temperature, refraction, altitude above the sea, and a host of circumstances of which the influence is wholly unappreciable in the practice of ordinary surveying. Geodetical measurements of this kind have been executed in various countries. (*See* DEGREE.) The first which was undertaken in our own country was that of General Roy, begun in 1783, for the purpose of connecting the Greenwich observatory with the French triangulation, which had been carried on from Paris to the coast opposite Dover, and consequently for determining the difference of the meridians of the two observatories by actual measurement. This gave rise to a more important operation; namely, a general survey of the kingdom, which was begun in 1791 under the direction of the Board of Ordnance, and has been carrying on up to the present time. A brief description of the methods employed in conducting the different parts of this splendid national undertaking will probably be the best means we could adopt to explain the nature and objects of an accurate trigonometrical survey.

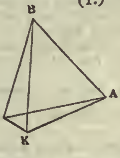
Measurement of Base. — This is the fundamental, and probably the most difficult part of the whole operation, and requires to be executed with the most minute accuracy, as any error committed in its determination will affect all the distances deduced from it, and be multiplied in the ratio of these distances to the length of the base. First of all, a suitable piece of ground, on which a straight line of not less than 5 or 6 miles can be laid down, must be selected and carefully levelled; and a measuring apparatus employed of which the length is exactly known in units of a standard scale. General Roy's base on Hounslow Heath was first measured with deal rods; but as these were found to be affected by the hygrometrical changes of the atmosphere, it was again measured with glass tubes 20 feet in length, furnished with a peculiar apparatus for making the contacts. In the subsequent measurement of the same line for the ordnance survey, two steel chains of 100 feet in length, made by the celebrated Ramsden, were made use of. One of these was used as a measuring chain; the other was kept for the purpose of the measuring chain being compared with it before and after the operation. In the act of measuring, the chain was laid in a trough supported on trestles, and stretched with a weight of 56 lbs. The same apparatus was employed in measuring five other bases in different parts of the country, for the purpose of verifying the accuracy of the work. For the measurement of a base in the survey of Ireland, Colonel Colby employed a compensating apparatus formed of bars of different metals, so arranged that the distance between two points viewed by microscopes remains constant under all changes of temperature. The length of the Hounslow Heath base was nearly 5·2 miles; that of the Irish base about 8 miles.

Selection of Stations. — The next step in the operation is to divide the country to be surveyed into a series of connected triangles. The choice of the stations which form the angular points must depend in some measure on the nature of the country; but where circumstances admit of a selection being made, it is very important to form the triangles so that the small unavoidable errors of observation shall produce the least errors possible in the resulting sides. The conditions required for this purpose are most nearly fulfilled by making the triangles as nearly as possible equilateral.

Signals. — Various plans have been adopted in the course of the survey for marking and rendering visible the stations at which the instrument is successively set up. At first flag-staffs were chiefly used, carrying lamps and concave reflectors for night observations. Such signals could be seen in the telescope of the great theodolite at distances of 20 or even 24 miles. Bengal lights, fixed in small sockets, were used for more distant stations. But night observations having been found by experience to be attended with much uncertainty as well as inconvenience, they have of late years been abandoned. In the mountainous countries of Scotland and Ireland, and where the sides of the triangles generally exceeded 50 and sometimes even 100 miles in length, conical piles of stone were erected on the tops of hills; and although these signals are attended with this disadvantage, that they can only be seen when the atmosphere is clear (and the surveying parties have been frequently compelled to remain weeks and even months encamped on the summits of the mountains before a single observation could be made), yet from the steadiness of the object observed they are found on the whole to be preferable to any night signals that have hitherto been tried. When the theodolite is to be set up at a station which has been already observed from another, the pile is thrown down, and the instrument placed exactly over its centre. The heliotrope, and small plane mirrors, have likewise been occasionally employed with success. (On this subject, see Mr. Drummond's paper in the *Phil. Trans.* for 1826.)

Reduction to Centre of Station.—In observing the angles at any station, it is supposed that the centre of the instrument is placed exactly at the centre of the station. This condition was rigidly adhered to in the ordnance survey of Britain by erecting signals on purpose; but where the saving of expense is an object, it will often be convenient to take advantage of spires, towers, &c., in which case the instrument cannot always be placed in the required position. In such circumstances, the observation is made at a point near the station, and the angle at that point subtended by two remote objects is reduced to that which would have been observed if the instrument had been placed exactly at the centre of the station. The reduction is made as follows: — Let C (fig. 1.) be the centre of the station, A, B the two remote objects observed; and suppose the instrument to be set up at a point K near to C; then the angle actually measured is A K B, while that which is to be determined is A C B. Put C A = b, C K = d, the angle B A C = A, A C B = C, A K B = K, B K C = k; then the difference between C and K expressed in seconds of a degree is

(1.)



$$C - K = \frac{d \text{ sin. } (A - k) \text{ sin. K}}{b \text{ sin. A sin. } 1''}.$$

The distance C K or d is measured; C A or b is found approximately by computing the triangle A C B with the approximate value of C observed at K; and the angles A, K, k are given by observation. The formula is not quite exact, but sufficiently so for all ordinary cases.

Reduction to the Horizon. — Another indispensable condition is, that the angles observed at each station be reduced to the plane of the horizon. When the theodolite is employed for measuring the angles this reduction is effected by the instrument itself, and hence the great advantage of the theodolite as a surveying instrument; but when the angles are measured with a repeating circle or sextant, a reduction is necessary, unless the two distant objects observed be in the same horizontal plane with the instrument, which will rarely happen. Suppose the observer stationed at A, and let B and C be the distant objects. Let the angular elevation of B above the horizontal plane (which is found by measuring its zenith distance) be β seconds, and the elevation of C be γ seconds; also let A′ be the horizontal projection of the angle A, and suppose A − A′ = x seconds; then

$$x = \left\{\left(\frac{\beta + \gamma}{2}\right)^2 \text{tan.}\left(\frac{A}{2}\right) - \left(\frac{\beta - \gamma}{2}\right)^2 \text{cot.}\left(\frac{A}{2}\right)\right\} \text{sin. } 1'',$$

which gives the correction to be subtracted from the observed angle A in order to have the corresponding angle A′. If one of the objects B or C be depressed, the arc of depression, β or γ, must be regarded as a negative quantity.

Spherical Excess. — The sum of the three angles of any spherical triangle exceeds 180° by a quantity which is called the spherical excess, and which we shall denote by E. If the observations could be made with absolute accuracy, the sum of the three observed angles of any triangle on the ground would be 180° + E; the difference of their sum from this quantity is the aggregate error of the three

observed angles, and must be distributed among those angles so as to render the sum precisely $180^\circ + E$ before the sides are computed. It is therefore necessary to determine E. Let S denote the area of the triangle in square feet, r the number of feet in the radius of the earth, and $\pi = 3{\cdot}14159$; then E is given in seconds by this formula (*see* SPHERICAL EXCESS),

$$E = \frac{S \times 648000''}{\pi r^2}$$

(648000 being the number of seconds in 180°). In order, therefore, to compute E, we must previously know the values of S and r. Now with respect to S, it is to be observed that in every case which can arise in practice the area of the triangle must be a very small quantity in comparison of r^2, so that in order to find E it is not necessary to compute S with great precision. A sufficiently near value will be obtained by calculating one of the unknown sides as if the triangle were a plane one, and computing the area from the formula $S = \frac{1}{2} a b \sin. C$.

With respect to r, which is here taken to represent the radius of curvature of the surface of the triangle in question, it is to be remarked that by reason of the ellipticity of the earth, the radius of curvature of any arc on the earth's surface varies not only with the latitude of the place of observation, but also with the direction of the arc in respect of the meridian. For the present purpose it would be sufficiently accurate to assume r as the radius of the meridian; but as the radius of the perpendicular and oblique arcs is required in other parts of the computation, we shall here state the formulæ from which they are computed. Let R be the radius of curvature of the meridian at latitude l, R′ the radius of the circle pependicular to the meridian, and r the radius of a great circle making an angle $= \theta$ with the meridian; also let p denote half the polar axis of the earth $= 20{,}852{,}394$ feet (*see* DEGREE), and e the ellipticity, or the difference between the equatorial and polar axes divided by the polar axis $(= 1 \div 301{\cdot}026 = {\cdot}003322)$; then

$$R = p\,(1 - e + 3e \sin.^2 l)$$
$$R' = p\,(1 + e + e \sin.^2 l)$$
$$r = R\,(1 + \frac{R' - R}{R'} \sin.^2 \theta)$$

Since the inclination θ is different for each of the sides of the triangle, a mean value of r may be found by making $\theta = 45^\circ$, in which case $\sin.^2 \theta = \frac{1}{2}$; and as the curvature varies very little through a considerable extent of country, the same value of r may be used for all the triangles within a zone of two or three degrees of latitude. Suppose, then, the value to be computed for the mean latitude of a chain of triangles, the formula for the spherical excess will be $E = \dfrac{a b \sin. C \times 648000}{2 \pi r^2}$; and on assuming the constant $648000 \div 2\pi r^2 = m$, the formula for computation will be

$$\log. E = \log. a + \log. b + \log. \sin. C + \log. m.$$

It is proper to remark that in general E is a very small quantity. When the sides of the triangles are about 20 or 30 miles, it will seldom exceed 4 or 5 seconds of a degree; but in some of the great triangles connecting Ireland with the west coast of Scotland its value was found to exceed 30 seconds.

Having computed the spherical excess E, make $e = A + B + C - (180^\circ + E)$, (A, B, C being the observed horizontal angles), then e is the error of the sum of the observed angles; and if there be no reason for supposing that any one of the angles has been less accurately determined than the others, the error e must be equally divided among them, or a third of e must be added to or subtracted from each angle, according as the error is in excess or defect, and the results will give the angles from which the sides are to be computed. Thus, if the angles for computation be A′, B′ C′, we have

$$A' = A + \tfrac{1}{3}e,\ B' = B + \tfrac{1}{3}e,\ C' = C + \tfrac{1}{3}e.$$

Calculation of the Sides. — The angles being thus corrected for errors of observation, it now remains to compute the two unknown sides of the triangles. The computation may be made by the ordinary rules of spherical trigonometry; but this method is seldom practised on account of the length of the calculations. A second method, which was practised by Delambre, and has been adopted in the ordnance surveys of Britain and Ireland, consists in first computing from the observed horizontal angles the corresponding angles formed by the chords of the terrestrial arcs, and then calculating the triangle as a plane one. In this manner the chords of the spherical arcs are found, whence the arcs themselves are easily obtained. The reduction of a horizontal or spherical angle to the corresponding chord angle is made as follows: — Let A be the observed spherical angle, b and c the lengths of the containing sides computed approximately as above explained, r the radius of curvature at the place of observation, and $A - x$ the plane angle contained by the chords of the sides b, c; then

$$x = \frac{1}{16}\left(\frac{b+c}{r}\right)^2 \frac{\tan.\frac{1}{2}A}{\sin. 1''} - \frac{1}{16}\left(\frac{b-c}{r}\right)^2 \frac{\cot.\frac{1}{2}A}{\sin. 1''}.$$

This formula gives the reduction x expressed in seconds, and consequently the chord angle $A - x$. If we now denote by x' and x'' the corresponding corrections for the other angles B and C, the sum of the three corrections will evidently be the difference between the sum of the three spherical angles of the triangle and the sum of the angles of the plane triangle formed by the chords, or 180°, and consequently

$$x + x' + x'' = E;$$

so that the spherical excess is obtained from the reduction, and does not require to be previously computed.

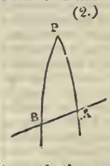
The three chord angles $A - x$, $B - x'$, $C - x''$, being computed from the above formula, the difference between their sum and 180° gives the error of the three observed angles, and must be apportioned among the three chord angles, so that their sum shall be precisely 180°. With these corrected angles the chords of the spherical sides are computed as in plane trigonometry; and the arcs are then found from the chords from the following formulæ, where a', b', c' are the chords of the three terrestrial arcs a, b, c; namely,

$$a = a' + \frac{a'^3}{24 r^2},\ b = b' + \frac{b'^3}{24 r^2},\ c = c' + \frac{c'^3}{24 r^2}.$$

Legendre's Theorem.—A third method of computing the sides, which has been generally adopted in the recent surveys on the Continent, is derived from a theorem which was discovered by Legendre, and is demonstrated in his *Elémens de Géométrie.* "If from each of the angles of any small triangle on the surface of a sphere or spheroid one third of the spherical excess be deducted, the sines of the angles thus diminished will be proportional to the lengths of the opposite sides, and consequently the sides may be computed as if the triangle were rectilineal." This is the easiest method of any; and in fact, if the three angles are assumed to have been equally well determined, the previous computation of the spherical excess is not necessary for the calculation of the sides, though it will be required for estimating the relative accuracy of the observations. The method of proceeding is this: — Let A, B, C be the three observed angles; and let $\delta = A + B + C - 180^\circ$; then, from each of the three observed angles subtract $\frac{1}{3}\delta$, and with the angles thus reduced compute the sides as in a plane triangle from the formula $b = a \sin. (B - \frac{1}{3}\delta) \div \sin. (A - \frac{1}{3}\delta)$. The sides thus determined are equal to the geodetical lines, or the spherical arcs on the ground.

Latitudes, Longitudes, and Azimuths.—When the sides of all the triangles have been computed the distances between the stations become known; but in order to complete the survey, it is still necessary to determine the astronomical positions of the principal stations, and the bearings of the sides of the triangles with respect to the terrestrial meridians. For this purpose the latitude and longitude of one of the stations, and the azimuth of another as seen from it, must be found by astronomical methods (*see* LATITUDE, LONGITUDE, AZIMUTH); but when this has been done these elements may be computed for each of the other stations in the chain of triangles, provided the dimensions and ellipticity of the spheroid are assumed to be known. The formulæ for computation are the following: —

(2.)



Let A and B (fig. 2.) be two stations, A P and B P the meridians passing through A and B and meeting in the pole P; and let the azimuths at each station be counted from the south towards the west. Assume

$l = 90^\circ - A P =$ latitude of A,
$l' = 90^\circ - B P =$ latitude of B,
$A = 180^\circ - P A B$ the azimuth of B as seen from A,
$B = 180^\circ + P B A$ the azimuth of A as seen from B,
$P = A P B$ the difference of the longitudes of A and B,
$d =$ length of the geodetical line A B in feet,
$R' =$ radius of the circle perpendicular to the meridian at A in feet,
$e =$ the ellipticity as above defined $= {\cdot}003322$;
then,

$$l' = l - \left\{\frac{d \cos. A}{R' \sin. 1''} + \frac{d^2 \sin.^2 A \tan. l}{2 R'^2 \sin. 1''}\right\} (1 + 2e \cos.^2 l)$$

$$P = \frac{d \sin. A}{R' \cos. l' \sin. 1''}$$

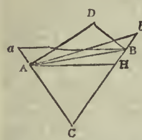
$$B = 180^\circ + A - P\frac{\sin. \frac{1}{2}(l + l')}{\cos. \frac{1}{2}(l - l')}.$$

These formulæ are theoretically sufficient to give the elements in question; but as some uncertainty must exist as to the ellipticity of the earth, and a small error in this respect will affect the convergency of the meridians, and produce a considerable error in the computed longitudes

and azimuths, it is necessary, in carrying a survey over a considerable tract of country, to check the azimuths by determining the direction of the meridian at different stations by astronomical observations.

Calculation of Altitudes. — The only element which remains to be determined, in order to complete the survey, is the relative altitudes of the different stations or principal points. At every station the elevation or depression of each of the others observed from it is measured with the theodolite; but owing to the curvature of the earth, and the refraction of light, a calculation is necessary in order to determine their true differences of level, or of distance from the centre of the earth.

(3.)



Let A and B (fig. 3.) be two stations, C the centre of the earth; and let b be the position of B as seen from A elevated by refraction, and a that of A as seen from B. Make C H = C A; then H B is the true difference of altitude of A and B, or the quantity to be determined from observation. Join A H, A B, A b, and draw the horizontal lines A D and B D, which will be respectively perpendicular to C A and C B. Assume in seconds,

d = D A b the observed depression of B,
d' = D B a the observed depression of A,
C = A C B the angle measured by the arc A B,
ϱ = the mean refraction,
ϕ = B A H the angular difference of altitudes;

then B H will be found by the following formulæ: —

$$\varrho = \tfrac{1}{2}\left\{C - (d + d')\right\} \quad \phi = \tfrac{1}{2}C - (d + \varrho)$$
$$BH = AB \times \phi \sin. 1''.$$

Thus B H is found in terms of A B, and the reciprocal observations at A and B. The mean refraction ϱ is also determined at the same time; but if this be assumed to be known, the observation of depression at one of the stations would be sufficient to give the difference of elevations. The two quantities d and d' have been both assumed to be depressions; if one of them is an elevation, it must be taken with the negative sign.

See the *Trigonometrical Survey of England and Wales;* Delambre, *Base du Système Metrique;* Puissant, *Traité de Geodesie;* Id. *Nouvelle Description Géometrique de la France; Encyc. Brit.* art. "Trigonometrical Survey."

SURVI'VORSHIP, in the doctrine of Life Annuities, is a reversionary benefit contingent upon the circumstance of some life or lives *surviving* some other life or lives, or of the lives falling according to some assigned order. For the solution of the different questions which can be put relative to the values of annuities and assurances in every order of survivorship, where there are only three lives, see the treatises of Baily and Milne; or the *Essay on Probabilities* by Professor De Morgan, in the *Cabinet Cyclopædia.*

SUSPE'NSION BRIDGE. In Architecture, a bridge in which the roadway, instead of being carried over the supporting points, is suspended from them, the supporting points being chains or other flexible materials. The principle has recently been carried to a great extent in this country, as in the case of the Menai bridge; but its application is old, and has long been practised among people who have attained very little if any skill in the arts. *See* BRIDGE.

SUSSEX MARBLE. A variety of limestone which constitutes one of the fresh-water deposits of the Wealdon group; it abounds in shells of *Paludinæ*, a genus of fresh-water Univalves. It occurs in layers varying from a few inches to upwards of a foot in thickness, the layers being separated by seams of clay or of friable limestone.

SU'TTEE. (More correctly written Sati or Satee; in Sanscrit, *pure.*) A word applied by the Brahmins to various rites of religious purification; but more especially, by usage, to the voluntary self-immolation of widows on the funeral pile of their husbands. This is nowhere commanded in the religious books of Hindoostan, although it is spoken of, in common with many other acts of similar fanaticism, as highly meritorious. The English government, up to a late period, had only interfered to ensure, as far as possible, that the sacrifice should be voluntary on the part of the sufferer, which was done by the presence of a government officer. Thus legalized, suttees became frightfully common in Bengal and the adjoining provinces in the present century. At length, in December, 1829, they were abolished in the British dominions by Lord W. Bentinck. (See *Forbes's Oriental Memoirs*, ii. 26.; *Heber's Journal*, i. 70.; and many other authorities.) There is a curious account of a suttee in Bali, an island in which the Hindoo religion now prevails, in *Crawford's Ind. Archipelago*, book vi. ch. 2.

SUTURE, in Mammalogy, is the line formed by the incumbent series of converging series of hairs of the integument. In Entomology, it is the line at which the elytra meet, and are sometimes confluent.

SUTURE, in Anatomy, means the junction of bones by their serrated or teethed margins: the bones of the skull are so united.

SWAB. A large bundle of old yarns hung by the middle, and swung right and left to dry the decks.

SWA'LLOW. A name equivalent to the subgeneric term *Hirundo*, appropriated in modern Ornithology to the British species called bank, chimney, and window swallow, and to foreign allied forms dismembered from the swifts.

SWAMP. Ground habitually so moist and soft as not to admit of being trod on by cattle, but, at the same time, producing particular kinds of trees, bushes, and plants. A swamp differs from a bog and a marsh in producing trees and shrubs, while the latter produce only herbage plants and mosses.

SWAN. Of the noble web-footed birds so called there are three British species, — the Hooper or Bewick's, the wild and the tame swan. These form the type of the subgenus *Cygnus.* The wild swan and Hooper ought perhaps to be regarded as the only true native species. The tame swan (*Cygnus olor*) is superior in bulk to either of the wild species, and is at once distinguished by a large black callous knob on the base of the bill. Both the wild species are peculiarly characterized by convolutions of the windpipe, extending in the mature bird through the whole length of the keel of the sternum. These convolutions are horizontal in the *Cygnus Bewickii*, and vertical in the *Cygnus ferus.*

SWARD. Green turf; that is, the surface of land under pasture grasses. A fine sward may be called the characteristic feature of British landscape, not being found in the same degree of perfection in any other country, not even in Ireland.

SWEDENBO'RGIANS. The followers of Emanuel Swedenborg, a Swedish nobleman, who died in 1772. He conceived the society which he founded to be the New Jerusalem spoken of in Revelations, and its members to be gifted with peculiar insight into spiritual things. The Swedenborgians imagine that they can see mentally, and hold conversation with spirits. They interpret Scripture by a system of correspondences, supposing it to have three distinct senses, accommodated respectively to particular classes both of men and angels. They date the last judgment of the spiritual world and the second advent of Christ from the year 1757. They abound principally in England, where they have at the present day several chapels in London and other large towns.

SWELL. The term for a succession of waves in a particular direction, and named after the point of the compass *from* which the waves move.

SWELL. In Music, a set of pipes in an organ acted upon by a key board, and capable of being increased in intensity of sound by the action of a pedal, which allows of its being thereby gradually augmented. *See* ORGAN.

SWIFT. The name of the largest and most powerful flier of the swallow tribe which visits this country. It is the type of the subgenus *Cypselus* of Temminck; the *Hirundo apus* of Linnæus. *See* HIRUNDO.

SWIFTER. The name given to the foremost and aftermost shrouds, which are not rattled with the rest. The term *swifter* is also applied in many cases to a rope used for the temporary purpose of tightening or keeping a thing in its place.

SWIMMERS. The web-footed or aquatic birds (*Natatores*, Ill.; *Palmipedes*, Cuv.) are so called; also a tribe of spiders (*Araneidæ natantes*) which live in water, and there spin and spread abroad filaments to entrap their prey.

SWINE POX. The *chicken pox*, which see.

SWINE STONE. Fetid or bituminous limestone, which exhales a disagreeable odour on friction.

SWING. The ship at anchor is said to swing when she changes her position at the turn of the tide.

SWIVEL. In Gunnery, a small cannon; so called from its being fixed in a *swivel*, by means of which it may be directed to any object. Swivels are chiefly used at sea, and are placed on the ship's side, stern, or bow, and also in the tops.

SWORD OF STATE. Four swords are used at the coronation of a British sovereign: 1. The sword of state properly so called. 2. The curtana (curtus, *shortened*), the sword of mercy, which is pointless: it is mentioned by Matthew Paris. 3. The sword of spiritual justice. 4. The sword of temporal justice. These three are carried before the sovereign: he is girt with the first.

SWORD, ORDER OF THE. A Swedish military order of knighthood, instituted by Gustavus Vasa.

SY'BARITE. A term used metaphorically to designate an effeminate voluptuary; so called from the inhabitants of Sybaris, formerly a town of Italy on the gulf of Tarentum, whom a devotion to sensual pleasures had so enfeebled that they became an easy prey to the Crotonians,

a people comparatively insignificant in point of numbers, by whom their city was levelled to the ground, B. C. 310.

SYCEE SILVER. The only approach to a silver currency among the Chinese. In it the government taxes and duties and the salaries of the officers are paid; and it is also current among the merchants in general. The term *sycee* is derived from two Chinese words *se sze*, "fine gloss silk;" which expression is synonymous with the signification of the term *wan*. This silver is formed into ingots (by the Chinese called shoes), which are stamped with the mark of the *office* that issues them and the dates of their issue. The ingots are of various weights, but most commonly of ten taels each.

Sycee silver is divided into several classes, according to its fineness and freedom from alloy. The kinds most current at Canton are the following: —

1. Kwan heang: The hoppos duties, or the silver which is forwarded to the imperial treasury at Pekin. This is of 97 to 99 tonch. On all the imperial duties a certain per-centage is levied for the purpose of turning them into Sycee of this high standard, and of conveying them to Pekin without any loss in the full amount. The hoppo, however, in all probability, increases the per-centage far above what is requisite, that he may be enabled to retain the remainder for himself and his dependants.

2. Fan hoo, or fan foo: the treasurer's receipts, or that in which the land tax is paid. This is also of high standard, but inferior to the hoppos duties; and being intended for use in the province. and not for conveyance to Pekin, no per-centage is levied on the taxes for it.

3. Yuen paon, literally "chief in value." This kind is usually imported from Soochan in large pieces of 50 taels each. It does not appear to belong to any particular government tax.

4. Yen, or een hearg, "salt duties." It is difficult to account for these being of so low a standard, the salt trade being entirely a government monopoly.

5. Muh tue; or wuh tue, the name of which signifying "uncleansed or unpurified," designates it as the worst of all. It is seldom used except for the purpose of plating. (Prinsep's "Useful Tables," *Appendix to Journal of Asiatic Society*, 8vo. Calcutta, 1834.)

SYCO'MA. (Gr. *συκον*, *a fig.*) A fig-shaped tumour.

SY'COPHANT. (Gr. *συκοφάντης*, from *συκον*, *a fig*, *φαίνω*, *I disclose.*) It was forbidden by the laws of Athens at one period to export figs. The public informers who gave notice of delinquencies against this fiscal law were extremely unpopular, and hence the word came into use to signify an informer or false accuser generally; in which sense it is constantly used by Aristophanes and the orators. In modern languages it has acquired the sense of a mean flatterer.

SYCO'SIS. A tubercular eruption upon the scalp, or bearded part of the face: it sometimes forms a very troublesome impediment to shaving.

SY'ENITE. A granitic rock from *Syene*, or *Siena*, in Egypt. It often has the appearance of a variety of granite. *See* GEOLOGY.

SY'LLABLE (Gr. *συλλαβη*, from *συλλαμβανω*, *I collect*), is defined by Girard, the celebrated French grammarian, "a simple or compound sound, pronounced with all its articulations by a single impulsion of the voice." The principal difficulty in arranging the syllabic construction of language is to ascertain in what cases two or more consonants following each other may be joined in a syllable; which can only be done by investigation of the mechanism of speech. (See a learned article on this subject in the *Encyclopédie.*)

SY'LLABUS. (Gr. *συν* and *λαμβανω.*) A compendium or abridgment, or a table of contents; as a syllabus of lectures, &c.

SYLLE'PSIS. (Gr. *συλληψις*, *connection or taking together.*) In Grammar, sometimes called substitution. A name given by some writers to that idiom of the Greek and Latin languages whereby an adjective predicated of a masculine and feminine substantive is made to accord in gender with the former: *e.g.* "rex et regina beati."

SY'LLOGISM. (Gr. *συλλέγω*, *I collect.*) In Logic, an argument stated in the correct logical form, consisting of three propositions, and having the property that the conclusion necessarily follows from the two premises; so that if the premises be true, the conclusion must be true also. (*See* PROPOSITION, LOGIC.) As often as the mind observes any two notions to agree with a third, it immediately concludes that they agree with each other: as, A is equal to B; B is equal to C; therefore A is equal to C. Or, if it finds that one of them agrees and the other disagrees with the third, it pronounces that they disagree with each other. In the first of these processes it produces a syllogism with an affirmative conclusion in the latter, a syllogism with a negative conclusion.

Syllogisms are variously divided: by some into single, complex, and conjunctive, &c.; by others (according to the Oxford system of logic) into categorical, hypothetical, conditional, &c. But the categorical syllogism, consisting of three categorical propositions, is the simplest form of reasoning, and that to which all other forms can be reduced.

The following are the two canons by which the validity of a categorical syllogism is explained: — 1. If two terms, *i.e.* notions expressed in language (*see* TERM), agree with one and the same third, they agree with each other. 2. If one term agrees and another disagrees with a third, the two first disagree with one another. Hence are deduced the six following rules.

1. Every syllogism has three terms only; viz. the middle term, and the two extremes. The subject of the conclusion is called the minor term; its predicate the major term: the middle term is that with which they are respectively compared. 2. Every syllogism has three propositions only: the major premiss, in which the major term is compared with the middle; the minor premiss, in which the minor term is compared with the middle; the conclusion, in which the major and minor terms are compared together. 3. The middle term must be, in logical language, distributed once at least in the premises; *i.e.* it must be the subject of a universal, or the predicate of a negative (*see* PROPOSITION); otherwise it may happen that one of the extremes is compared with one part of it, and the other with another part. 4. No term must be distributed in the conclusion which is not distributed in one of the premises; otherwise the whole term would be employed in the conclusion, where part only are employed in the premiss: this error is called an illicit process of the major or minor premiss. 5. From negative premises you can infer nothing; *i.e.* if two terms disagree with a third, you cannot conclude either their mutual agreement or disagreement. 6. If one premiss be negative, the conclusion must be negative; for if one term disagree with the middle, it must of necessity also disagree with the other. The other rules are corollaries deducible from these six.

The *mood* of a syllogism is the designation of its three propositions in their order, according to their respective quantity and quality. By reference to the head PROPOSITION, it will be seen that arbitrary symbols are adopted in logic to mark the quality and quantity of propositions: thus A stands for a universal affirmative; E represents a universal negative; I a particular affirmative; O a particular negative. These four letters will afford sixty-four different combinations of three letters; but of these the greater part will afford syllogisms erring against some one or more of the rules previously laid down: thus E E E would be at once inadmissible, as exhibiting two negative premises, — against rule 5. By an accurate examination, it is found that eleven moods only will afford correct syllogisms: A A A, A A I, A E E, A E O, A I I, A O O, E A E, E A O, E I O, I A I, O A O.

The figure of a syllogism consists in the situation of the middle term with reference to the major and minor terms. 1. The first figure is where the middle term is the subject of the major premiss, and predicate of the minor. 2. Where the middle term is the predicate of both premises. 3. Where it is the subject of both. 4. Where it is the predicate of the major, and subject of the minor. Multiplying the moods by the figures, we should have forty-four different syllogisms. But it will be found, on examination, that five moods in each figure (twenty in all) would err against some one or other of the rules before laid down: *e.g.* I A I is an allowable mood in the third figure; but, in the first, it would have an undistributed middle. Of the twenty-four remaining, five are unnecessary; *i.e.* they are moods in which a particular conclusion only is inferred from premises which would warrant a universal. The nineteen remaining are expressed in the following mnemonic lines:—

Fig. 1. 4 moods: B*A*r*b*A*r*A, c*E*l*A*r*E*n*t*, d*A*r*I*I, f*E*r*I*O-*que*, prioris.
Fig. 2. 4 moods: C*E*s*A*r*E, c*A*m*E*s*t*r*E*s, f*E*s*t*I*n*O, b*A*-r*O*k*O, secundæ.
Fig. 3. 6 moods: Tertia d*A*r*A*p*t*I, d*I*s*A*m*I*s, d*A*t*I*s*I, f*E*l*A*p*t*O*n*, B*O*k*A*r*d*O, f*E*r*I*s*O*n*, habet: quarta insuper addit.
Fig. 4. 5 moods: B*r*A*m*A*n*t*I*p*, c*A*m*E*n*E*s, d*I*m*A*r*I*s, f*E*s*A*p*O, f*r*E*s*I*s*O*n*.

One mood in each figure may be given by way of example. The letter M designates the middle term; the letter preceding the proposition its quantity and quality.

1. A. All excess (M) is sinful.
   A. All gluttony is excess (M): therefore
   A. All excess is sinful. (A syllogism in Barbara.)
2. A. Every thing expedient is lawful (M).
   E. Nothing unjust is lawful (M): therefore
   E. Nothing unjust is expedient. (A syllogism in Camestres.)
3. A. All conquerors (M) are cruel.
   I. Some conquerors (M) are just: therefore
   I. Some just men are cruel. (A syllogism in Datisi.)

4. A. Whatever is expedient is conformable to nature (M).
   E. Whatever is conformable to nature (M) is not hurtful: therefore
   E. What is hurtful is not expedient. (A syllogism in Camenes.)

It will be observed that in all these instances the major premiss is presumed to precede the minor; but although this is the most convenient form of reasoning, the minor premiss is, with equal validity, made the first in the series: *e.g.*

Brutus is an honourable man:
Honourable men affirm the truth; therefore
Brutus affirms the truth.

This is a syllogism in Barbara, with the minor premiss placed before the major.

The fourth figure is considered to be inverted and unnatural; and the first three figures, with their fourteen moods, furnish almost every argument which is employed, however far it may be removed in appearance, through the intricacy of language, from the syllogistic form. But all arguments may be brought, by an ingenious process termed *reduction*, into one or other of the four moods of the first figure.

In reducing a syllogism, the premises may be illatively converted (*see* ILLATIVE CONVERSION), or transposed; since the force of the argument can be altered by neither of these processes. By employing this liberty, we deduce either the same conclusion with the original, or another conclusion from which the original conclusion follows by illative conversion. We have not space to explain, by examples, these various processes. The letters which compose the names of the syllogistic moods are framed to express the manner in which those of the three last figures are reduced into those of the first. The first letter indicates the mood into which those beginning with the same letter are to be reduced: *e.g.* Bramantip is reducible into Barbara; *m* indicates that the premises are to be transposed; *s* and *p* that the proposition denoted by the vowel immediately preceding is to be converted, — *s* simply, *p* per accidens; *k*, which occurs only in Baroko and Bokardo, indicates that the proposition denoted by the vowel immediately before it must be left out, and the contradictory of the conclusion (*see* CONTRADICTORY) substituted, which is termed the *reductio ad impossibile*.

A hypothetical syllogism is one in which the conclusion is deduced from an hypothetical premiss (called the major) and a categorical premiss (called the minor). It is of two kinds, — conditional and disjunctive: the first subdivided into constructive and destructive.

1. Conditional constructive. { If the demand increases, the supply will increase:
But the demand increases;
Therefore the supply will increase.

2. Conditional destructive. { If the country is flourishing, agriculture is flourishing:
But agriculture is not flourishing;
Therefore the country is not flourishing.

3. Disjunctive. { Either A is B, or C is D:
But A is not B;
Therefore C is D.

It is evident that a disjunctive syllogism may easily be reduced to a conditional. (See the *Compendium of Logic* by Dean Aldrich, commonly used at Oxford; and the Treatise of Archbishop Whately.)

SYLPH. (Gr. σιλφη, *a kind of insect.*) The name given to the spirits of air in the fantastic nomenclature of the Rosicrucians and Cabalists. (See those articles.) The use which Pope has made of this fancy in his *Rape of the Lock* is well known. He seems to have borrowed it from the enigmatical romance called the *Count de Gabalis*.

SY'MBOL. (Gr. σύμβολον; from συν, *together*, and βαλλω, *I throw.*) A word of many meanings, although now commonly used in one only. 1. The primary meaning of the verb συμβαλλειν expresses the act of several in constituting or throwing together portions to form a whole. Hence συμβολον signified a treaty or agreement. (*Arist. Polit.*) And it seems to be in this sense that the creeds are termed by early ecclesiastical writers symbols: either because (as Augustine says) all the fundamental doctrines of Christianity are *collected* in them; or from the old traditionary story, related by Rufinus, that the creed called the Apostles' was formed by each of them contributing a sentence. (*See* CREED.) 2. The mind may be said to put together (συμβαλλειν) outward appearances, and collect from them the notion of a thing signified by them; and hence the outward appearances themselves derive the appellation of *symbols*, signs, or emblems; while the act of the mind is termed *conjecture* (Lat. conjicio). Thus, the standards of military bodies were called by the Greeks symbols; as likewise omens and portents; and expressions or figures denoting a received meaning, as the Pythagorean symbols. In this sense, the early Christian church called all rites, ceremonies, and outward forms bearing a religious meaning, by the general name of symbols; the sacraments themselves, and the sacramental elements, the Cross, and, in later times, images and pictures. Symbols, properly so called, must be distinguished from types, *i.e.* phenomena, manifestations recorded in the Old Testament, of which the full meaning is developed by correlative manifestations in the New; and from mere symbolical attributes, such as the figures usually introduced in company of the four Evangelists. *Symbolical books* are such as contain the creeds and confessions of different churches; such as the three creeds, received by all; the Confession of Augsburg, received by the Lutherans; the articles of the Church of England, &c. The Germans call the study of the symbols and mysterious rites of antiquity, and also the study of the history and contents of Christian creeds and confessions of faith, by the name of Symbolics (mythological or theological). *Marheineke's Institutiones Symbolicæ*, of which the first edition appeared in 1812, is one of their most distinguished works in the latter class.

SYMME'TRICAL SOLIDS. In Geometry, a name given by Legendre to solids which, though equal and similar, cannot be brought to coincide with each other, or to occupy the same portion of space. A man's two hands afford an example of symmetrical solids. The equality of plane figures is proved by showing that they may be made to coincide, but it is evident that this mode of proof cannot be extended to all solids.

SY'MMETRY. In the Fine Arts. *See* PROPORTION.

SY'MPATHY. (Gr. συμπασχω, *I suffer with.*) In Moral Philosophy, the quality of being affected by feelings common to our fellow-men. In his *Theory of Moral Sentiments*, Dr. Smith maintains that sympathy is the real foundation of morals. (*See* VIRTUE.) For a succinct statement of this theory, see "The Life of Dr. Smith," prefixed to M'Culloch's edition of the *Wealth of Nations*, p. iv. In the Fine Arts, the term signifies conformity of the parts to each other; but in Painting it is more usually applied to the effective union of colours.

SY'MPHONY. (Gr. σὺν, *with*, and φωνη, *voice.*) In Music, a composition which, from the etymology of the term, evidently implies that the voice anciently formed an essential part of its construction. In the present day, however, the term is otherwise applied, and is exclusively used for a piece in which instruments only are engaged. It is, in fact, a composition for a perfect instrumental orchestra, which, until the beginning of the eighteenth century, was unknown. The *Concerti grossi* of Corelli were the first of the species, which was carried out to a greater extent in the works of Geminiani and Vivaldi; but it does not seem to us that before the time of Haydn it can be said to have assumed the form which the name now imports. There is, perhaps, no musical composition in which the power of the author is so completely developed as in a symphony. The musician in it becomes a poet, or perhaps rather a painter. Scenes and the passions are represented therein by a combination of musical sounds; in illustration of which we need only cite that splendid work of Beethoven, known to all under the name of *Il Pastorale*. The general form of the symphony may be thus described: — It opens with a short, serious, slow movement; this is followed by and forms a contrast to one of spirit and of a lively nature; then comes an andante varied, or an adagio or slow movement; a minuet with its trio follows; and the symphony usually closes with a lively rondo, or a finale of rapid motion.

SY'MPHYSIS. (Gr. συμφυειν, *to grow together.*) A term applied to the junction of certain bones, or to joints not admitting of motion; as the *symphysis of the pubes*.

SYMPIESO'METER. (Gr. συμπιεζω, *I compress*; μετρον, *measure.*) An instrument contrived by Mr. Adie of Edinburgh for measuring the weight of the atmosphere by the compression of a column of gas. It consists of a glass tube ABC of about 18 inches in length, bent as represented in the annexed figure, and having an enlarged portion or bulb of about 2 inches in length and half an inch in diameter at each end. The top at A is hermetically sealed, and the other extremity C can be stopt by a cork. The upper part of the tube A *m* is filled with some permanently elastic gas different from common air (hydrogen gas is found to answer best), and the lower *m* B *n* with a fixed oil, or some fluid which does not act upon the gas and is not acted upon by air.

The tube being opened at C, the oil is exposed to the pressure of the atmosphere, and stands at a height *m*, corresponding to the difference of the pressures of the atmosphere and of the column of enclosed gas. Consequently as the atmospheric pressure becomes greater the gas will be compressed, and the column of oil will rise. The change in the bulk of the gas occasioned by a change of pressure is measured by a scale, which is formed experimentally, and of which the divisions are entirely arbitrary.

But as the bulk of the enclosed gas is altered by any change of temperature as well as of pressure, it is necessary to apply a correction on this account. For this purpose a common thermometer is attached to the instrument to indicate the temperature; and the principal or barometric scale, which measures the compression of the gas, is made to slide upon another scale divided so as to represent the change of bulk in the gas produced by a change of temperature under the same pressure, and corresponding to the graduation of the thermometer. In making an observation, the temperature is first observed by the thermometer; an index or pointer, which is fixed to the top of the sliding scale, is then set opposite to the degree of temperature on the fixed scale, and the number on the sliding scale opposite the top of the column of oil gives the pressure of the air in inches of the mercurial barometer.

The principle of the sympiesometer is the same as that of the *manometer*, or air barometer, which was long ago proposed by Hooke; and Mr. Adie's great improvement consists in the substitution of a gas for common air, which has the defect of being absorbed by the enclosing fluid. It is a valuable instrument at sea, as it is not affected in any degree by the motion of the ship; and it possesses several advantages over the barometer in its convenient size, its greater portability, and in being less liable to accident. (See the *Edinburgh Encyclopedia*, art. "Meteorology;" *Edin. Phil. Journal*, No. 1.; *Edin. Journal of Science*, No. 20.)

SYMPO'SIARCH. (Gr. συμποσιον, *feast*, and αρχω, *I rule*.) The ruler or master of a feast; one selected by the consent of the party to be their president for the occasion, whom the Greeks sometimes called βασιλευς. The word rendered "governor of the feast," in John, ii. 8., is αρχιτρίκλινος. Some think that a priest or Levite was chosen to fill this office in Jewish feasts.

SYNÆ'RESIS. (Gr. συναιρεω, *I contract*.) Otherwise called *Crasis*. (Gr. κρασις, *mixture*.) In Grammar, the contraction of two syllables into one by the formation of a diphthong, or by rendering one of them mute: as, Atreides for Atreïdes. *See* METAPLASM.

SY'NAGOGUE. (Gr. συναγω, *I assemble*.) The religious assemblies of the Jews are so called by Hellenic writers. The Jews had no synagogues, it is thought, before the Babylonish captivity. They were first formed after the return of the Jews to the Holy Land. The rule was, that a synagogue was to be erected in any place where there were ten persons of full age and free condition ready to attend the service of it. Others, however, consider the ten *batelnim*, to use the Hebrew word, to have been ten elders, or stationary men of the synagogue. (See *Lightfoot*.) The service performed in the synagogues consisted, and still consists, of prayers, reading the scriptures, and preaching and expounding of them. The prayers are contained in liturgies. The reading of the scripture consists of three portions: the "Shema," certain selected passages from Deuteronomy and Numbers; the law and the prophets. The third part of the service is mentioned in several places in the narratives of the life of our Saviour, and the Acts: Luke, iv. 16. Acts xiii. 5. The times of the synagogue service were three days a week (Monday, Thursday, and Saturday), besides the holydays. The ministration of the synagogue was not confined to the order of priests; the elders, or "rulers of the synagogue," were persons qualified, and duly admitted, of all tribes. (Prideaux, *Connection*, vol. i.)

SYNALÆ'PHA. (Gr. συν, *together*, αλειφω, *I anoint*; from the melting together of two sounds.) In Classical Prosody, the usage by which, when a word ends with a vowel, with the letter *m*, and the next begins with a vowel, the final syllable of the one runs into the first of the other. This, in Latin verse, also takes place when the last letter is *m*; but the usage in this instance is called *ecthlipsis*, or elision. The synalæpha is commonly, though not with equal regularity, adopted in Italian and Spanish poetry, and is not unfrequently attempted, especially by Milton, in our own; in French it extends only to the *e* mute at the end of words.

SYNARTHRO'SIS. (Gr. συν, *with*, and αρθρον, *a joint*.) The immoveable connection of one bone with another.

SYNCA'RPOUS. (Gr. συν, and καρπος, *fruit*.) In Botany, a term applied to the carpels of a compound pistil when they are completely united into an undivided body; as in the orange.

SY'NCATEGOREMA'TIC. (Gr. συν, and κατηγορημα; a word employed together with categorematics or terms.) In Logic, a word which cannot be employed by itself as a term, but requires to be conjoined with another or others for that purpose. Such are adverbs, prepositions, nouns in other cases besides the nominative, &c. *See* TERM.

SY'NCHONDRO'SIS. (Gr. συν, and χονδρος, *a cartilage*.) The junction of one bone with another by an intervening cartilage.

SY'NCHRONISM. (Gr. συν, and χρονος, *time*.) The tabular arrangement of history according to dates, by which contemporary persons and things in different countries are brought together.

SYNCLI'NAL. *See* ANTICLINAL.

SYNCOPA'TION. In Music. *See* DRIVING NOTES.

SY'NCOPE. (Gr. συν, and κοπτω, *I cut*.) A figure of Grammar, by which one or more letters are omitted in the middle of a word; as in the Latin *litus* for *littus*. *See* METAPLASM.

SYNCOPE. In Pathology, fainting. A disease in which the circulation and respiration temporarily cease, or become extremely feeble.

SYNCOPE. In Music. *See* LEGATO.

SY'NCRETISM. (Gr. συν, and κρασις, *mixture*.) In Philosophy, the blending of the tenets of different schools into a system. A party among the Platonists at the revival of letters, to which belonged Ammonius, Pico della Mirandola, Bessarion, and other distinguished men, have received the name of Syncretists.

SY'NCRETISTS. In Ecclesiastical History, the partisans of Calixtus, a Lutheran divine of the 16th century, who endeavoured to form a comprehensive scheme which should unite the different professors of Christianity. The opinions of Calixtus raised a strong controversy in the Lutheran church. A new confession of faith was drawn up in Saxony for the purpose of excluding his partisans. As doctrines, however, they did not long survive his death, although not without effect on the spirit of the age. (*Mosheim*, cent. xvii. sect. 2.)

SYNDA'CTYLES, *Syndactyli*. The name of a tribe of Perchers, including those which have the external and middle toe united as far as the second joint.

SYNDESMO'SIS. (Gr. συνδεσμος, *a ligament*.) The union of one bone with another by means of ligament.

SY'NDIC. (Gr. συν, *with*, δικη, *justice*.) A title given at different times to various municipal and other officers. The syndics of cities in Provence and Languedoc, under the old French government, were officers delegated by the municipality as agents or mandatories. Such were also the syndics of trading companies. The creditors of a bankrupt, under the law of France, appoint syndics or directors from among their number.

SYNE'CDOCHE. (Gr. συν, *with*, εκ, *out*, and δεχομαι, *I receive*.) In Rhetoric, a figure by which the whole is put for a part, or part for the whole. It is a species of trope. (*See* TROPE.) There are six ordinary instances of synecdoche: 1. When genus is put for species (as "being" in the sense of "man"). 2. When species is put for genus. 3. When the essential whole is put for one of its parts. 4. When the matter, or form, is put for the whole being. 5. The whole for a part. 6. The part for the whole.

SYNE'CHIA. (Gr. συνεχω, *I adhere*.) A disease of the eye in which the iris adheres to the cornea, or to the capsule of the crystalline lens.

SYNE'RGISTS. (Gr. συνεργιζω, *I co-operate*.) A name given to a party in the Lutheran church in the latter end of the 16th century. Those who were thus called appear to have held the doctrine that the divine grace requires a correspondent action of the human will in order to become effectual; which, or something resembling it, is termed semi-pelagian in early ecclesiastical history. Some sentiments expressed by Melanchthon, towards the close of his life, seem to have introduced it into that church.

SYNEURO'SIS. (Gr. συν, and νευρον, *a nerve*, or *ligament*, or *membrane*.) The union of one bone with another by means of an intervening membrane.

SYNGNA'THIANS, *Syngnathii*. (Gr. συν, *with*, γναθος, *a jaw*.) The name of a family of Lophobranchiate fishes, including those in which the lengthened jaws are united by a surrounding integument, so as to form a tubular mouth: the genus *Syngnathus*, or pipe fish, is the type. *Syngnathæ* is a name given by Dr. Leach to an order of Myriapodous insects.

SY'NGRAPHA. (Gr. συν, and γραφω, *I write*.) In Diplomatics, contracts signed by the creditor and debtor, and of which a duplicate original was kept by each.

SYNIZE'SIS. (Gr. συνιζω, *I meet*.) An obliteration of the pupil of the eye; a closed pupil.

SY'NOCHA. (Gr. συνεχω, *I continue*.) A continued inflammatory fever. The term *synochus* is applied to continued fevers, which are in their symptoms intermediate between *synocha* and *typhus*. They are also called *mixed fevers*.

SY'NOD. (Gr. συνοδος, employed in that language to signify a council or ecclesiastical assembly.) Among the moderns a distinction is sometimes made between a council and a synod; the former term representing a general assembly of the episcopal, provincial, or national order; the latter the convention of the inferior clergy of a diocese under its bishop or archdeacon. *See* COUNCIL.

SYNOD. In the Scottish Kirk, an assembly composed of two or more presbyteries. It consists of every parish minister within its limits, and of the elders who have last represented the different sessions in the presbytery. There are sixteen synods in Scotland. *See* PRESBYTERY.

SY'NOD OF DORT. *See* DORT, SYNOD OF.

SYNO'DIC. (Gr. *συν, together, οδος, pathway.*) In Astronomy, the synodic revolution of a planet (or the moon), with respect to the sun, is the time between two consecutive conjunctions or oppositions. The duration of this period is easily found when the difference between the mean motion of the planet and sun in a given interval of time is known; for this difference is to 360° as the given interval to the synodic revolution. The *synodical month* is the period of the moon's synodic revolution, and is the same with *lunar month* or *lunation*. *See* MOON.

SY'NONYMS. (Gr. *συν*, and *ονομα, a name.*) Words of the same language which have a similar signification. Strictly speaking, words having exactly the same signification are not to be found in any language, unless one of them has been borrowed from another language; but in this case the shades of difference are often so slight that words may be frequently used for one another, and this interchange produces a pleasing variety in composition, necessary in poetry. Synonyms form an important object of philological study, demanding, on the part of the inquirer, great knowledge of the principles of language. The chief works on this subject are the *Onomasticon* on Greek, Dumesnil on Latin, Blair, Booth, and Crabbe on English, Stosch and Eberhard on German, and Girard, Beauzée, and Roubaud on French synonyms.

SYNO'PSIS. (Gr. *συν, together, οψις, view.*) A collective view of any subject; as a synopsis of astronomy, theology, &c.

SYNO'VIA. (Gr. *συν*, and *ωον, an egg.*) The fluid which lubricates the cartilaginous surfaces of the joints: it is glairy, and resembles the white of egg.

SY'NTAX. (Gr. *συντασσω, I arrange together.*) In Grammar and Rhetoric, the disposition of the words and members of a sentence in the grammatical arrangements proper to the language. *See* GRAMMAR.

SY'NTHESIS. (Gr. *συν, with; τιθημι, I place.*) In Geometry and Logic, the method of demonstration which sets out from some principle established or assumed, or proposition already demonstrated, and ascends through a series of propositions to that which is enunciated. Synthesis is also called the direct method or *composition*, and is the reverse of analysis or resolution. It is the method followed in *Euclid's Elements*. For the sense in which analysis and synthesis were understood by the ancient geometricians, see ANALYSIS.

SYNTHESIS. In Chemistry, those chemical operations by which compounds are obtained by the union of the separate component parts are called *synthetic*. The term is especially used as opposed to *analysis*. Thus I demonstrate the composition of water *analytically* by resolving it into oxygen and hydrogen gases; and *synthetically*, by recombining those gases so as again to produce the water which had previously been decomposed; the terms *synthesis* and *analysis* being, in fact, synonymous with *composition* and *decomposition*.

SY'PHILIS. (Probably from Gr. *σιφλος, unclean.*) The venereal disease.

SY'RINGE. In Hydraulics, a machine consisting of a small cylinder with an air-tight piston or sucker, which is moved up and down in it by means of a handle. The lower end of the cylinder terminates in a small tube, through which a fluid is forced into the body of the cylinder by the atmospheric pressure when the handle is drawn up, and then expelled in a small jet by pushing the handle in the opposite direction. The syringe acts on the principle of the sucking pump. The syringe is also used as a pneumatic machine for condensing or exhausting the air in a close vessel, but for this purpose it must be furnished with two valves. In the condensing syringe, the valves open downwards and close upwards; in the exhausting syringe they are closed downwards and opened upwards. *See* AIR GUN and AIR PUMP.

SY'RMA. (Gr. *συρμα*, from *συρω, I draw.*) A long garment; so called from its train reaching the ground. It was the proper dress of actors in the classical tragedy.

SYSSARCO'SIS. (Gr. *συν, with*, and *σαρξ, flesh.*) The junction of bones by intervening muscles.

SYSSI'TIA. (Gr. *συσσίτια, common messes.*) An institution of some ancient states, particularly Lacedæmon and Crete, by which the male freemen had their meals together in common messes, instead of eating with their families in private.

SYSTEM. (Gr. *συν, together*, and *ιστημι, I stand.*) In Astronomy, an hypothesis of a certain order and arrangement of the celestial bodies by which their apparent motions are explained. For an account of the systems of Ptolemy, Copernicus, and Tycho Brahe, see ASTRONOMY.

SYSTEM. In the Fine Arts, a collection of the rules and principles upon which an artist works.

SYSTEM. In Music, an interval composed, or supposed to be composed, of several lesser ones; as an octave, which is a system. *See* DIASTEM.

SY'STOLE. (Gr. *συστελλω, I contract.*) In Greek and Latin prosody, a licence by which a long syllable is used as short: *e.g.*

Matri longa decem tulĕrunt fastidia Menses.

SYSTOLE. The contraction of the heart

SY'STYLE. (Gr. *συν, with*, and *στυλος, a column.*) In Architecture, the arrangement of columns in such a manner that they are two diameters apart.

SY'ZYGIES. (Gr. *συζυγια, union, conjunction.*) In Astronomy, the places of the moon or planets when in conjunction or opposition with the sun.

T.

T, the nineteenth letter in the English alphabet, belongs to that order of consonants called *dentals*, or *palato-dentals*, and is susceptible of numerous interchanges, both in the ancient and modern languages. As an abbreviation, T was used for Titus, Tilius, and Tullius. The Roman tribunes indicated their assent to the decrees of the senate by subscribing a T. The sound of *th* is peculiar to the English language.

T BANDAGE. A bandage so named from its shape; it is used to support the dressings after certain surgical operations. (See *Cooper's Surgical Dictionary*.)

TABA'RD. A sort of tunic, or mantle, covering the body before and behind, reaching below the loins, but open at the sides from the shoulders downwards: an ordinary article of dress in England and France in the middle ages. It was at first chiefly used by the military, afterwards by other classes. The tabard, with coats of arms blazoned before and behind, is the state-dress of heralds to this day. It is the dress worn by the knaves in cards. Long tabards, reaching to the mid-leg, were a peculiarly English fashion.

TABASHE'ER. A Persian word signifying a light white porous substance found in the joints of the bamboo: it consists almost entirely of silica. It is said to be used medicinally in the East Indies; but its virtues must be merely imaginary.

TA'BBY. (Ital. tabino.) A term formerly applied to certain figured silks and other goods upon which an irregular pattern had been stamped, either by the pressure of engraved rollers, or by folding the stuffs in such a way as to produce, by the mutual pressure of their fibres, an inequality of surface, which, by reflected light, gives rise to the appearance called *watering*.

TABE'LLION. (Lat. tabula, from the tablets on which they wrote.) In the Roman empire, officers who had charge of public documents were so called; they were also secretaries, or registrars, and in some cases judges. (See Savigny, *Hist. of the Roman Law*, vol. i.) The notaries were their assistants. In France, the titles of "Tabellion" and "Greffier" were confounded, and Henry IV. united the functions of tabellion with those of notary; but the old title seems still to be retained (or was until the Revolution) in some few places.

TA'BERNACLE. (Lat. tabernaculum.) A Latin word signifying a *tent* or *cabin*. The tabernacle which was carried from station to station by the Jews during their wanderings in the desert, was a tent of sails and skins stretched upon a framework of wood, and divided into two compartments; the outer, named *the Holy*, being that in which incense was burned, and the shew bread exhibited; and the inner, or *Holy of Holies*, in which was deposited the ark of the covenant. (Exod. xxvi. xxvii. See *Archæologia*, vol. i.)

The Feast of Tabernacles was one of the three principal festivals among the Jews. It commenced on the 15th of the month Tisri, corresponding with the 30th of September, and lasted seven days, during which the people dwelt in booths formed of the boughs of trees. It was instituted in commemoration of the habitation of their ancestors in similar dwellings during the forty years of their pilgrimage in the wilderness. (See Leviticus, xxiii.)

TA'BES. (Lat.) A wasting away of the body; emaciation; atrophy.

TA'BLATURE. (Lat. tabula, *a table.*) In Music, the use of the letters of the alphabet, or any other character, for expressing the notes or sounds of a composition. It is not now a usual mode of writing. In its stricter and more original sense it is a mode of writing music for a particular instrument on parallel lines (of which each represents a string of the instrument) by means of certain letters of the alphabet. Thus A denotes that the string is to be struck open, B that one of the fingers is to be put on the first stop, C on the second, D on the third, and so on through the octave.

TA'BLE. (Lat. tabula.) In Physics, Astronomy, &c. This term has two different significations. In the first place, it is used to denote merely a collection of numbers, exhibiting the measures or values of some property common to a number of different bodies in reference to some common standard. Thus we have tables of specific gravity, of refractive powers, of the expansion of substances by heat, &c. In its second signification, it denotes a series of numbers which proceed according to

some given law expressed by a mathematical formula. Of this kind are the logarithmic tables; tables of the powers or roots of the different numbers; of the sines, cosines, and other angular functions; of astronomical refractions; of the equations of the planetary orbits, &c. Tables of this sort, by exhibiting at once to the eye all the different values which a given formula can have, save endless labour in calculation, and are of the utmost importance in every branch of natural philosophy. The logarithmic tables, for example, form the universal instrument of astronomical calculation; and it may be safely affirmed that without them the computations necessary for determining the places of the different bodies of the solar system, and rendering astronomy a science of practical utility, would be altogether impossible.

Table is also used in a popular sense to denote a collection of particulars brought under one view. Thus, in history, we have chronological tables; in statistics, tables of mortality at different ages, &c. The mere titles of the useful tables which have been formed in the various departments of knowledge would fill a large volume.

TABLEAUX VIVANTS. (Fr. *living pictures.*) The name given to an amusement in which groups of persons dressed in appropriate costume are made to represent some interesting scene in the works of distinguished painters or authors. It is thus managed:—The room in which the spectators are placed being darkened, the group assume their respective attitudes behind a frame (or some other contrivance intended to represent it) covered with gauze; and candles being so placed as to reflect light upon the group from above, the illusion is complete. These representations are not unfrequently resorted to in England; but their home is chiefly in France and Germany, where they form an important feature on all festive occasions. They owe their present popularity to the celebrated M. Händel-Schutz, whose genius for imitation and declamation was unrivalled in Germany. (See the *Damen-Lexicon.*) Tableaux are often employed to represent some scene in which a riddle is concealed.

TA'BLE LANDS. In Physical Geography, the name given to an extensive system of plains with steep acclivities on every side, and differing from other plains, which are either not much elevated above the sea, or rise by imperceptible degrees. Some of these are very extensive, and retain a general level of several thousand feet above the sea. Sometimes they are bordered with chains of mountains much less elevated on the side towards the table land than in the opposite direction: and sometimes they have surfaces much undulated or broken. The chief table lands are in Central Spain, Southern Africa, Central Asia, Persia, Southern India, Mexico, and the Southern Andes. (See *Traill's Physical Geography*, p. 25. *et seq.*)

TABLE SPAR, TABULAR SPAR. *Schaalstein* of Werner. A greyish white mineral, which occurs in masses and in granular concretions: it is a silicate of lime.

TABLETS. In Roman Antiquities, pieces of ivory, metal, stone, or other substance, used in judiciary proceedings, or in the passing of laws.

TA'BOR. (Fr. tabourine.) A small drum.

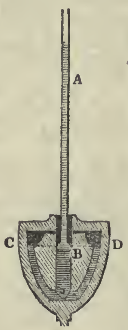
TA'BORITES, or THABORITES. The denomination of one of the parties into which the followers of Huss, in Bohemia, separated after the death of their leader. They were so called from Tabor, a hill or fortress of Bohemia, upon which they encamped during the struggle which they maintained against the civil and ecclesiastical power. At their head stood John Ziska von Brockznow, who was distinguished at once for his indomitable courage and his remorseless cruelty. After various fanatical exhibitions, which were met by their adversaries with determined hostility, the better and more quietly disposed portion of the Taborites formed themselves into a religious society under the denomination of the Bohemian Brethren. They established several Christian communities, elected their own bishops, priests, and elders; drew up a rigorous plan of ecclesiastical discipline; and sent forth missionaries to various parts, though with little success. Though harassed by persecutions, they continued to augment their numbers, and at the end of the 15th century they counted about 200 communities of adherents. At the end of this period the distinctive name and opinions of the Taborites were lost among the various assailants of the Romish corruptions, who formed the vanguard of the Reformation in Germany. (*See* CALIXTINES, HUSSITES.) An interesting picture of the horrors of the bloody religious war in which this sect was engaged at the period of its institution is to be found in the historical romance of Herlosssohn, called *The Last Taborite* (*Der Letzte Taborit*)—a work well worthy of being translated into English.

TABULA'TUM. (Lat.) In Ancient Architecture, a term used to denote the floors, ceilings, and other wood work in a house: occasionally also it was applied to balconies and projections of that nature.

TA'CAMAHA'C. (An Indian word.) A brownish aromatic resin formerly used in medicine, supposed to be the produce of the *Populus balsamifera.*

TACET. (Lat. taceo, *silent.*) In Music, a term denoting that through the movement to which it is affixed in any part that part is to lie still or be silent during its performance.

TACHO'METER. (Gr. ταχος, *speed*, and μετρον, *measure.*) A contrivance invented for the purpose of indicating minute variations in the velocity of machines. When a vessel containing a fluid is whirled rapidly round a vertical axis, the centrifugal force produced by the whirling motion causes the fluid to recede from the axis, and to rise on the sides of the vessel, so that the surface of the fluid assumes a concave parabolic form; and the distance to which the centre of the surface falls below its original level is proportionate to the velocity of rotation, and subject to corresponding variations. Any method, therefore, of measuring or rendering visible the depression of the central surface will indicate the variations of velocity. The method usually adopted is the following:—A glass tube A, open at both ends, and expanding at one extremity into a bell B, is immersed with its wider end in mercury contained in a cup C D. The tube is so suspended as to be unconnected with the cup. This tube is then filled to a certain height, A, with spirits tinged with some colouring matter, to render it easily observable. The cup is attached to a spindle turned by the machine. Now as the cup is whirled round by the spindle, the level of the mercury in the bell falls, and the spirit therefore descends in the tube. As the motion is continued, every change of velocity causes a corresponding change in the level of the mercury, and consequently also in the height of the spirits in the tube at A; and as the capacity of the bell B is much greater than that of the tube A, a very small change in the level of the mercury causes a considerable change of the height of the spirits in the tube. (*Cabinet Cyclopedia*, art. "Mechanics," p. 235.)



TACHYDRO'MIANS, *Tachydromii.* (Gr. ταχυς, *swift*, and δρομος, *a course.*) The name of a family of wading birds, of which the genus *Tachydromus* is the type. The term is also applied to a family of Saurian reptiles by Fitzinger, and to a family of Dipterous insects by Mirgen.

TACHY'DROMUS. (Gr. ταχυς, and δρομος, *a course.*) A subgenus of *Lacertidæ*, differing from the true lizards in having a very long body and tail, with their fore legs very distant from the hind legs, and the back covered with scales similar to those on the belly. They are found in the Indian islands and China, and run with great velocity; whence their name of swift lizards.

TACHY'GRAPHY, or TACHE'OGRAPHY. (Gr. ταχος, *quick*, and γραφω, *I write.*) One of the many names of Greek derivation which have been given to the art of short hand.

TACK. The weather clue or corner of a course, as also of any sail set with a boom or gaff, and of a flag. Also, the rope by which such clue is extended: thus, the *main tack* is the rope by which the tack or weather clue of the mainsail is drawn down to the ship's side.

A ship is said to be on the *starboard tack* when she is close-hauled, having the wind on the starboard side; and on the *larboard tack*, when the wind is on the larboard side. *To tack* is to change from one tack to the other by turning the vessel round with her head to the wind.

TA'CKLE. The Sea term for a pulley composed of two or more blocks. The rope is called the *fall.* The term appears to have been derived thus:—Gr. τροχαλια; Lat. trochlea; Ital. taglia; Dutch taakel. (See *Willis's Principles of Mechanics*, p. 198.)

TA'CTICS. In a general sense, the evolutions, manœuvres, and positions which constitute the main spring of military and naval finesse.

The expression *naval tactics* is commonly understood to relate to the attack or defence of fleets or single ships; but as tactical manœuvres are necessarily practised also in keeping any number of ships together, and in the communication of single ships, whether for hostile purposes or not, the subject, in fact, includes all considerations relative to the closing or separating of vessels at sea. We can of course here merely attempt to convey such general notions on the subject as may assist the reader in the study of it.

The subject of tactics, as applied in war, naturally divides itself into two parts; viz. disposing the fleet for closing with or avoiding the enemy while distant, and bringing on the engagement. The former alone of these

can be made the subject of fixed rules; but the manner of bringing on the action with the whole or part of the enemy's fleet, the choice of the weather or lee *gage* (as the windward or leeward position is called), under given circumstances of weather, locality, armament, relative numbers, discipline, &c., must depend on the experience, skill, and *coup d'œil* of the commander-in-chief.

The evolutions by which the ships of the fleet pass from one position to another are given in all works on naval tactics; and those in most common use are often contained in Signal Books, both English and foreign. The elementary evolutions really necessary are but few, though, especially in foreign works, they are multiplied to an inconvenient, if not impracticable extent. The opinions of officers and writers have differed on many points of great importance; such as the position of the commander-in-chief, the tacking or wearing of the fleet together, or in succession, and also in the general disposition of the fleet.

In regard to the action itself, it appears it was the custom formerly to endeavour to engage the enemy's whole fleet, ship to ship. This, however, was, in most cases, easily avoided, and actions were consequently often indecisive. The circumstance of Lord Rodney's passing through the French fleet on the 12th of April, 1782, seems to have drawn attention strongly to the principle of separating the enemy's fleet into portions which might be attacked in detail. The merit of suggesting the breaking of the enemy's line on this occasion having been attributed to Mr. Clerk of Eldin, author of a work on Tactics which appeared at the time, has become the occasion of much controversy; but the manœuvre had been already treated in French and Spanish works on Tactics. One of the most striking applications of the principle was exhibited in Lord Nelson's attack at the battle of the Nile. Among the works on Tactics may be noticed here, *Tactique Navale*, by the Count Morogues, which was considered an improvement on Le Pere Hoste's work; *Tactica Naval*, by Salazar; and Mr. Clerk of Eldin's *Naval Tactics*, above quoted. Much information is contained in Admiral Ekins's *Naval Battles;* and remarks on the tactics of single actions are found in Sir Howard Douglas's *Naval Gunnery*. Some other works on the subject will be found in any good catalogue of naval books.

TA'CTION. (Lat. tango, *I touch.*) In Geometry, the same as tangency or touching. *See* TANGENT.

TÆ'NIA. (Gr. ταινια, *a fillet.*) An intestinal worm, commonly called the *tape worm*. When this worm infests the bowels, it often produces a variety of anomalous symptoms, and is very difficult to get rid of. The most effective remedies are purges, and especially oil of turpentine, half an ounce of which is taken in the morning, fasting, mixed with a little barley water. If it does not purge briskly, a dose of castor oil may be taken after it, or the oil of turpentine repeated. If any portion of the tape worm remains in the intestines, the symptoms are apt to recur, so that much attention is requisite to ensure its total evacuation.

TÆNIA. In Architecture, the listel above the architrave which separates it from the frieze in the Doric order.

TÆ'NIOIDS, *Tænioides*. (Gr. ταινια, *a riband;* εἶδος, *form.*) The name given by Cuvier to a family of Acanthopterygious fishes, comprehending those which have a flattened riband-shaped body; also the name of a family of Sterelminthoid intestinal worms, of which the tape worm (*Tænia*) is the type.

TA'FFETY. A thin glossy silken fabric, formerly much used in England. It is extensively used on the Continent for window curtains.

TA'FFRAIL. The uppermost rail of a ship's stern.

TA'GES. An old Italian divinity, who is represented to have sprung as a beautiful boy from the earth, which a Tuscan ploughman had furrowed too deep. The first act of this earth-born god was to foretel from the wings of birds what was to happen to the peasants by whom he was quickly surrounded; and hence he was worshipped as the inventor of augury. (*See* AUGURS.) A collection of his prophecies was made and preserved in the sacred records of Etruria.

TA'GLIA. (Ital.) In Mechanics, the name given to a particular combination of pulleys. "The taglia consists of a system of fixed pulleys collected in one common block, and also of a system of moveable pulleys in a separate block, to which the weight is attached, with one string going round all the pulleys, and having one of its ends fixed to a point in the system, and the other end going from one of the fixed pulleys drawn by the power." (*Venturoli's Mechanics*, by Cresswell.) Sometimes several taglias are combined, so that one acts upon the other; the system is then a *compound taglia*. *See* PULLEY.

TAGLIACO'TIAN OPERATION. The operation for the restoration of the nose. *Rhinoplastie* of the French. The merit of inventing this operation is usually given to Tagliacotius, a Venetian surgeon, who wrote upon the subject in 1598, and proposed the replacement of the deficient organ by an artificial nose cut out of the skin of the shoulder or arm. A supposed modern improvement consists in having recourse for the new materials to the skin of the forehead, out of which a triangular piece is so cut that it may retain connection at its apex, which is downwards, and so admit of being twisted or turned down to form the artificial nose by adhesion to the recently cut surfaces of the truncated organ. It appears that this operation was practised in India from time immemorial, and that it was also not uncommonly resorted to by the Italians, and especially the Romans, among whom the loss of the nose was a punishment of not unfrequent infliction. (See *An Account of Two Successful Operations for restoring a lost Nose*, by J. C. Carpue, Lond. 1816; *Liston's Practical Surgery*, Lond. 1837; and *Cooper's Surgical Dictionary*.)

TA'GUS. (Gr. ταγός.) In ancient Greek History, the title of the president of the Thessalian confederacy.

TAIL. In Architecture, the bottom or lower end of any member, as of a slate or tile. A *tail trimmer* is that next the wall into which the ends of joists are fastened to avoid the flues. Used as a verb, *to tail in* any thing is to fasten it by one of its ends into a wall.

TAILLE. In ancient French Jurisprudence, any imposition levied by the king or any other lord on his subjects. There is some obscurity about the derivation of this word. It is commonly deduced from talcæ, *tallies*, little pieces of wood with which reckonings were made. But whether these were not so called from their use in *telling* or counting (Germ. zahlen), does not appear. Again, it is apparently connected with the Germ. zoll, Engl. *toll;* but these words are derived by some, through the Ital. tolta, from the Lat. tollere, *to raise*. Perhaps the whole series of words is from the same original root; but it is not easy to trace the affinities. The *Royal Taille*, in old France, which was the impost commonly understood under the general name, was a personal or rather mixed constitution, from persons not noble or ecclesiastical, or enjoying certain other exemptions imposed according to their supposed ability, measured by their goods. In the respect in which it fell on the agricultural class, from which it was chiefly levied, it is described by Adam Smith as "a tax on the supposed profits of the farmer, which they estimate by the stock which he has upon the farm." (Book iii. ch. 2.) In Languedoc, and one or two other districts, the taille was real; *i. e.* imposed on land and goods. This tax was rendered annual and permanent in 1445. The "real" taille is now replaced by the "contribution foncière," and the personal by the "contribution personnelle et mobiliaire."

TAILLOIR. (Fr.) In Architecture, the same as *abacus;* which see.

TAI'LZIE, or ENTAIL (Fr. tailler, *to cut off*), in Scottish Law, signifies, in general, any deed whereby the legal course of succession is cut off, and an arbitrary one substituted. But, more strictly, a deed of tailzie is one framed in terms of the statute 1685, c. 22., and intended for the purpose of securing the descent of an heritable estate to the series of heirs and substitutes called to the succession by the maker of the tailzie. The principal difference between Scottish and English entails lies in the absence of any provision, in the law of the former country, similar to the fictions of fines or recoveries in the latter, whereby parties in possession were enabled to cut off the entail. Several statutes have been passed since that of 1685 to give heirs of entail in possession certain liberties which they could not otherwise possess; as, to sell superiorities (2 G. 2. c. 50, 51.); to grant leases for 31 years, 14 years, and a life or two lives, and building leases for 99 years; and to exchange lands (10 G. 3. c. 51.), redeem the land tax (42 G. 3. c. 46.), make provisions for wives and children (5 G. 4. c. 87.).

TALAPO'INS. The title, in Siam, of the priests of Fo; who are called in China, Seng; in Tartary, Lamas; and by Europeans, Bonzes.

TALC. A foliated magnesian mineral of an unctuous feel, often used for tracing lines on wood, cloth, &c., which are not so easily effaced as those of chalk. Talc is employed in the composition of *rouge végétal*. The Romans prepared with it a beautiful blue, by combining it with the colouring fluid of particular kinds of testaceous animals. Talc is met with in Aberdeenshire, Perthshire, and Banffshire in Scotland, and in various parts of the Continent, where rocks of serpentine and porphyry occur. The talc brought from the Tyrolese mountains is called in commerce Venetian talc. Several varieties are found in India and Ceylon.

TA'LCITE. In Mineralogy, a synonym of *nacrite;* which see.

TA'LENT. (Gr. ταλαντον.) A Grecian weight, which was much used in the computation of money. It contained 60 minæ; but its value varied in different states. The Attic talent was equivalent to about 198*l.* of English money; the Æginetan to 331*l.* (See as to the Attic talent, *Boeckh*, i. 25.; *Gibbon's Miscellan. Works* iii. 410.)

TA'LES. In Law. If by reason of challenges or other causes a sufficient number of jurors do not appear at a trial, either party may pray a tales; that is, may pray the sheriff (since 6 G. 4. c. 50. the judge at the trial) to allow a sufficient number of qualified men who happen to be present (tales circumstantibus) to be joined with the other jurors to make up the twelve. In practice this seldom arises, except in the case of special jury trials, when the talesmen are taken from the common jury panel in the same court. *See* JURY.

TALIO'NIS LEX. (Lat.) A punishment in which a person convicted of a crime suffered exactly in the same manner as he had offended: thus an eye was required for an eye and a tooth for a tooth. This mode of punishment was established by the Mosaic law, and was in some cases imitated by the Romans.

TA'LISMAN. (From the Arabic, dual of the noun telesm; Gr. τελεσμα, in the sense of an astrological wonder, or effect of the stars.) Among the Eastern nations, a figure cut in metal, stone, &c., supposed to have been made with particular ceremonies, and under particular astrological circumstances, and to possess various virtues, but chiefly that of averting disease or violent death from the wearer. In a more general sense, any portable object endowed with imaginary influence in controlling evil spirits, &c. has been so designated. The term is frequently used as synonymous with amulet (which see); but, strictly speaking, the latter is not believed to possess such extensive powers as the talisman. (See a curious article in the *Enc. Metropolitana*.)

TA'LLAGE (from the Fr. taille), in the language of the old English law, is said to be a general name for all taxes by Sir E. Coke. *See* TOLL, TAILLE.

TA'LLOW. (Germ. talg.) The fat obtained by melting the suet of the ox and sheep, and straining it so as to free it from membrane.

Tallow is an article of great importance. It is manufactured into candles and soap; and is extensively used in the dressing of leather, and in various processes of the arts. Besides our extensive supplies of native tallow, we annually import a very large quantity, principally from Russia. The exports of tallow from Petersburgh amount, at an average, to between 3,500,000 and 4,000,000 poods, of which the largest portion by far is brought to England; the remainder being exported to Prussia, France, the Hanse Towns, Turkey, &c.

TALMUD. The traditionary or unwritten laws of the Jews. It is called *unwritten*, to distinguish it from the textual or *written* law; and, is in fact, the interpretation which the rabbins affix to the law of Moses, which embodies their doctrine, polity, and ceremonies, and to which many of them adhere more than to the law itself.

The word is derived from Heb. lamad, *he taught*. The Talmud, therefore, is a book or volume, which contains such doctrines and duties as are *taught* to the Jews by their own authorized *teachers*, the ancient rabbins.

There are two Talmuds, that of Jerusalem and that of Babylon; not to mention those of Onkelos and Jonathan, which are rather paraphrases than volumes of traditionary doctrines.

The Talmud of Jerusalem consists of two parts — the *Gemara*, and the *Mishna*. The *Mishna* signifies a doubling or reiteration; the *Gemara*, a work brought to perfection or completed, — from the Chaldee *gamar*, to finish or complete. The Gemara and the Mishna together, strictly speaking, form the Talmud; but the rabbins are wont to designate the Pentateuch of Moses the *first* part of the Talmud, and which is simply the law. The *second* part is the *Mishna*, which is a more extensive explication or amplification of the law; and the *third* part, the *Gemara*, as finishing and completing it.

The Mishna is the work of Rabbi Judah Hakkadosh, 120 years after the destruction of the temple of Jerusalem. It is written in a tolerably pure style, and its reasonings are much more solid than those of the Gemara, which the Jewish doctors, it is stated, have stuffed with dreams and chimeras, and many ignorant and impertinent questions and disputations. The Gemara was written about 100 years afterwards by Rabbi Jochanan, the rector of the school at Tiberias. These two works form the Jerusalem Talmud.

But the Talmud of Jerusalem is less esteemed than the Talmud of Babylon formed by Rabbi Asa or Aser, who had an academy for forty years at a place called Sara, near Babylon, whence it was denominated the Babylonish Talmud. It is this Talmud which the Jews more frequently consult; and it is especially esteemed by those Jews who live beyond the Euphrates, from the circumstance that it was compiled at Babylon. Rabbi Asa was called to his fathers before this celebrated commentary on the Mishna was completed; but it was finished by his disciples (some say his children) about 500 years after Christ. With the exception of the sacred authors, these Talmuds, after the Chaldee paraphrases, are the most ancient books of doctrine possessed by the Jews.

A converted Jew in the year 1238 detected several errors in the Talmud, which he laid before Pope Gregory IX., who required the archbishops of France and the kings of Spain and Portugal to seize and burn all such books of the Jews, and twenty cartloads of Hebrew books were accordingly burnt in France alone.

Pope Paul IV. and Clement VIII. also signalized themselves in destroying all the Talmudic books that could be found, and many thousand volumes of the Talmud were by their orders juridically condemned to the flames. These acts, worthy of Roman pontiffs, might have suggested that famous list, entitled *Libri Prohibitorum*, which afterwards received much augmentation; and among the many *heretical* works enumerated might be found Addison's *Spectator*.

The Talmud of Jerusalem was printed in one vol. folio, and that of Babylon in twelve and fourteen vols. folio, which we find in a bookseller's catalogue thus described, "Talmud Babylonicum Hebraicum integrum ex Sapientum Scriptis et Responsis compositum a Rab. Aser, additis Comment. Rab. Sal. Iarchi, et Rab. Mosis Maimonidis, Hebraice, 14 tom. folio, Amstelodami, 1644."

Two curious works on the traditions and doctrines of the Jews, and selections from the Talmud, were written by Peter Stehelin and W. Wotton; the former entitled *Traditions of the Jews, with the Expositions and Doctrines of the Rabbins contained in the Talmud and other Rabbinical Writings*, 2 vols. 8vo. 1742; the latter, *Miscellaneous Discourses relating to the Traditions and Usages of the Scribes and Pharisees in our Saviour's Time*, 2 vols. 8vo. 1718. (See the *Enc. Metropolitana*; Wolff, *Bibl.* ii. 658.; Eisenmenger, *Das Entdeckte Judenthum*; Remarks on the study of it in *Quart. Rev.* vol. xliii.)

TA'LON. (Fr.) In Architecture, the same as *ogee*; which see.

TA'LPA. In Surgery, a tumour under the skin or cuticle, commonly called a *mole*.

TA'LUS. The sloping heap of fragments accumulated at the foot of a steep rock. The term talus has also been applied to the *astragalus*, one of the bones of the ankle.

TA'MARIND. (Arab. tamor-hindy, *Indian date*.) A large tree of the Leguminous order, whose pods supply the subacid preserve commonly sold in the shops under this name. The pods in their natural state are acid, and acquire their sweetness by the sugar in which they are packed after their hard brittle shell has been taken off. The tree itself is a native of both the East and West Indies.

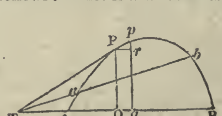
TA'MARIX (Tamarisia, the people among whom it grows), is a name given by botanists to some shrubs of slender growth, clothed with very small green leaves and long spikes of pink flowers, the natural country of which seems to extend from Spain to Delhi, occupying a band of ten or twelve degrees of latitude. They are in this country merely ornamental plants; but in Syria and the adjoining countries they secrete a kind of manna, which some authors have asserted was the manna of scripture; but this opinion is not regarded as well founded.

TAMBOURI'NE. (Fr. tambour.) A musical instrument of procession of the drum species, being a cylinder of about 6 inches wide, in which bells are suspended. It is covered at one end with parchment, after the fashion of a drum.

TA'MPING. A term used by miners to express the filling up of a hole bored in a rock for the purpose of blasting.

TA'NGENCIES. (Lat. tango, *I touch*.) In the ancient Geometry, the *problem of tangencies* was one of the six branches of the geometrical analysis created by Apollonius of Perga. Its general object was to describe a circle passing through given points, and touching straight lines or circles given in position, the number of data in each case being, of course, limited to three. Of the treatise of Apollonius some lemmas only were preserved in the mathematical collections of Pappus; from which the treatise was restored by Vieta, of whose restoration there is an English translation by Lawson, with the addition of a supplement by Fermat, on Spherical Tangencies. The principal cases of the problem of plane tangencies are given, and neatly demonstrated, in *Leslie's Geometrical Analysis*.

TA'NGENT. (Lat. tangens; from tango, *I touch*.) In Geometry, the tangent to a curve is a straight line which meets or touches the curve without intersecting it. The nature of the tangent may be explained as follows: — Let A P B be an arc of a curve, and let the straight line T A B intersect it in two points, A and B. Conceive the straight line to revolve about the point T. When it comes into the position T *a b* the intercepted arc *a* P *b* is shorter than A P B, or the points *a* and *b* have approximated. Let the motion of the line about T still be continued, and the length of the intercepted



arc of the curve will become less and less, until the straight line comes into the position T P, when the two points a and b coalesce, or rather their distance becomes smaller than any assignable quantity. In this ultimate position, the direction of the vanishing arc is that of the tangent, or the element of the arc coincides with the tangent.

From this it is easy to deduce an expression which determines the direction of the tangent at the point P. Let A be the origin of the rectangular co-ordinates, the abscissa being measured on A B. Through P draw the ordinate P Q; and taking P p an indefinitely small element of the curve, draw $p\ q$ the ordinate through p, and P r parallel to A B; also let the tangent meet A B produced in T. The line Q T is called the subtangent; and the point P being assumed, it is only necessary to determine T, or the distance Q T, in order to have the tangent P T. Now the triangles P $p\ r$ and P Q T are similar, whence $p\,r : r\,\mathrm{P} : \mathrm{P\,Q} : \mathrm{Q\,T}$; but by the principles of the infinitesimal calculus $p\,r = d\,y$, $r\,\mathrm{P} = d\,x$; and we have also $\mathrm{P\,Q} = y$, therefore $d\,y : d\,x : : y : \mathrm{Q\,T}$; that is, the subtangent $\mathrm{Q\,T} = y\dfrac{d\,x}{d\,y}$.

See Differential Calculus, p. 343.

This is the general formula for the subtangent of any curve at the point whose co-ordinates are x and y; and therefore the position of the tangent can always be determined when the relation between x and y is defined by an equation, by differentiating that equation.

One of the earliest uses which was made of the differential calculus was to find the positions of tangents to curve lines; and hence the calculus itself, in its early period, was often denominated the *method of tangents*. When the equation of the curve is given, it is easy to find the tangent at any point, as only a simple differentiation is required in addition to the ordinary operations of algebra; but the inverse problem, to determine the equation of the curve when its subtangent at any point is given, requires an integration, and is consequently, in general, attended with much greater difficulty. The first problem was called the *direct*, and the second the *inverse* method of tangents. The terms are synonymous with differential and integral calculus.

Euclid has shown that no straight line can be drawn between a circle and its tangent which does not cut the circle. This property is true of all other curves, and the contact of a curve with its tangent is called a contact of the first order. *See* Contact, Angle of.

Tangent, in Trigonometry, is the straight line which touches a circular arc at one of its extremities, and is terminated by the production of the radius passing through the other extremity. The arc and its tangent have always a certain relation to each other; and when the one is given in parts of the radius, the other can always be computed by means of an infinite series. Let ϕ denote an arc, and tan. ϕ the tangent of the arc ϕ; we have the following series:—

$$\phi = \tan\phi - \tfrac{1}{3}\tan^3\phi + \tfrac{1}{5}\tan^5\phi - \tfrac{1}{7}\tan^7\phi + \&c.$$

$$\tan\phi = \phi + \frac{\phi^3}{3} + \frac{2\,\phi^5}{3\cdot 5} + \frac{17\,\phi^7}{3^2\cdot 5\cdot 7} + \frac{62\,\phi^9}{3^2\cdot 5\cdot 7\cdot 9} + \&c.$$

The tangents were introduced into trigonometry by the Arabians, and the introduction has been of the most important use in simplifying calculations. For the manner of using the sines, cosines, tangents, and other angular functions, see Trigonometry.

TA'NISTRY. An ancient Irish custom of descent, defined as "descent from the oldest and worthiest of the blood." (See *Sir J. Davies's Cases before the Irish Judges*, 1762.) Some have derived it from thane or thegn; but this seems to be a word of Teutonic origin. (See also *Quart. Rev.* vol. lvi. p. 223.)

TANK. In the Navy, a case of sheet iron about 4 feet square, and containing about 2 tons. Bilge tanks are of various forms, in order to employ the vacant spaces near the sides in small vessels. Iron tanks have for many years been used in the navy from their incomparable superiority over casks in keeping the water sweet.

Tank. In Gardening, a cistern or reservoir, made of stone or timber or some other material, used in collecting and preserving water during a scarcity or drought. Tanks are sometimes built in the ground, and lined with lead or cement. (*Loudon's Encyc. of Gardening*, p. 603.)

TA'NNER'S BARK. The bark of oak, chestnut, willow, larch, and other trees, which abounds in tannin, and is used by tanners for preparing leather. After being exhausted of the tanning principle by being chopped into small pieces, or bruised, and steeped in water, it is laid up in heaps to dry, and sold to gardeners for the purpose of producing artificial heat by fermentation in pits or beds, in bark-stoves or other out-houses, or pits. *See* Stove.

TANNIC ACID. This term has been especially applied to a substance obtained by Pelouze by acting upon bruised galls by common ether; it is a white uncrystalline powder, very astringent, little soluble in water, and reddening litmus. When moistened and exposed to air it becomes converted into gallic acid. It is extremely astringent, and appears to be the active principle of tanning substances (tannin) in general. Its equivalent, deduced from the analysis of the neutral *tannates*, appears to be 426. Its ultimate elements are 30 atoms of carbon, 18 of hydrogen, and 24 of oxygen.

TA'NNIN. The pure astringent principle of vegetables, upon which their power of converting skin into leather depends. Its leading character is its property of producing a dense whitish precipitate in a strong solution of animal jelly, such, for instance, as isinglass. It may be obtained tolerably pure by infusing bruised grape seeds in cold water; or more circuitously by adding acetate of copper to filtered infusion of galls, washing the precipitate, and decomposing it (diffused through water) by sulphuretted hydrogen. On evaporating its solution, it is obtained as a pale yellow extract of a strong astringent taste. The action of astringents upon persalts of iron has given rise to its distinction into two varieties; the first changing them to deep blue or black, the second to green. The tan of galls, oak bark, grape seeds, &c., possesses the former property; that of catechu and tea the latter.

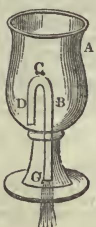
By digesting powdered charcoal in nitric acid, and carefully evaporating the solution so obtained, Mr. Hatchett succeeded in procuring a brown substance of an astringent taste, and precipitating solution of gelatine, which he terms, therefore, *artificial tan*.

TANTALITE, or COLUMBITE. The ferruginous oxide of columbium. It occurs in small masses, and in octoedral crystals. It has been found in Finland and in the United States of America.

TANTA'LIUM. *See* Columbium.

TA'NTALUS. In Greek Mythology, a king of Lydia, Phrygia, or Paphlagonia, according to different authors, whose punishment in the infernal regions is well known to classical readers. He was condemned to be plunged in water, and have delicious fruits hanging continually over his head, without the power of satisfying either thirst or hunger. His crime is differently represented. According to some, he served to the gods at a feast the limbs of his own son Pelops; according to others, he revealed the mystery of the gods, of whom he was high-priest; while others attribute to him the vices of pride and too great wealth. (For a learned interpretation of the myth, see *Bryant's Ancient Mythology*, i. 364.)

TANTALUS'S CUP. A philosophical toy which amusingly exhibits the principle of the siphon. Into a



hole in the bottom of a cup A the longer leg of a siphon B C D is cemented, so that the end D of the shorter leg nearly touches the bottom of the cup within. When water is poured into the cup, it rises in the shorter leg of the siphon until it reaches the level of the top of the bend at C, when it flows over into the larger leg, and is carried off at G; so that if water is not supplied to the cup faster than it is drawn off by the siphon, the cup will be emptied. To form the toy, the legs of the siphon are concealed by the hollow figure of a man whose chin is on a level with the bend of the siphon; so that the figure stands like Tantalus in the fable,—up to the chin in water, but unable to quench his thirst.

TA'NYSTOMES, *Tanystoma*. (Gr. *τεινω, I stretch*, and *στομα, a mouth*.) The name of a family of Dipterous insects, comprehending those which have a projecting proboscis, with the last joint of the antennæ undivided.

TA'PESTRY. (Fr. tapisserie.) An ornamental figured textile fabric of worsted or silk for lining the walls of apartments. The most celebrated manufacture of this kind is produced at the Gobelins royal manufactory, near Paris. In Painting, *tapestry* is applied to a representation of a subject in wool or silk, or both, worked on a woven ground of hemp or flax.

TAPE WORM. *See* Tænia.

TAPIO'CA. The prepared starch of the root of the *Jatropha manihot*. The root abounds with a milky juice, which is poisonous, but which deposits an inert starch when diffused through water. The root is called *cassava*, and is rendered harmless by boiling.

TA'PIR. (Lat. tapirus.) The name of a genus of Pachydermatous Mammals, of which three existing and several extinct species have been determined. Of the existing species one is a native of Sumatra, the other two of South America. They have a short proboscis; four toes on the fore foot, and three toes on the hind foot.

TAR. A dark-brown viscid liquid, obtained by heating the wood of the fir tree: it consists of resin, empyreumatic oil, and acetic acid. When inspissated by boiling, it is converted into *pitch*. The varieties of tar have lately been the subject of an elaborate investigation by Dr.

Reichenbach, who has obtained from it six distinct substances, which he terms *paraffine*, *eupion*, *kreasote*, *picamar*, *capnomar*, and *pittacal*.

TAR, MINERAL. A variety of bitumen, much resembling petroleum.

TA'RANIS. In Mythology, a Celtic divinity, confounded by Latin writers with their Jupiter. He was regarded as the evil principle, and worshipped with human sacrifices; whence the verse of Lucan,—

Et Taranis Scythicæ non mitior ara Dianæ.

(See *Mem. de l'Acad. des Inscr.* vol. xxiv.)

TARA'NTULA. (So called from Taranto in Sicily.) The name of a Fabrician genus of Pedipalpous Pulmonary Arachnidans, infesting the torrid regions of Asia and America. The group is now divided into the genera *Phrynus* and *Thelyphonus*. The term is also applied to a genus of spiders found in some parts of Sicily, whose bite produces a train of symptoms long believed to be curable only by music. From this word is derived the term *tarantella*, the national dance of the Sicilians.

TA'RDIGRADES, *Tardigrada*. (Lat. tardus, *slow*; gradior, *I march*.) A family of Edentate Mammals, comprising those which are remarkable for the slowness of their motions when upon the ground, as the sloths.

TA'RDO. (It. *slow*.) In Music, a term denoting that the movement to which it is affixed is to be performed slowly. It is nearly the same in signification as *largo*.

TARE. In Commerce, an abatement or deduction made from the weight of a parcel of goods on account of the weight of the chest, cask, bag, &c. in which they are contained. Tare is distinguished into *real tare*, *customary tare*, and *average tare*. The first is the actual weight of the package; the second its supposed weight according to the practice among merchants; and the third is the medium tare, deduced from weighing a few packages and taking it as the stnadard for the whole. In Amsterdam, and some other commercial cities, tares are generally fixed by custom; but in this country the prevailing practice, as to all goods that can be unpacked without injury, both at the custom-house and among merchants, is to ascertain the real tare. Sometimes, however, the buyer and seller make a particular agreement about it.

TARE. In Agriculture. *See* VETCH.

TA'RGUM. A Hebrew word, denoting a paraphrase of some portion of scripture in the Chaldean language, of which there are ten in existence: the two principal ones being those of Jonathan (or rather the Pseudo-Jonathan), an author who wrote a paraphrase, or rather a commentary, upon the Greater and Lesser Prophets, about thirty years B. C.; and of Onkelos, upon the Pentateuch, which is considered the most valuable of all, and is referred to the first century of our era. Two others are supposed to be of considerable antiquity. The remaining six are comparatively modern. (See *Enc. Metr.*)

TA'RIFF. A table alphabetically arranged, specifying the various duties, drawbacks, bounties, &c. charged and allowed on the importation and exportation of articles of foreign and domestic produce.

TARPAW'LING. A painted or tarred canvass cover generally.

TARRAS, or TERRAS. A volcanic product, which, mixed with mortar, gives it the property of hardening under water. Several argillo-ferruginous minerals possess this property, and are often indiscriminately used under this term.

TARSE, *Tarsus*. (Gr. ταρσος, *sole of foot*.) In Mammalia, signifies the collection of small bones between the tibia and metatarsus, or those which constitute the first part of the foot. In Birds, it is sometimes applied to the third segment of the leg, which is rarely fleshy or feathered; and corresponds with the tarsus and metatarsus conjoined. In Insects, it signifies the aggregate of minute joints which constitute the fifth principal segment of the leg or the foot.

TA'RTAR. (Gr. ταρταρος, *infernal*; because it is the sediment or dregs of wine.) The substance which concretes upon the inside of wine casks. It is called red and white *argol*, according to the wine from which it is obtained. When purified it is often called *cream of tartar*: it is a bitartrate of potash.

TARTAR EMETIC. A double salt, consisting of tartaric acid in combination with potassa and protoxide of antimony. *See* ANTIMONY.

TARTA'RIC ACID. The acid of tartar. This acid is contained in grape juice, and in tamarinds and several other fruits. It is usually obtained from purified tartar: 4 parts of powdered tartar and 1 of chalk are mixed in hot water, and the white powder which subsides (tartrate of lime) is decomposed by dilute sulphuric acid, which combines with the lime to form sulphate of lime, and the tartaric acid being liberated is obtained by evaporation. When pure it forms white crystals, composed of one equivalent of dry acid and one of water ($66 + 9 = 75$). The anhydrous tartaric acid, as it exists in the dry tartrates (tartrate of lead, for instance), is composed of

	Atoms.	Equiv.	
Carbon	4	24	36.36
Hydrogen	2	2	3·03
Oxygen	5	40	60·61
	1	66	100·00

TARTAR OF THE TEETH. This substance, which occasionally concretes upon the teeth, consists, according to Berzelius, of

Salivary mucus	13·5
Animal matter soluble in muriatic acid	7·5
Phosphate of lime (earthy phosphates)	7·9
	100·0

TA'RTARUS (Τάρταρος; called also the house of Hades by the Greeks, and Orcus by the Latins), was the name of the infernal regions, over which Pluto or Hades had dominion.

TARTRA'TES. Salts in which the tartaric acid is combined with bases.

TARTROVI'NIC ACID. An acid composed of tartaric acid in combination with the elements of ether.

TARTU'FFE. A common French nickname for hypocritical pretenders to devotion. It is derived from the celebrated comedy of Molière, of which the hero is so called. Whether Molière invented, or took it from the popular language of the time, does not appear: some say that he intended to attack Louis XIV.'s confessor, Père la Chaise, whom he had once seen eating truffles with peculiar *goût;* and thence the name. The play was written in 1664, but not acted till 1669; great difficulties being thrown in the way of the author by the clergy and the papal legate. On one occasion it was prohibited when the curtain was on the point of rising, and Molière announced to the public its disappointment in the well-known equivocal words, "Monsieur le président ne veut pas qu'on le joue." When at last licensed (through the influence, it is said, of the king himself), it had a run of three months with unparalleled success; and the eager attention and applause which it still excites bear testimony at once to the keenness of the wit, and the peculiar relish of the public for the exposure of the frailties of those who profess a religious character. In England, this play has been made more than once to serve the popular passions of the day. Cibber translated it, and made the hero a nonjuring churchman; and the play is still acted under the name of *The Hypocrite*, in which the Tartuffe is a methodistical divine.

TASTE. That power of the mind which is conversant about the beautiful, both of nature and of art. In the Latin language, the same metaphor obtained a very wide application, and the term sapientia was employed to signify quickness and correctness of judgment generally. Shaftesbury's use of the term is nearly as extensive, being applied by him to manners, morals, and government, and to wit, ingenuity, and beauty. In its modern use it is restricted to those objects which fall within the province of imagination. Now, although imagination derives its objects pre-eminently from those of the sight and hearing, and although the epithet *beautiful* is, for the most part, confined to these; yet the mental power which judges of them borrows its name from a third sense. The reason of this is satisfactorily shown by Coleridge. (*Literary Remains*, vol. i.) The senses, he observes, are either purely organic, or mixed. The former present their objects to the mind distinct from its perception of them, while the latter invariably blend the perception of the object with a certain consciousness of the percipient subject. To the latter class belong the touch, the smell, and the taste. Of these taste and smell differ from the touch, as adding to that reference to our vital being which is common to the three a degree of enjoyment or otherwise; while the taste is distinguished from the smell only by its more frequent and dignified use in human nature. By taste then, as applied to the fine arts, we must be supposed to mean an intellectual perception of any object, blended with a distinct reference to our sensibility of enjoyment or dislike.

In the same essay Coleridge gives another and a wider definition of taste: as "a metaphor taken from one of the mixed senses, and applied to objects of the more purely organic, and of *our moral sense*, when we would imply the coexistence of an immediate personal dislike or complacency." Now, by the constitution of man's nature, every exertion of human activity in the pursuit of the good, the beautiful, and the true, combines a sense of pleasure, or the contrary, with the perception of their respective objects; and this fact would justify the widest application of the metaphor. While, however, in the case of the true, this coexistent pleasure has not received any distinctive appellation, and while conscience, as comprehending the sense of approbation and disapprobation, is characteristically applied to the moral energy, that of taste has been confined to the perception of beauty and the accompanying gratification.

But taste, like all other metaphorical terms, is extremely inaccurate; and by directing attention exclusively to this element of pleasure, it has led to a very inadequate conception of the true nature of the faculty which it designates. Thus Hutcheson (*Inquiry into the Idea of Beauty and Virtue*) maintains that the faculty is peculiar, and a sense which, similarly to the other senses, procures a pleasure totally distinct from a cognition of principles, or of the causes, relations, and usages of an object; that beauty strikes at first sight, and that knowledge the most perfect will not increase the pleasure which it gives rise to; and lastly, that all the diversity of sentiments excited in different minds by the beautiful arise solely from the modifications of the sense by association, custom, example, and education. Among the advocates of the theory of a moral taste we may reckon Hume, Akenside, Blair, Lord Kames, and Beattie.

Blair accordingly defines taste to be the power of receiving pleasure from the beauties of nature and art; while Akenside describes it as "certain internal powers feelingly alive to each finer impulse." Dr. Beattie (*Essay on Poetry and Music*) supposes taste to have its origin in a mutual harmony and sympathy between the soul in its first formation and the rest of nature, which experience may confirm, but no perverse habits subdue. In the *Essay on the Delicacy of Taste*, Mr. Hume talks of it as a natural sensibility; while in the *Essay on the Standard of Taste*, he seems to admit of no other criterion than the decisions of a due and sufficiently extensive experience. Lastly, Lord Kames declares a taste in the fine arts to be nearly allied to the moral sense; but yet, like morals, capable of being raised to a rational science by an examination of the sensitive branch of the human constitution, and an enumeration of the objects which are either agreeable or disagreeable by nature.

But taste is not only a sensitive, but also a cognitive faculty. When a beautiful object is presented to the mind, not only does it make on it a delicious impression of pleasure, but the mind in the first place passes judgment upon it, and declares it to be beautiful; that is, conformable to a standard called the beautiful. In this complex operation of taste, the judgment is the antecedent, and the pleasure the consequent. When the impassible judgment has passed sentence upon the object, then the sensibility is awakened to certain sentiments, which are, as it were, the echo of the reason. (Cousin, *Sur le Vrai, le Bien, et le Beau.*)

Thus, too, Ancillon (*Melanges Literaires, &c.*):—"The impression which an object makes on the senses is insufficient to give rise to the sentiment of the beautiful. The impression on the senses is but the occasion on which the taste declares that the idea which it impressed on the sensible object, and which that object expresses, is the idea of beauty." To this view of taste we may refer the opinions of Addison and Burke. According to the latter, taste is that faculty or those faculties of the mind which are affected with, or form a judgment of, the works of imagination and the elegant arts; while Addison connects the emotion of pleasure with the power of distinguishing the beauties and imperfections of an author. To this class also we must refer the views of Sir Joshua Reynolds, Dr. Gerard, and Mr. Alison. According to the latter, taste is that faculty of the human mind by which we both perceive and enjoy whatever is beautiful and sublime in the works of nature and art, the perception of these two qualities being attended with an emotion of pleasure distinguishable from every other pleasure of our nature. In the sketch of his proposed work, which unfortunately he has never completed, he intended to show the nature of the faculty, and, in refutation of the theory of Hutcheson, to prove that it has no resemblance to a sense; and that it is not even a separate and peculiar faculty, but admits of being ultimately resolved into more general principles of our mental constitution. If taste were only a sense, it would be difficult to explain the fact, that amidst the inexhaustible variety of sensations which different minds experience from the beautiful, there nevertheless reigns a certain unanimity in men's judgments with respect to it, which cannot have any other source than the identity of reason in the human species. The sense of pleasure, however, is still a necessary and essential element of the faculty of taste. Without it we should be condemned to a perfect uniformity of sentiment in the presence of the beautiful, in the same manner as the absence of judgment would reduce us to an endless diversity.

The same conclusion will follow from an examination of some of the principal definitions of beauty. According to St. Austin (Ep. 18.), "unity is the universal form of beauty;" and to Malespina (*Delle Leggi del Bello*), "beauty consists in unity, multiplicity, and propriety." De Crousaz (*Traité du Beau*) makes beauty to consist in variety, unity, regularity, order, and proportion. Winckelmann and Sulzer agree also in making unity and multiplicity to be essential constituents of the beautiful. And lastly, the definition of beauty in the Italian schools of painting, was, "il più nell' uno,"—variety in unity; which is nearly identical with Hutcheson's explanation of it,—uniformity in variety. The justness of these views will readily appear, if we consider that while variety satisfies the demands of the imagination by affording the gratification most conformable to its nature and laws, unity is necessary for its being apprehended by the judgment, and in order to its appreciation as a work of art.

A few definitions of beauty remain to be noticed, which apparently favour the theory of Hutcheson. According to Burke (*On the Sublime and Beautiful*), and Price (*Essay on Beauty*), beauty consists in such qualities as induce in us a sense of tenderness and affection. Alison declares that the qualities of matter are neither beautiful nor sublime in themselves, but only such so far as they are signs or expressions of qualities capable of producing emotion. Wieland makes beauty to consist in the unity of an *agreeable* variety; and Kant teaches that the beautiful pleases irrespectively of any idea of utility, or of any conception of design, simply by the correspondence of the object and and the sensitive organ.

The emotions of taste are usually distinguished into those of the sublime and beautiful; but Dugald Stewart seems with justice to have denied the existence of any intrinsic difference between them. According to Burke, indeed, the terrible is a fruitful source of the sublime; and this idea does not seem capable of being made an ingredient of the beautiful. In the same way, on the other hand, there are ideas eminently beautiful which can never give rise to an emotion of sublimity. Nevertheless, this does not constitute an essential difference between the two. It is with reference to their several effects upon the imagination that they may perhaps be most correctly distinguished. Considered in itself, a beautiful object ought to present the greatest possible unity combined with the greatest possible variety; and considered in the effect it produces on the mind, its beauty consists in the free, facile, and harmonious play of the imagination. On the other hand, the imagination is lost and overpowered in the contemplation of the sublime, which in its infinity presents at once unity and variety.

TASTO. (It. *the touch.*) In Music, a term used in conjunction with *solo*, to signify that the instruments that can accompany by chords are only to play single sounds till the direction is contradicted by the word *accordo*, or *accompanimento*.

TA'TTA. (Indian.) A bamboo frame or trellis, over which water is suffered to trickle with a view of cooling the air as it enters the windows or doors.

TATTOO'ING. The name given to a practice common to several uncivilized nations, which consists in puncturing the skin and rubbing a dye or gunpowder into the wounds, by means of which certain figures are represented on the face and other parts of the body on which the operation has been performed.

TAU'RUS. (Lat. *the Bull.*) In Astronomy, the second in order of the twelve zodiacal constellations. There are several remarkable stars in this constellation: Aldebaran, of the first magnitude, in the eye; the well-known cluster called the Pleiades, in the neck; and the Hyades, in the face. *See* CONSTELLATION, ZODIAC.

TAU'TOCHRONE (Gr. ταυτος, *the same*, and χρονος, *time*), in Mechanics, is a curve line having this property, that a heavy body descending along it by the action of gravity will always arrive at the lowest point in the same time, wherever the point from which the body begins to fall be taken in the curve. Huygens first showed that this is a property of the common cycloid when the motion takes place in a vacuum, and gravity is supposed to act in parallel straight lines. (*See* CYCLOID.) Newton and Hermann also determined the tautochrone in a vacuum, when gravity is supposed to be directed towards a given centre. Newton likewise showed that the cycloid is also the tautochrone in a resisting medium, when the resistance is proportional to the velocity (*Principia*, b. ii. prop. 26.); and Euler first determined the nature of the curve when the resistance is proportional to the square of the velocity (*Mechanica*, vol. ii.) See also Joh. Bernoulli, *Opera*, vol. iii.

TAUTO'LOGY. (Gr. ταυτὸ, *the same thing*, and λογος, *discourse.*) In Rhetoric, a vicious diction, by which the same idea is expressed in two or more different words or phrases, apparently intended to convey different meanings.

TAWING. The art of preparing certain kinds of leather by imbuing the skins with saline, oily, and other matters. *See* LEATHER.

TAXATIO ECCLESIASTICA. A name given to several public records. The oldest is that of Norwich, made in 1253, for the purpose of assessing the first fruits and tenths of ecclesiastical benefices; sometimes called Pope Innocent's valor, that pontiff having made a present of them for three years to Henry III. All taxation was regulated by this assessment until the reign of Henry VIII., when the *Valor Ecclesiasticus*, sometimes called the *King's Books*, was compiled by his commissioners.

TAXATION. A tax is a rate or duty laid by government on the incomes or property of individuals, or on the

products consumed by them; the produce of such duty or rate being placed at the disposal of government.

A tax may be either general or particular; that is, it may either affect all classes indiscriminately, or only one or more classes.

Taxation (Lat. taxatio) is the general term used to express the aggregate of particular taxes. It is also the name given to that branch of the science of political economy which explains the mode in which the revenue required for the public service may be most advantageously raised.

It would be quite superfluous to enter into any lengthened arguments to show the utility, or rather necessity, of raising a revenue for the use of the public. *Neque quies gentium, sine armis; neque arma, sine stipendiis; neque stipendia, sine tributis habere queunt.* (*Tacit. Hist.* iv. cap. 74.) It is admitted on all hands that security from foreign invasion, the speedy and impartial administration of justice, and the maintenance of good order and tranquillity, are absolutely indispensable to the successful exertion of industry, and to the advancement of society. And when such is the case, no individual can justly complain that he is made to contribute, in the same proportion to his means as others, for the attainment of such objects; or, which is the same thing, that he is made to pay his fair share of the sum required to procure the services of the soldiers and sailors necessary to repel hostile aggression, and to support the various institutions and public functionaries required to maintain internal peace, to promote prosperity, and to protect every citizen in the undisturbed enjoyment of his property and rights. In most countries the public has frequently had to contribute larger sums than have been required for the ends of good government. But abuses of this kind obviously originate either in the misconduct of administration, or in the defective political organization of the states in which they occur, and do not, therefore, properly come within the scope of our inquiries. In treating of taxation, the object of the political economist is, not to inquire whether the revenue raised by the state exceed its necessary wants, or whether it be judiciously expended; but to point out the effect of taxation on individual and public wealth, and, by analyzing the various methods in which a revenue may be raised, and comparing them together, to show which is most advantageous, or rather which is least injurious. But as such inquiries, were they prosecuted at any considerable length, would involve discussions nowise suited for a work of this kind, and far exceed its limits, we must confine ourselves to a few observations illustrative of the principles that should be especially kept in view in the imposition of taxes.

Taxes may be either direct or indirect; that is, they may be either imposed on the incomes or property of individuals, or on the articles on which these incomes or property are expended. But before proceeding to inquire into the nature and influence of different taxes, it may be proper to premise the maxims laid down by Adam Smith with respect to taxes in general, inasmuch as they are drawn up with singular judgment and comprehensiveness.

First Maxim — "The subjects of every state ought to contribute towards the support of the government, as nearly as possible in proportion to their respective abilities; that is, in proportion to the revenue which they respectively enjoy under the protection of the state. The expense of government to the individuals of a great nation is like the expense of management to the joint tenants of a great estate. In the observation or neglect of this maxim consists what is called the equality or inequality of taxation."

Second — "The tax which each individual is bound to pay ought to be certain, and not arbitrary. The time of payment, the manner of payment, the quantity to be paid, ought all to be clear and plain to the contributor and to every other person. When it is otherwise, every person subject to the tax is put, more or less, in the power of the tax-gatherer, who can either aggravate the tax upon any obnoxious contributor, or extort, by the terror of such aggravation, some present or perquisite to himself. The uncertainty of taxation encourages the insolence and favours the corruption of an order of men who are naturally unpopular, even where they are neither insolent nor corrupt. The certainty of what each individual ought to pay is, in taxation, of so great importance, that a very considerable degree of inequality, it appears, I believe from the experience of all nations, is not so great an evil as a very small degree of uncertainty."

Third — "Every tax ought to be levied at the time and in the manner in which it is most likely to be convenient for the contributor to pay it. A tax upon the rent of land or of houses, payable at the same term at which rents are usually paid, is levied at the time when it is most likely to be convenient for the contributor to pay, or when he is most likely to have wherewithal to pay. Taxes upon such consumable goods as are articles of luxury are all finally paid by the consumer, and generally in a manner that is very convenient for him. He pays them by little and little as he has occasion to buy the goods; and as he is at liberty, too, either to buy or not to buy as he pleases, it must be his own fault if he ever suffers any considerable inconveniences from such taxes."

Fourth — "Every tax ought to be so contrived as both to take out and to keep out of the pockets of the people as little as possible, over and above what it brings into the public treasury of the state." (*Wealth of Nations*, M'Culloch's ed. 1 vol. 8vo. p. 371.)

It may be, and in fact often has been supposed, that direct taxes, or taxes laid on property or income, or both, would have the advantage of corresponding better with the first of Smith's maxims than any other description of taxes, by making individuals contribute to the wants of the state proportionally to the revenue which they enjoy under its protection; and so, no doubt, were it possible to assess them fairly, such would be the case. But the obstacles in the way of their fair and equal assessment are such as can never be overcome; and the truth is, that taxes on either income or property, though theoretically equal, are practically the most unequal that can be imagined. We may get a pretty accurate notion of the income derived from lands, houses, funded property, and mortgages; but all beyond this is mere guess-work. There are no means by which to ascertain the amount of farming capital, stock in trade, the profits derived from them, or the incomes of professional men. No inquisition into the private affairs of individuals can ever discover these particulars. There is nothing, in fact, to depend upon in such cases but the declarations of the parties; and we need not dwell on the impolicy of any system of finance that sets the duty and the interests of the contributors in opposition, and makes them profit by concealing or perverting the truth. Besides, although these preliminary and insuperable difficulties were overcome, and we learned the capital and incomes of different parties, we should have other and greater difficulties to surmount before the tax could be fairly assessed. The same deduction should not be made from incomes derived from sources that are not equally lasting. To assess them on a just principle, the present value of different incomes, or their value reduced to a perpetuity, would have, in the first place, to be determined.

But it may be unhesitatingly affirmed that to do this upon a large scale would be quite impracticable. It is clear, therefore, that taxes on income or property should not be introduced, except as a *dernier resort*, as a means of filling the coffers of the treasury when the other and more legitimate sources of revenue are insufficient, and when, as in the late war, money must be had at all hazards.

It is besides absurd to suppose, as has been done, that the burdens that at present fall on the labouring classes could be sensibly reduced by repealing the duties on tea, sugar, soap, &c., and imposing in their stead taxes on property. Suppose that the attempt were made, and observe what the result must be. A manufacturer employs a certain number of men, who pay 1000*l.* a year in taxes on commodities. Now, if the taxes that are at present paid by the labourers be repealed, those that fall on their employers must be equally increased; so that the manufacturer in question will have 1000*l.* more to pay in taxes after the change takes place, and will of course have 1000*l.* less to lay out on wages. It is consequently contradictory and absurd to suppose that you can improve the condition of the labouring classes by repealing the taxes that fall on them to lay them on capitalists.

Direct taxes on property have been the curse of every country into which they have been introduced, and are at once a consequence and a cause of a low and impoverished state of society. To evade them, people that are not poor counterfeit poverty; some of the most powerful incentives to industry and economy are in consequence destroyed, at the same time that inferior stock, machinery, &c. are made use of. Such taxes are besides most unpopular, as well from their requiring an odious though ineffectual inquisition into the affairs of individuals, as from their being direct. So much is this the case, that we are well convinced that the raising of eighteen or twenty millions by taxes on income would be felt to be a much greater burden, and would really be far more injurious, than the raising of fifty or sixty millions by well-devised indirect taxes, such as the greater number of those that now exist in England.

Luckily, however, indirect taxes have almost invariably been the greatest favourites both of princes and subjects; and there are many solid reasons why this should be the case. The burden of direct taxation is palpable and obvious. It admits of no species of disguise or concealment, but makes every one fully sensible of the exact amount of income taken from him by government. Every one, however, is extremely averse from parting with property, unless he obtain some more acceptable equivalent in its

stead; and as the benefits derived from the institution of government are neither so very obvious nor striking as to be easily and readily felt and appreciated by the bulk of the people, there is, in the great majority of cases, a a decided disinclination to pay a large amount of direct taxes. Hence it is that governments have so generally had recourse to indirect taxes. Instead of exciting the prejudices of their subjects by openly demanding a specific portion of their incomes, they have taxed the articles on which these incomes are usually expended. This ingenious plan conçeals the amount of taxation, and makes its payment appear in some measure voluntary. The tax being generally paid, in the first instance, by the producers, the purchasers confound it with the natural price of the commodity. No separate demand being made upon them for the tax, it escapes their recollection, and the article which they receive seems the fair equivalent of the sacrifice made in acquiring it. Such taxes have also the advantage of being paid by degrees, in small portions, and at the time when the commodities are wanted for consumption, or when it is most convenient for the consumers to pay them.

That indirect taxes labour under some considerable disadvantages is most true, though these have been much exaggerated. It is alleged, in the first place, that taxes on commodities necessarily alter the natural distribution of the capital and industry of a country, and force them into less advantageous channels; because, where a tax is laid on a particular class of commodities, the producers, in order to raise the price proportionally to the tax, diminish the supply in the market by transferring a portion of the capital employed in the production of the taxed commodities to some other business. But it is to be observed that this effect, if it be sensible at all, is experienced only when a duty is first imposed, and that after a short while the duty is blended with the cost of production, and has no further influence over the distribution of capital. It is also true, that, provided the tax be not oppressive, or so high as to drive capital wholly from the business, it acts as a stimulus to invention, and makes those engaged in the business exert themselves, by new efforts of ingenuity and economy, to find out means of paying the tax without adding to the price of the articles produced, or withdrawing any portion of their capital from the business. In many instances these efforts have been completely successful; and in some instances the influence of the tax has been more than neutralized by the exertions made to defeat it.

Taxes on commodities being almost always paid by the producers before they are sold to the consumers, they not only, it is said, increase prices by the whole amount of the duties, but also by the profits due to the manufacturers by whom they have been advanced. But though this circumstance undoubtedly operates to increase prices, its influence in this respect has been greatly over-rated by M. Say, M. Sismondi, and others. The latter has calculated that a tax of 4000 francs, paid originally by a manufacturer whose profits were 10 per cent., would, if the manufactured commodity only passed through the hands of five different persons before reaching the consumer, cost the latter the sum of 6734 francs. This calculation proceeds on the supposition that he who first advanced the tax would receive from the next manufacturer 4400 francs, and he, again, from the next, 4840 francs; so that at each step 10 per cent. on its value should be added to it. "But," as Mr. Ricardo has justly observed, "this is to suppose that the value of the tax would be accumulating at compound interest; not at the rate of 10 per cent. per annum, but at an absolute rate of 10 per cent. at every step of its progress. M. Sismondi's statement would be correct if five years elapsed between the first advance of the tax and the sale of the taxed commodity to the consumer; but if one year only elapsed, a remuneration of 400 francs, instead of 2734, would give a profit at the rate of 10 per cent. per annum to all who had contributed to the advance of the tax, whether the commodity had passed through the hands of five manufacturers or fifty." (*Principles, &c.* 3d edit. p. 459.)

It is certainly true that duties on commodities encourage smuggling. "They tempt," says Dr. Smith, "persons to violate the laws of their country who are frequently incapable of violating those of natural justice, and who would have been in every respect excellent citizens, had not the laws of their country made that a crime which nature never meant to be so." (P. 378.) In consequence of this tendency, duties on commodities require the employment of a number of revenue officers; and as they expose the producers of the taxed articles to considerable inconvenience and hardship from domiciliary visits, they force them to indemnify themselves by making a corresponding addition to the price of their goods. But this, after all, is not so much a consequence of duties on commodities, as of their abuse, or of their being carried to an oppressive extent. So long as they are confined within reasonable limits, the temptation which they create to engage in smuggling transactions may be very easily obviated; and it has been shown over and over again, that duties so restricted are uniformly more productive than those which are carried to such a height as to hold out any great encouragement to smuggling.

It may also be said that duties on commodities do not fall on individuals in proportion to their means of paying them; and that while they press with undue severity on persons with large families, or who occupy prominent stations, they may be almost wholly avoided by rich misers and those in the more obscure walks of life. But in taxation we have only a choice of difficulties. However desirable, it is, as already seen, quite impossible to tax individuals in proportion to their incomes; and as any attempt to impose an equal income tax would not only be sure to fail, but would be attended with the most disastrous effects, resort must necessarily be had to the best practicable taxes, that is, to duties on commodities. And it does not really appear that such duties can be considered as unequal. If duties be laid on sugar or wine, those who abstain from their use will, of course, escape them; but those who use such articles have no good right to complain of this, seeing that they may also, by exercising the same self-denial as the others, exempt themselves from the duties.

Taxes on commodities are most commonly divided into two great classes; the one consisting of external or frontier, and the other of internal duties. The first class, called in England customs duties, are principally charged on commodities brought from foreign parts on their importation into a country, and sometimes also on native commodities when exported. The second class, which are here called excise duties, are charged on certain articles produced within a country, and intended for home consumption. In addition to these great sources of indirect taxation, duties are sometimes laid on the paper or other materials necessary to the completion of deeds and other contracts, on the liberty to use certain articles and to exercise certain privileges, &c.

Customs duties formed an important branch of the public revenue of most ancient states, and in modern times they have been very extensively imposed. In England they have been charged from a very remote period; and though inconsiderable at first, they have increased with the increase of civilization and commerce, till they have long formed one of the most copious sources of the public revenue. The various duties were collected, for the first time, in a book of rates, or tariff, published in the reign of Charles II.; but there is hardly a year in which the customs duties do not undergo considerable modifications. It is now the practice to consolidate the different acts imposing or varying the customs duties before they become inconveniently numerous; and tariffs, or tables of duties, drawbacks, &c., are annually published for the convenience of merchants and others.

Owing principally to the vast increase of the commerce, wealth, and population of the country, but partly also to the increase of the rates, the progress of the customs duties has been quite extraordinary. The revenue derived from the customs duties in 1596, in the reign of Elizabeth, amounted to no more than 50,000*l*. In 1613, it had increased to 148,075*l*., of which no less than 109,572*l*. was collected in London. In 1660, at the Restoration, the customs produced 421,582*l*.; and at the Revolution, in 1689, they produced 781,987*l*. During the reigns of William III. and Anne, the customs revenues were considerably augmented, the nett payments into the exchequer in 1712 being 1,315,422*l*. During the war terminated by the peace of Paris in 1763, the nett produce of the customs revenue of Great Britain amounted to nearly 2,000,000*l*. In 1792, it amounted to 4,407,000*l*. In 1815, at the close of the war with revolutionary France, it amounted to 11,360,000*l*.; and in 1840, the customs revenue of the United Kingdom amounted to 23,341,813*l*., of which Great Britain furnished 21,209,082*l*., and Ireland 2,132,731*l*.

For a lengthened period customs duties were charged indifferently on all sorts of commodities, whether exported or imported; the duty on wool sent to the Netherlands, France, &c. being formerly, in fact, the principal item in the customs revenue. But for a long time past customs duties have been almost exclusively laid on imported articles; those laid on exports being, in most instances, imposed rather to check or prevent the exportation of the articles, than in the view of raising revenue.

Customs duties, when judiciously imposed, and confined within reasonable limits, are perhaps the least exceptionable of all taxes. (*See* CUSTOMS.) But if they be carried to such a height as to give any overpowering stimulus to smuggling, they contradict and defeat the very purpose for which they are intended. Our finance ministers have not, however, been sufficiently alive to this obvious consideration. There can be no articles better fitted to bear customs duties than tobacco and spirits; but the duties with which they are loaded are so extravagantly high that they occasion a great deal of smuggling, with its accompanying crime and demoralization, and would certainly be a good deal more productive were they effectually reduced. The existing duties on brandy and geneva are, perhaps, the very worst in our tariff; but

they would be about the very best were they reduced from 22*s*. 6*d*. to 8*s*. or 10*s*. a gallon.

As already stated, the customs revenue of 1840 amounted to 23,341,813*l*.; and we hesitate not to affirm that no equal amount of revenue was ever raised in any country, or in any period of time, with so little difficulty and inconvenience. The assessed taxes, exclusive of the land-tax, produced, in 1840, 2,971,005*l*.; and no one familiar with the facts can doubt that their payment produced more irritation, and was regarded as a greater burden by the public, than the payment of the customs duties, though the latter brought between six and seven times as great an amount of income into the coffers of the treasury.

The customs revenue of 1840 was collected in Great Britain at a charge of 4*l*. 18*s*. 10*d*. per cent. on its gross produce; and in Ireland, at a charge of 10*l*. 8*s*. 3*d*. on ditto.

Excise Duties. — The next great branch of the public revenue consists of inland or excise duties; that is, as already seen, of duties charged on certain commodities produced or manufactured at home.

Excise duties were introduced into England by the Long Parliament in 1643; being then laid on the makers and venders of ale, beer, cider, and perry. The Royalists soon after followed the example of the Republicans, both parties declaring that the excise should be continued no longer than the termination of the war. But it was found too productive a source of revenue to be again relinquished; and when the nation had been accustomed to it for a few years, the parliament declared, in 1649, that the "impost of excise was the most easy and indifferent levy that could be laid upon the people." It was placed on a new footing at the Restoration; and notwithstanding Mr. Justice Blackstone says, that "from its first original to the present time its very name has been odious to the people of England" (*Com.* book i. c. 8.), it has continued progressively to gain ground; and it is at this moment imposed on several most important articles, and furnishes nearly a third part of the entire public revenue of the kingdom. *See* EXCISE DUTIES.

Some excise duties that were justly objected to have been repealed within these few years; and with the exception of the duty on glass, which interferes injuriously with the manufacture, we are not sure that there is one of the existing duties that can be fairly objected to on principle, though the rate of duty might, in some instances, be advantageously reduced. We subjoin an account of the articles subject to excise duties in Great Britain in 1840, with the nett produce of the duties in the same year.

It has been said that the excise duties "greatly raise the cost of subsistence to the labouring classes." But this assertion has really no solid foundation. We have seen above that, in 1840, the excise duties in Great Britain produced 13,386,774*l*. Now of this sum the duties on spirits, malt, and licences, produced 9,905,937*l*. In fact, the only excise duty that can be said to fall on a necessary of life is that on soap, which produced in 1840 (in Great Britain) 806,705*l*.; and as the population of Great Britain amounts at present to above 18,500,000, the soap tax, at an average, does not impose a burden of above 10*d*. a year on each individual! If we estimate its annual pressure on a labouring family of five persons at 2*s*. 6*d*., we shall not be within, but considerably beyond the mark. In Ireland there is no tax on soap.

Latterly some reductions have been made in the duties on glass. Still, however, they are most objectionable, inasmuch as they interfere most materially with the processes carried on in the manufacture, and, by obstructing the introduction of new discoveries and improved methods, enhance the prices of the article in a much greater degree than might be inferred from the amount of the duty.

The only taxes in the departments of customs and excise, or of the revenue generally, that can be truly said to fall on articles necessary to the labourer are, besides soap, those on tea, sugar, and one or two more. It is pretty certain that the duties on tea and sugar, which are by far the most important, might be materially reduced without affecting the revenue; and the presumption is, that the duty on sugar, which enters so largely into most descriptions of food, will be speedily reduced, and the trade in it placed on an entirely new footing.

Even though they were not required by the public exigencies, the duties on spirits obstruct a pernicious habit, and should not be given up. They are the best of all possible duties; and the only thing to be attended to in their imposition is, not to carry them to such a height as to defeat their operation by encouraging smuggling. We have yet to learn, supposing they are not carried beyond this limit, that a single good objection can be made to these duties.

The obscurity and complexity of the excise laws have been justly complained of; in this respect, however, they have been materially improved of late years; and the statutes under which they are collected are now, for the most part, sufficiently perspicuous, and easily understood.

The capacity of a tax on a commodity to raise a revenue depends partly on the nature and extent of the demand for the taxed article, and partly on the means of preventing its being smuggled or the duty evaded. Every tax, by raising the price of the article on which it is laid, has a tendency to bring it within the command of a smaller number of purchasers, and to lessen its consumption. An individual who might be able and disposed to pay 1*s*. a bottle of duty on wine might neither have the means nor the inclination to pay 2*s*. or 3*s*.; and instead of being augmented, the revenue might be diminished by such an increase of duty. And hence, whenever the duties on commodities are raised beyond certain limits, — which, however, it is impossible to define *à priori*, seeing that they necessarily vary according to the description of commodities charged with duties, the varying tastes and circumstances of society, and the means of counteracting smuggling, — they depress consumption to such an extent as to become less productive than if they had been lower.

Variations in the amount of the duties affecting commodities have exactly the same effect on their price, and consequently on their consumption, as corresponding variations in the cost of production. But it is clear that any reduction in the price of articles the necessary cost of which is very considerable, and can therefore be used only by the rich, would not so powerfully increase their consumption as an equal reduction in the price of cheaply produced commodities in general demand. Thus, a reduction of 25 or even 50 per cent. in the price of coaches, would not add greatly to the demand for them; for, notwithstanding this reduction, they would still be luxuries for which none but the rich could afford to pay. But a reduction of 25 or 50 per cent. in the price of tea, sugar, beer, gin, or any article in general demand, would extend its consumption in a much greater ratio. The reason is plain. The lower classes form by far the most numerous portion of society; the articles referred to, and others of the same description, are highly esteemed by them, and are, even at their present prices, extensively consumed. But a reduction of a half, or even a fourth from their price, would add prodigiously to the demand for them. It would enable their present consumers to use them in larger quantities; while it would at the same time bring many of them fully under the command of a very large class, by whom they are now used as luxuries only on rare occasions. The history of taxation in this and other countries fully confirms this statement. When carried beyond due limits, taxes on commodities cease to be productive, and recover that quality when they are reduced. There is much truth in the shrewd remark of Dr. Swift, that in the arithmetic of the customs two and two do not always make four, but sometimes only one. In 1808, the duty on coffee was 1*s*. 7½*d*. per lb.; the quantity entered for consumption that year being 1,069,691 lbs., producing a nett revenue of 161,246*l*. In the course of the year the duty was reduced to 7*d*. per lb.; and next year no fewer than 9,251,837 lbs. were entered for home consumption, producing a nett revenue of 245,886*l*. The coffee duty has since been lowered to 6*d*.; and the quantity entered for consumption is now (1842) about 28,500,000 lbs., and the revenue about 850,000*l*. a year.

The history of the duties on tea, spirits, wine, sugar, and indeed of every other article in extensive demand, is precisely similar. When carried to an oppressive height, the duty either occasions the use of the article to be given up; or, which is the most common case, it makes it be supplied through clandestine channels in defiance of the law. But when the duty is moderate, a taste for the article is diffused; and the profits to be made by trampling on the law not being sufficient to remunerate the smuggler, he is forced to abandon his hazardous occupation, and the article is wholly supplied through legitimate channels. After the various disastrous consequences entailed on the country by the exorbitant height to which many duties were carried previously to 1825, and the signal advantages that have resulted to the revenue and the public from their subsequent modification, it may be hoped that the principle now stated will meet with more attention in future.

The attempts that have been made in Great Britain and elsewhere to suppress smuggling, and at the same time to maintain exorbitant duties, have all signally failed. It has been invariably found that no severity of the law, nor vigilance on the part of the officers, can prevent the smuggling of commodities loaded with excessive duties. At this moment it is supposed that from 500,000 to 600,000 gallons of foreign brandy and geneva find their way into our market without paying any duty, in defiance of the coast guard, and of all the other machinery for keeping them out. Large quantities of tobacco are also smuggled. In fact, there are no means of effectually putting down smuggling other than a reduction of duty. The very severity of the laws prevents their execution. It creates a sympathy in favour of the smuggler; it stimulates the trader to corrupt the officer to conceal a fraud; and it makes the officer overlook what he might otherwise discover.

Stamp Duties.—These duties form the next most important branch of the public revenue, after the customs and excise. They are mostly laid on the parchment or paper on which certain deeds, contracts, receipts, acquittances, bills of exchange, newspapers, policies of insurance, indentures of apprenticeship, &c. are written or printed; and derive their name from the parchment or paper being impressed with a stamp stating the amount of the duty. When imposed on fair principles, and not carried to too great a height, stamp duties seem to be one of the most legitimate sources of revenue. They assist in authenticating legal instruments, and render it much more difficult than formerly to forge deeds of any standing. It is needless, perhaps, to say, that if stamp duties be carried to such a height as to oppose any serious obstacle to the free circulation of property, or to the execution of necessary deeds, they become exceedingly injurious. Perhaps the duty on fire insurance is the most objectionable of the existing stamp duties. It amounts to 3*s.* per cent. on all property insured; whereas the premium paid to insurance offices, for common risks, is no more than 1*s.* 6*d.* per cent., or only half the duty. Thus, if a person wish to insure 1000*l.* on a dwelling-house, a shop, warehouse, or other commonly hazardous property, he pays 15*s.* to an insurance office as an indemnification for the risk, and 30*s.* to government for leave to enter into the transaction. So exorbitant a duty cannot be too severely condemned. It discourages that providence and foresight the encouragement of which ought to be an object with all prudent governments; and it is the principal cause that much property is not insured at all, and that what is insured is seldom sufficiently covered. Every individual, in fact, who insures any commonly hazardous property, is obliged to pay three times as much as the risk is really worth. Under such circumstances, the wonder certainly is, not that a great deal of property is uninsured, but that such is not the case with a great deal more. Seeing the vast importance of insurance, it may well be doubted whether it ought to be charged with any duty, however slight. But were the duty fixed at 9*d.* per cent., or at half the premium, its influence in repressing insurance would not be very sensible; and the increase of business to which such a reduction of the duty would lead would be so very great, that we have little doubt that in a few years the reduced duty would yield nearly as large a revenue as is derived from the present exorbitant duty.

The duties on legacies, and on the probates of wills, are included under the head of STAMP DUTIES, of which they are very important items. These duties affect only personal or moveable property. The first, or legacy duty, varies according to the propinquity of the successor; being 1 per cent. on property devolving on children and lineal heirs, 3 per cent. on property devolving on brothers and sisters, 4 per cent. on property devolving on cousins, and 10 per cent. on property devolving on strangers. The probate duty varies according to the amount of property in the will. The duties on stage and hackney coaches, gold and silver plate, &c., come under the head of STAMPS.

Land Tax.—The existing land tax originated in 1692, being intended to replace the subsidies and such like grants previously made to the crown. According to the valuation at which it was assessed, it was found that a charge of 1*s.* per pound on the rental of the country produced 500,000*l.* No subsequent change has been made in this valuation. The tax, which was annually voted, usually amounted to 4*s.* per pound of the valued rent. In 1798, it was made perpetual at that rate, leave being at the same time given to the proprietors to reduce it.

The land tax has always been very unequal. When imposed, the proprietors friendly to the Revolution returned their estates at a much higher value than those attached to the House of Stuart. The different degrees of improvement that have since taken place in the various districts of the country have, in some instances, tended to correct the inequalities in the original imposition of the tax; but their more common effect has been to increase them.

Assessed Taxes.—These form the fourth great head of revenue. They include the duties on windows, servants, horses, carriages, armorial bearings, game, &c. The house duty, that used to be one of the principal items in the assessed taxes, has been recently repealed. A hearth tax, or duty proportioned to the number of fireplaces in a house, was established in this country at a very early period; but owing to its being necessary to the assessing of the tax that the government officers should be admitted to view the inside of each house, the hearth tax became exceedingly unpopular, and was repealed by the stat. 1 Will. & Mary, c. 10. This statute declares hearth money "not only a great oppression to the poorer sort, but a badge of slavery upon the whole people, exposing every man's house to be entered into and searched at pleasure by persons unknown to him; and therefore to erect a lasting monument of their majesties' goodness in every house in the kingdom, the duty of hearth money was taken away and abolished."

But six years afterwards "the prospect of this monument of goodness was," to use Blackstone's words, "somewhat darkened," by the passing of an act (7 Will. III. c. 18.) laying a duty on all inhabited houses except cottages, and also on windows. These duties were afterwards considerably increased: they were, however, materially modified within the last few years; and neither the existing window tax, nor the house tax previously to its repeal, could be said to be oppressive. Indeed, out of 2,850,937 inhabited houses in Great Britain in 1831, only 442,482, or not a sixth part of the entire number, paid duty in 1833. All houses below 10*l.* a year of rent were exempted from the duty; the rate of charge on those that were assessed being 1*s.* 6*d.* per pound on houses worth from 10*l.* to 20*l.* a year, 1*s.* 3*d.* per pound on those worth from 20*l.* to 40*l.*, and 2*s.* 10*d.* per pound on those worth 40*l.* and upwards. The assessed taxes do not extend to Ireland. The cost of their collection amounted, in 1840, to 4*l.* 11*s.* 10*d.* per cent. of the gross produce.

The house tax being assessed according to the rent, it frequently happened that private houses, shops, and taverns in towns, were assessed in a larger sum than the finest houses of the nobility and gentry in the country. There was not, however, any injustice in this; for, in point of fact, had any attempt been made to let the latter, they would rarely have found a tenant or brought any rent. This apparent inequality afforded, however, a convenient topic for declamation, and for raising an outcry against the tax, which was, in consequence, repealed in 1835.

With the exception of the duties on the postage of letters, which have been noticed elsewhere (*see* POST OFFICE), the observations now made will probably suffice to give the reader a general idea of the principles on which taxes should be imposed, and of the leading characteristics of the principal taxes now in force in this country.

Collection of Taxes.—Taxes in Great Britain are almost wholly collected by government officers, paid by salaries. The customs duties, the excise duties, and the duties on stamps, with the assessed taxes, are each under the management of a particular department, having at its head a board of commissioners, with various classes of inferior officers. The post office revenue is managed by a postmaster-general and a principal secretary. The heads of the different revenue departments correspond with and receive their instructions from the treasury, to which is committed the charge of supervising, controlling, and regulating all matters connected with the assessment and collection of taxes. The number of commissioners in the different revenue boards was formerly much greater than at present; and it is contended by some very high authorities that their number might still be advantageously reduced, and that the whole responsibility should rest with the head of each department. Various reforms and retrenchments have been also introduced into the subordinate departments, and not a few abuses have been rectified in the assessment and collection of most duties. Perhaps the only very material reforms that need now be looked for in this department, must arise rather from changes and modifications of duties than from any changes in the way in which they are charged and collected. The reduction of the present exorbitant duties on brandy, geneva, and tobacco, by taking away an overwhelming temptation to their clandestine importation, would enable a large saving to be effected in the customs departments, at the same time that it would be productive of various other beneficial consequences. In the excise there remains little to be amended; and were the glass duties repealed, and the regulations as to some of the other duties simplified, the system would have received all the perfection of which it seems capable.

Those who wish for further information on the subjects treated of in this article may consult the article on Taxation in the new edition of the *Encyclopædia Britannica; Ricardo's Principles of Political Economy;* M'Culloch's edition of the *Wealth of Nations*, &c.

ACCOUNT of the Public Income of the United Kingdom; specifying its different Sources, and the Amount derived from each, during 1838, 1839, and 1840.

In corresponding Perpetuities, as estimated by Mr. Finlaison		1,830,654	- -	1,771,430	- -	1,710,761
DIFFERENCE		2,461,519	- -	2,527,290	- -	2,403,260

* No part of this income is at present paid for the use of King Leopold. The trustees, after discharging certain annuities and pensions to the servants and establishment of the late Princess Charlotte, repay the balance of the annuity to the Exchequer: the sum so repaid in the last year was 34,000*l.*

TA'XICORNS, *Taxicornes*. (Lat. taxus, *a yew tree*; cornu, *a horn*.) The name of a family of Coleopterous insects, including those in which the antennæ gradually augment in size as they extend from the head, or terminate in an enlargement.

TA'XIDERMY. (Gr. *ταξις*, *arrangement*, and *δερμα*, *skin*.) The art of arranging and preserving the skins of animals. The most popular treatise on taxidermy is Mr. Swainson's volume in *Lardner's Cyclopedia*.

TA'XIS. In Surgery, the replacement of parts which have quitted their natural situation by the hand, and without instrument or operation; as in reducing hernia or rupture.

TAXIS. In Architecture, the fitness of the parts to the end for which a building is erected.

TA'XUS (Lat.), is the botanical name of the yew tree, celebrated for the hardness and elasticity of its wood. Its berries are harmless; but its leaves are poisonous, partaking of the property of foxglove. It is the most simple form of the Coniferous alliance, and is usually taken as the best illustration of the gymnospermous structure among Exogens; because its female flower is quite solitary, and readily examined. What travellers in New Zealand call yews appear to be species of *Dacrydium*.

TAYLOR'S THEOREM. In Mathematics, a very general and remarkable formula of most extensive application in analysis, discovered by Dr. Brook Taylor, and given in his *Methodus Incrementorum*, published in 1715. The formula is this:— Let u be any function whatever of a variable x, and let u' be what u becomes when x receives an increment $= h$; then

$$u' = u + \frac{du}{dx}\cdot\frac{h}{1} + \frac{d^2u}{dx^2}\cdot\frac{h^2}{1\cdot 2} + \frac{d^3u}{dx^3}\cdot\frac{h^3}{1\cdot 2\cdot 3} + \&c.$$

Demonstrations of this important theorem are given in every treatise on the differential calculus; and it is made by Lagrange the foundation of the calculus itself. (See Lagrange, *Théorie des Fonctions Analytique*.)

TEA. The dried leaves of the tea tree, of which there are two varieties. 1. The *Thea nigra*; black or bohea tea. 2. *Thea viridis*; green tea. The boheas include souchong, pekoe, and congou; and the greens are hyson, singlo, and imperial or bloom tea. The leaves are collected and dried on iron plates by a gentle heat. Tea taken in moderation, especially as we use the infusion, with sugar and milk, is strengthening and invigorating; it also appears to possess certain stimulating and narcotic properties, of which some individuals are peculiarly susceptible, and which renders it improper in hypochondriacal and hysterical patients. We know little of the chemical properties of the varieties of tea; but the following table shows that, in regard to its more obvious constituents, the different varieties are not widely dissimilar. The column showing the weight of the precipitate by jelly may be taken as indicating the relative proportion of the astringent matter.

100 Parts of Tea.	Soluble in Water.	Soluble in Alcohol.	Precipitate with Jelly.	Inert Residue.
Green: hyson - 14*s*. per lb.	41	44	31	56
— 12*s*. —	34	43	29	57
— 10*s*. —	36	43	26	57
— 8*s*. —	36	42	25	58
— 7*s*. —	31	41	24	59
Black: souchong, 12*s*. —	35	36	28	64
— 10*s*. —	34	37	28	63
— 8*s*. —	37	35	28	63
— 7*s*. —	36	35	24	64
— 6*s*. —	35	31	23	65

Of the above precipitate by jelly, about 40 per cent. may be regarded as *tannin*; and the difference between the second and the first column shows the quantity of resin contained in the above teas: the resin has an agreeable flavour of the tea. Water distilled off tea has an agreeable flavour, and is said to be narcotic: it contains a trace of volatile oil. Oudry's statement of the existence of a peculiar principle in tea (*thein*) requires confirmation.

The late rise and present magnitude of the British tea trade are among the most extraordinary phenomena in the history of commerce. Tea was wholly unknown to the Greeks and Romans, and even to our ancestors, previously to the end of the 16th or the beginning of the 17th century. It seems to have been originally imported in small quantities by the Dutch; but was hardly known in this country till after 1650. In 1660, however, it began to be used in coffee houses; for, in an act passed in that year, a duty of 8*d*. is laid on every gallon of "coffee, chocolate, sherbet, and tea," made and sold. But it is abundantly evident that it was then only beginning to be in[illegible]red. The following entry appears in the Diary of [illegible] Pepys, secretary to the Admiralty:— "September 26. 1661. I sent for a cup of tea (a China drink), of which I had never drunk before." In 1664, the East India Company bought 2 lbs. 2 oz. of tea as a present for his Majesty. In 1667, they issued the first order to import tea, directed to their agent at Bantam, to the effect that he should send home 100 lbs. of the best tea he could get! (See the references in *Milburne's Orient. Com.* vol. ii. p. 530.; *Macpherson's Hist. of Com. with India*, pp. 130—132.) Since then the consumption seems to have gone on regularly, though slowly, increasing. In 1689, instead of charging a duty on the decoction made from the leaves, an excise duty of 5*s*. per lb. was laid on the tea itself.

The great increase that took place in the consumption of duty paid on tea in 1784 and 1785, over its consumption in the preceding years, is to be ascribed to the reduction that was then effected in the duties. In the *nine* years preceding 1780, above 180,000,000 lbs. of tea were exported from China to Europe in ships belonging to the Continent, and about 50,000,000 lbs. in ships belonging to England. But, from the best information attainable, it appears that the real consumption was almost exactly the reverse of the quantities imported; and that while the consumption of the British dominions amounted to above 13,000,000 lbs., the consumption of the Continent did not exceed 5,500,000 lbs. If this statement be nearly correct, it follows that an annual supply of above 8,000,000 lbs. was clandestinely imported. It was well known, indeed, that smuggling was carried on to an enormous extent; and after every other means of checking it had been tried to no purpose, Mr. Pitt proposed, in 1784, to reduce the duties from 119 to $12\frac{1}{2}$ per cent. This measure was signally successful. Smuggling and the practice of adulteration were immediately put an end to, and the legal imports of tea were about trebled. In 1795, however, the duty was raised to 25 per cent.; and after successive augmentations in 1797, 1800, and 1803, it was raised, in 1806, to 96 per cent. *ad valorem*, at which it continued till 1819, when it was raised to 100 per cent. on all teas that brought above 2*s*. per lb. at the Company's sales.

Down to the 22d of April, 1834, the duty on tea was an *ad valorem* one, being 96 per cent. on all teas sold under 2*s*. a pound, and 100 per cent. on all that were sold at or above 2*s*. Seeing that tea may now be considered almost as a necessary of life, this was certainly a high duty; though, as a large amount of revenue must be raised, we do not know that it could be fairly objected to on that ground. But under the monopoly system the duty was, in fact, about 200 per cent. *ad valorem!* For, the price of the tea sold by the Company being forced up to nearly double what it would have been had the trade been free, it followed, inasmuch as the duty varied directly as the price, that it also was doubled when the latter was doubled. The price of congou at Hamburgh, for example, varies from 1*s*. 2*d*. to 1*s*. 4*d*. per lb.; and had the Company supplied our markets with congou at the same rate, it would have cost us, duty included, from 2*s*. 2*d*. to 2*s*. 8*d*. per lb. But instead of this, the congou sold by the Company has been, at an average, a good deal above 2*s*. per lb.; and the duty being as much, it has invariably cost us from 4*s*. to 5*s*. per lb. Hence, though the duty was only 100 per cent. on the Company's price, it was really above 200 per cent. on the price of tea in an open market! The mischief of the monopoly was thus aggravated almost beyond endurance, inasmuch as every addition made by it to the cost of the article made an equal addition to the duty on it.

But this system is now happily at an end. The *ad valorem* duties ceased on the 22d of April, 1834; and all tea imported into the United Kingdom for home consumption is now charged with a customs duty as follows:—

Bohea - - - - -	1*s*. 6*d*. per lb.
Congou, twankay, hyson skin, orange pekoe, and campoi - - -	2*s*. 2*d*. —
Souchong, flowery pekoe, hyson, young hyson, gunpowder, imperial, and other teas not enumerated - -	3*s*. 0*d*. —

We subjoin an account of the quantities of tea entered for home consumption in the United Kingdom in 1840 and 1841, with the gross amount of duty received on the same:—

	Quantities. *lbs.*	Revenue. *L.*
1840 -	32,262,892	3,473,964
1841 -	36,396,078	3,978,198

TEAK WOOD, or INDIAN OAK. The produce of the *Tectona grandis*, a large forest tree, that grows in dry and elevated districts in the south of India, the Burman empire, Pegu, Ava, Siam, Java, &c. Teak timber is by far the best in the East; it works easily, and, though porous, is strong and durable; it is easily seasoned, and shrinks very little; it is of an oily nature, and therefore does not injure iron. Mr. Crawfurd says that, in comparing teak and oak together, the useful qualities of the former will be found to preponderate. "It is equally strong, and somewhat more buoyant. Its durability is more uniform and decided; and to insure

that durability it demands less care and preparation; for it may be put in use almost green from the forest, without danger of dry or wet rot. It is fit to endure all climates and alternations of climate." (See *Tredgold's Principles of Carpentry*, p. 206.; *Crawfurd's East. Archip.* vol. i. p. 451.)

The teak of Malabar, produced on the high table land of the south of India, is deemed the best of any. It is the closest in its fibre, and contains the largest quantity of oil, being at once the heaviest and the most durable. This species of teak is used for the keel, timbers, and such parts of a ship as are under water: owing to its great weight, it is less suitable for the upper works, and is not at all fit for spars. The teak of Java ranks next to that of Malabar, and is especially suitable for planking. The Rangoon or Burman teak, and that of Siam, is not so close-grained or durable as the others; it is, however, the most buoyant, and is therefore best fitted for masts and spars. Malabar teak is extensively used in the building yards of Bombay. Ships built wholly of it are almost wholly indestructible by ordinary wear and tear; and instances are not rare of their having lasted from 80 to 100 years; they are said to sail indifferently; but this is probably owing as much to some defect in their construction as to the weight of the timber. Calcutta ships are never wholly built of teak; the timbers and framework are always of native wood, and the planking and deck only of teak. The teak of Burma, being conveyed with comparatively little difficulty to the ports of Rangoon and Martaban, is the cheapest and most abundant of any. It is largely exported to Calcutta and Madras.

A species of timber called African teak is pretty largely imported into England, from the west coast of Africa. But, in point of fact, it is not teak, and it is destitute of several of its most valuable properties. It is, however, for some purposes, a useful species of timber.

TEANY, TAWNY, or BRUSK. In Heraldry, a colour compounded of red and yellow, employed in blazonry, but rarely met with in English coats of arms, and reckoned one of the dishonourable colours. In engraving, it is represented by diagonal and horizontal lines crossing each other.

TEARS. The fluid which lubricates the cornea of the eye, when secreted in excess, forms *tears;* they are limpid, saline, perfectly miscible with water, and have a slight alkaline reagency, owing to the presence of free soda: their principal saline contents are common salt and a trace of phosphate of soda, and they contain traces of albumen; but the whole solid matter scarcely amounts to 1 *per cent.* When the lachrymal duct by which the tears are conveyed into the nostrils is obliterated, and they flow over the angle of the eye, they become concentrated by evaporation, and leave an irritating muco-saline crust. The exact nature, however, of the animal matter contained in the tears has not been determined.

TECHNO'LOGY. (Gr. τεχνη, *art*, and λογος, *a discourse.*) A term invented to express a treatise on art or the arts.

TECTIBRA'NCHIATES. (Lat. tego, *I cover*, and branchia, *gills.*) A name given by Cuvier to an order of Hermaphrodite Gastropods, comprehending those species in which the gills are covered by a process of the mantle, containing a shell, or enveloped in a reflected margin of the foot: for this name that of *Monopleurobranchiata* has been substituted by M. De Blainville.

TECTO'RIUM OPUS. (Lat. tector, *a plasterer.*) In Architecture, the plasterers' work used on ceilings and interior walls: it was a composition of lime and sand, and differed from stucco, which was called albarium opus. Great pains were taken to prevent its cracking, by crossing layers of reed upon it coated with argillaceous earth previous to coating it with paint.

TECTRI'CES, *Coverts.* (Lat. tego, *I cover.*) The name of the feathers which cover the quill feathers and other parts of the wing. *See* COVERTS.

TE DEUM. (From the first words of the original Latin, "Te Deum laudamus;" *We praise thee, O God.*) The authorship of this sublime hymn has been ascribed by some to Ambrose and Augustine; by others to Ambrose alone, to Hilary, and other less distinguished persons. It is, however, generally thought to have been composed in the Gallican church: the most ancient mention of it being in the rule of Cæsarius, bishop of Arles in the fifth century. The Te Deum, in the office of matins, is always sung after the reading of scripture; in the English morning service, between the two lessons. (Palmer, *Origines Liturgicæ*, ch. i. part 1. sec. 2.)

TEETH. *See* DENTES.

TEETH OF WHEELS, are generally the means by which the power of the first mover is conveyed to the working point of a machine; and it is obviously of great importance that they should be of such a form that as little as possible of the original power may be lost in transmission, and that the impulse should be conveyed through the train of wheels with a uniform force.

In the formation of the teeth of wheels, the object aimed at is to give them such a curvature that the angular velocities of the two pieces working together shall maintain the same constant ratio in all positions of contact. In order to preserve the constancy of the angular velocity ratio, it is only necessary that the acting faces of the teeth shall have such a form that the normal common to the two surfaces in contact shall always divide the *line of centres* (that is, the line joining the centres of the wheel and pinion) in a fixed point. Now, the teeth of one wheel being assumed to have any form whatever, it is always *geometrically* possible to assign the form of those of another so that they shall fulfil this condition, and, consequently, work together correctly; but the forms which are found to answer in practice are limited to a comparatively small number. We subjoin the following cases from Brewster's edition of *Ferguson's Mechanics:* —

Case 1. — If the acting faces of the teeth of a wheel are epicycloids whose generating circle has the same radius as the primitive radius of the pinion, and whose base has the same radius as the primitive radius of the wheel; and if these teeth drive the pinion by acting upon infinitely small pins in its circumference, — the motion of the wheel and pinion will be uniform.

Case 2. — If the acting faces of the teeth of a wheel are epicycloids whose generating circle is of any magnitude whatever, and whose base is the convex circumference of the wheel; and if the acting faces of the leaves of the pinion are epicycloids described by the same generating circle, and whose base is the concave circumference of the pinion, — the motion of the wheel and pinion will be uniform.

Case 3. — If the acting faces of the teeth of a wheel are epicycloids whose generating circle has a radius equal to half the radius of the pinion, and a base of the same radius as the wheel; and if the acting faces of the leaves of the pinion are straight lines directed to the centre of the pinion, — the motion of the wheel and pinion will be uniform.

Case 4. — If the teeth of a rack drive a pinion; then, when the acting faces of the teeth of the rack are cycloids whose generating circle has the same radius as the pinion, and when their teeth drive the pinion by acting upon infinitely small pins placed in its circumference, the motion of both will be uniform.

Case 5. — If the acting faces of the teeth of the rack are cycloids whose generating circle has a radius equal to half the radius of the wheel; and if they drive the wheel by acting upon rectilinear teeth which are a continuation of the radii, — the motion of both will be uniform.

Case 6. — When the teeth of a wheel driving a rack have their acting faces formed of the involutes of a circle having the same radius as the pinion, and drive the rack by acting upon infinitely small pins fixed in its rectilinear edge, the motion will be uniform.

For detailed information connected with this subject, the reader may be referred to the following works: — Camus, *On the Teeth of Wheels; Buchanan's Treatise on Mill Work*, by Rennie; Airy, *On the Teeth of Wheels* (*Cambridge Phil. Trans.* vol. ii.); and particularly to *Willis's Principles of Mechanism*, 1841. *See* WHEEL.

TEGME'NTA. (Lat. tego, *I cover.*) In Botany, the scales covering the leaf-buds of the deciduous trees of cold climates.

TE'GUMENT, or TEGMEN. In Anatomy, the general covering of the body. In Entomology, the term is applied to the coverings of the wings of the order *Orthoptera*, or straight-winged insects.

TEINDS. In Scottish Law, tithes. By the course of various usurpations, the whole teinds of Scotland had become vested after the Reformation in the crown; or in private individuals, termed *titulars*, to whom they had been granted by the crown, or to the *feuars* or renters from the church. By a succession of decrees and enactments these tithes were generally rendered redeemable at a fixed valuation; and the clergy are provided for by stipends, paid by the commissioners of tithes (when these are vested in the crown) or by the titular. The minister can seek the increase of these stipends by process of augmentation and modification; and, if augmented, every heritor becomes liable in proportion to the amount of his teinds.

TEI'NOSCOPE. The name given by Sir David Brewster to an instrument otherwise called the *prism telescope*, formed by combining prisms in a particular manner, so that the chromatic aberration of the light is corrected, and the linear dimensions of objects seen through them increased or diminished.

"If we take a prism, and hold its refracting edge downwards and horizontal, so as to see through it one of the panes of glass in a window, there will be found a position, viz. that in which the rays enter the prism and emerge from it at equal angles, when the square pane of glass is of the natural size. If we turn the refracting edge towards the window, the pane will be extended or magnified in its length or vertical direction, while its breadth

remains the same. If we now take the prism, and hold its refracting edge vertically, we shall find, by the same process, that the pane of glass is extended or magnified in breadth. If two such prisms, therefore, are combined in these positions, so as to magnify the same both in length and breadth, we have a telescope composed of two prisms; but unfortunately the objects are all highly fringed by the prismatic colours. We may correct these colours in three ways: — 1st, We may make the prisms of a kind of glass which obstructs all the rays but those of one homogeneous colour; or we may use a piece of the same glass to absorb the other rays when two common glass prisms are used. 2d, We may use achromatic prisms in place of common prisms. Or, 3d, what is best of all for common purposes, we may place other two prisms exactly similar in reverse positions." (*Brewster's Optics, Cabinet Cyc.* p. 363.)

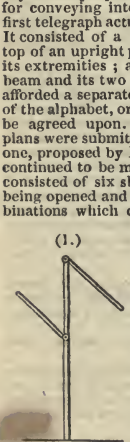
Professor Amici, of Modena, has recently constructed a combination of prisms of the same glass, in which the chromatic aberration is corrected, and a power of about three times obtained. The plan is well suited for opera glasses. Amici's teinoscope consists of four rectangular prisms, having their refractive angles different, and connected by pairs; the two pairs being similar, those next the eye or the first pair are vertical, and the second pair horizontal, so that equal refraction is produced in every direction. The distance between each pair is about an inch and a half. (*Library of Useful Knowledge*, "Optical Instruments," p. 55.) Sir D. Brewster (*Optics*, p. 364.) states that this instrument had been made by Dr. Blair as well as by himself, before it was proposed or executed by Amici.

TELAMO'NES. (Gr. τλαω, *I bear up.*) In Architecture, figures of men used for supporting entablatures, similar to Caryatides: see that word.

TE'LEGRAPH. (Gr. τηλη, *afar off*, and γραφω, *I write.*) The name given to a mechanical contrivance for the rapid communication of intelligence by signals. Of late years, the term *semaphore* (Gr. σημα, *sign;* φερω, *I bear*) has been introduced by the French, and frequently adopted by English writers.

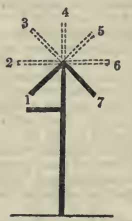
Although the art of conveying intelligence by signals was practised in the earliest ages, and is known even to the rudest savages; and although its importance is not only obvious, but continually felt wherever government is established, it has been allowed to remain in its original state of imperfection down almost to our times. The first description of a telegraph universally applicable was given by Dr. Hooke, in the *Philosophical Transactions* for 1684. The method which he proposed, for it was not carried into practice, consisted in preparing as many differently shaped figures, formed of deal, — for example, squares, triangles, circles, &c.,—as there are letters in the alphabet, and exhibiting them successively, in the required order, from behind a screen; and he proposed that torches or other lights, combined in different arrangements, should supply their place by night. About twenty years later, Amontons exhibited some experiments before the royal family of France, and the members of the Academy of Sciences, by which the practicability of the art was demonstrated. But although both the proposal of Hooke and the experiments of Amontons were made public, telegraphic communication was not applied to any useful purpose until 1794, when the plan was adopted for conveying intelligence to the French armies. The first telegraph actually used was the invention of Chappe. It consisted of a beam which turned on a pivot in the top of an upright post, having a moveable arm at each of its extremities; and each different position in which the beam and its two arms could be placed at angles of 45° afforded a separate signal, which might represent a letter of the alphabet, or have any other signification that might be agreed upon. In the following year, 1795, several plans were submitted to the English admiralty; of which one, proposed by Lord George Murray, was adopted, and continued to be made use of down to the year 1816. It consisted of six shutters, arranged in two frames, which being opened and shut according to all the different combinations which can be formed, afforded the means of giving sixty-three separate and distinct signals. In 1803, the French erected *semaphores* along their whole line of coast, formed of an upright post, carrying two, or sometimes three beams of wood, each turning on its own pivot, one above the other. In 1807, Captain (now General) Pasley, of the Royal Engineers, published his *Polygrammatic Telegraph*, differing from the French semaphores by having beams turning on the same pivot; and, in order to obtain a sufficient number of different signals, he proposed to erect two or three posts at each station. In 1816, Sir Home Popham considerably simplified this construction. His telegraph, which was adopted in that year by the Admiralty instead of the shutter telegraph, and has continued in use ever since, consists of merely two arms, moveable on different pivots on the same mast, as represented in the annexed figure (1.). It is capable of giving forty-eight independent signals. Lastly, in 1822, General Pasley still further simplified the construction, by placing the two arms on the same axis. As this form of the instrument appears to be the most perfect at present in use, we shall give a few details repecting its construction, and the mode of using it.

(1.)



For day signals, the telegraph consists of an upright post of sufficient height, with two arms moveable on the same pivot on the top of it, and a short arm, called the *indicator*, on one side; as in the annexed figure (2.). Each arm can exhibit the seven positions, 1, 2, 3, 4, 5, 6, 7, besides the position called the *stop*, which points vertically downwards, and is hid by the post. In order to show the number of signals that may be made with this machine, we may suppose the arm nearest the indicator, reckoning in the order of the numbers as shown in the figure, to indicate tens, and the other units; then the signal represented in the figure will be 17, which may be taken to denote a letter of the alphabet. If the arm on the left had the position indicated by 3, and that on the right the position indicated by 6, the signal would be 36. In this manner, the number of separate and independent signals, with their signification, will be as in the following table: —

(2.)



No. of Signal.	Signification.	No. of Signal.	Signification.	No. of Signal.	Signification.
1	A	15	L	36	V
2	B	16	M	37	W
3	C	17	N	45	X
4	D	23	O	46	Y
5	E	24	P	47	Z
6	F	25	Q u	56	
7	G	26	R	57	
12	H	27	S	67	
13	I	34	T		
14	K	35	U		

There are thus, as already stated, 28 independent signals, which are more than sufficient for spelling any message, though not enough for indicating both the letters of the alphabet, and also the numeral digits; and it may be remarked that No. 4. is a bad signal, when used by itself, because it appears in the telescope as a prolongation of the post. Advantage may, however, be taken of the indicator, if made moveable, to increase the number of combinations.

The use of the indicator is to show the order or direction in which the signals are to be reckoned; that is, whether from right to left, or from left to right. This is indispensable at sea, or wherever it is required to convey intelligence in different directions at the same time.

In order to adapt the telegraph to the purpose of making night signals, a lantern, called the central light, is fixed to the pivot on which the arms move, and one is also attached to the extremity of each arm. A fourth lantern, used as an indicator, is fixed in the same horizontal line with the central light, at a distance from it equal to twice the length of one arm, and as nearly as may be in the plane in which the lights revolve.

The arms and the indicator are made of wood, framed and panelled for the sake of lightness. The arms are fixed one on each side of the post, and counterpoised by weights, or by light frames of iron-work, which at a little distance are quite invisible. The precaution of counterpoising is necessary, as the arms would not otherwise remain in any given position unless held by the hand, or stopped by some mechanical contrivance, which would be attended with inconvenience. Motion is communicated to the arms by means of an endless chain passing over two pulleys; one fixed to the arm itself, and turning on the same pivot; and the other on a pivot fixed to the lower part of the post, within the reach of the signalman. The pulleys are of the same size, and worked with great care, so that the arms can be set with the greatest exactness; and the required positions are pointed out by a dial-plate, the index of which is moved by a lever attached to the lower pulley.

It is found from experience that the length of the arm should be about one foot for each mile of distance, and the width of the arm should be from one sixth to one eighth of its length. The indicator should be of the same width, but only about four fifths of the length of the arm.

Instead of employing the different telegraphic signals to represent the letters of the alphabet, each may have

a signification entirely arbitrary, but settled by previous agreement; and thus a message may be communicated by a single sign. When this plan is adopted, a much greater number of signals is required; but this is obtained by successively exhibiting two or more of the different single signs. Thus, supposing the telegraph capable of exhibiting 20 independent signs; then by two successive changes 400 signals may be made, and 8000 by three successive changes. Every system of telegraphic signals according to this plan is of necessity accompanied with a telegraphic dictionary, containing the signification of the different combinations of signs. Several works of this kind have been compiled. One by Sir Home Popham, at present used in the English navy, contains about 13,000 words or sentences, which is probably more than is necessary for any practical purpose, though there are others much more extensive. The Admiralty adheres to the safer, though somewhat less rapid practice, of spelling all the sentences.

In the management of a fleet at sea, telegraphic communication is indispensable. In the English navy, the signals are generally made by flags; though, from the difficulty of making out their figures and colours in calm weather, or when the wind blows in the direction in which the signal is to be communicated, the communication, it might be supposed, would be made with greater certainty by means of the semaphore.

Various attempts have been made at different times, particularly on the Continent, to supersede the optical telegraph, which is always useless in hazy weather, by applying the agency of electricity or galvanism to the rapid communication of intelligence. An apparatus for accomplishing this purpose by means of galvanism has recently been contrived by Professor Wheatstone, of King's College, London, which, if experiments on a relatively small scale may be trusted to, appears to be completely successful. It has been adopted on some of the principal lines of railway in this country.

TELEO'LOGY. (Gr. τελος, *an end*, and λογος, *a discourse.*) The doctrine of final causes is so called. The *teleological argument* for the existence of a Deity is derived from the marks of design apparent in the universe, which not only imply an intelligent Creator, but demonstrate at the same time his benevolence and other moral attributes. When these are derived from material nature, the argument is styled the *physico-theological*. The reader will find in *Whewell's Bridgewater Treatise* an explanation of Bacon's meaning in banishing final causes from the domain of physical science.

TE'LEOSAUR, *Teleosaurus*. (Gr. τελειος, *perfect;* σαυρος, *a lizard.*) The name of a genus of fossil Saurian reptiles, resembling the *Gavials;* but having the vertebræ united by flat surfaces, instead of ball-and-socket joints.

TE'LESCOPE. (Gr. τηλη, *distant;* σκοπεω, *I look at.*) An optical instrument for viewing distant objects.

For several reasons a distant object is seen less distinctly than a similar near one. The angle which an object subtends diminishes as the distance increases; the density of the light which renders it visible also diminishes with the distance, but in a much faster ratio; and a considerable portion of light is always lost in its passage through the atmosphere.

It is found by experience that to be discernible at all in ordinary daylight, a detached object must subtend at the eye an angle of not less than 30″, and that the least angle under which contiguous objects can be satisfactorily distinguished is about one minute. By the aid of a telescope a magnified image of the object is obtained; and within certain limits the object is not only apparently enlarged, but rendered brighter than it appears to the unassisted eye.

The invention of the telescope, to which practical astronomy is indebted for its most important discoveries, has been ascribed to various persons. Sir David Brewster (*Encyc. Brit.*, art. "Optics") says, "We have no doubt that this invaluable instrument was invented by Roger Bacon or Baptista Porta, in the form of an experiment; though it had not, perhaps, in their hands assumed the maturity of an instrument made for sale, and applied to useful purposes, both terrestrial and celestial. If a telescope is an instrument by means of which things at a distance can be seen better than by the naked eye, then Baptista Porta's concave lens was a real telescope; but if we give the name to a tube having a convex object-glass at one end, and a convex or concave lens at the other, placed at the distance of the sum or difference of their focal lengths, then we have no distinct evidence that such an instrument was used before the beginning of the 17th century." Descartes ascribes the invention to James Metius, a citizen of Alkmaer in Holland; Huygens to John Lippersey, or Zacharias Jansen; Borellus also to Jansen. Professor Moll, who has discussed these rival claims, after examining the official papers preserved in the archives at the Hague, comes to the conclusion that Metius (whose proper name was Jacob Adriaansy), on the 17th of October, 1608, was in possession of the art of making telescopes; but that from some unexplained reason he concealed his invention, and thus gave up every claim to the honour he would have derived from it; that on the 21st of October in the same year, 1608, John or Hans Lippersey, a spectacle-maker of Middleburg, was actually in possession of the invention; and that there is little reason to believe that either Hans or Zacharias Zanz (or Jansen, father and son) were inventors of the telescope, though one of them invented a compound microscope about 1590. (*Journal of the Royal Institution*, vol. i.)

The telescope soon made its way into other countries. In April or May, 1609, the illustrious Galileo, having heard a rumour of the invention, set about considering the means whereby distant objects could be seen distinctly, and was soon in possession of a telescope which magnified three times. In subsequent trials he succeeded in increasing the magnifying power; and before the beginning of 1610, he had observed the satellites of Jupiter. Our countryman Harriot also, in 1609, began to use the telescope for examining the disc of the moon, and before he had heard of the discoveries of Galileo. (*Priestly's History of Discoveries relating to Vision, Light, and Colours.*)

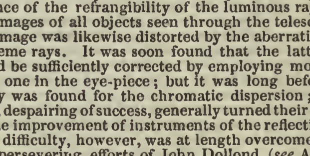
Telescopes are of two kinds, *refracting* and *reflecting* telescopes: the former depending on the use of properly figured lenses, through which the rays of light pass; and the latter on the use of specula, or polished metallic mirrors, which reflect the rays; an inverted image of the object being formed in both cases in the focus of the lens or mirror.

Refracting telescopes were those which were first constructed. They were of the most simple character, consisting merely of an object-glass of one lens, and an eye-glass of one lens, but of a shorter focus. But in this construction the prismatic colours produced by the difference of the refrangibility of the luminous rays tinged the images of all objects seen through the telescope, and the image was likewise distorted by the aberration of the extreme rays. It was soon found that the latter defect could be sufficiently corrected by employing more lenses than one in the eye-piece; but it was long before a remedy was found for the chromatic dispersion; and artists, despairing of success, generally turned their attention to the improvement of instruments of the reflecting class. The difficulty, however, was at length overcome through the persevering efforts of John Dollond (*see* ACHROMATISM); and the *achromatic refracting telescope* may now be regarded as an instrument all but perfect.

The principles on which telescopes depend having been explained under the terms REFLEXION and REFRACTION, and the properties and construction of their principal parts under ACHROMATISM, LENS, MIRROR, we shall here describe some of the principal forms which the instrument has assumed. It will be borne in mind that the general aim in the construction of a telescope is to form, by means of lenses or mirrors, as large, bright, and distinct an image of a distant object as possible, and then to view the image with a magnifying glass in any convenient manner. We shall first describe those of the refracting class.

Galilean Telescope. — This is the most ancient form of the telescope, and is that which was used by Galileo. It consists of a converging object-glass A B (fig. 1.), and

(1.)



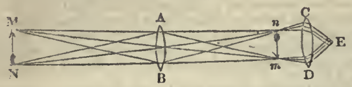
a concave diverging eye-glass C D. On passing through the object-glass A B, the rays of light coming from the different points of a distant object in parallel pencils are rendered convergent, and proceed towards the principal focus, where they would form an inverted image; but before they arrive at this point they fall upon the concave lens C D, by which they are again rendered parallel, or at least their convergence is corrected so as to give distinct vision of the object to the eye at E. The lens C D is therefore placed between the object-glass and the image, and at a distance from the image equal to its principal focal distance. The magnifying power is equal to the principal focal distance of the object-glass divided by the principal focal distance of the eye-glass. *See* LENS.

In this telescope the object is seen erect, and the length of the tube is only the difference between the focal lengths of the two lenses. These properties render it preferable to any other telescope for many ordinary purposes; as, for example, an *opera-glass*. When used for this purpose, the magnifying power is hardly ever greater than 4; and it is often as low as 2.

Astronomical Telescope. — This is composed of a converging object-glass A B (fig. 2.), and of a converging eye-glass C D. Rays of light proceeding from any point

M of a distant object M N, and falling on the different points of the object-glass, are refracted into a point m in

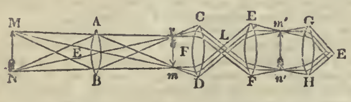
(2.)



the principal focus. In like manner, those proceeding from the point N are refracted into the point n; and thus an inverted image $m\ n$ is formed at the focus of the object-glass. The eye-glass is placed so that its focus shall coincide with the place of the image; consequently rays diverging from any point of the image, and falling on the lens C D, are refracted into a parallel direction before they enter the eye at E, and are thereby rendered fit to produce distinct vision. The length of the telescope is equal to the sum of the focal distances of the two lenses; and the magnifying power is equal to the focal distance of the object-glass divided by the focal distance of the eye-glass. This telescope was first described by Kepler in his *Dioptrice* (1611); but it does not appear to have been executed until about twenty or thirty years later.

Terrestrial Telescope. — This differs from the astronomical telescope only in having two additional lenses E F, G H (fig. 3.), placed in the tube of the eye-glass for the purpose of restoring the inverted image to its erect position, and thereby accommodating the telescope to terrestrial objects. The focal lengths of these additional lenses are usually the same as that of the eye-glass. The two pencils of rays proceeding from the points M and N cross each other in the anterior focus of the second lens E F, and falling parallel on E F form in its principal focus an inverted image of mn, and consequently an erect image of the object M N. This image $m'\ n'$ is seen by the eye at E through the lens G H, as the rays diverging from m' and n' in the focus of G H enter the eye in parallel pencils. When the three first lenses are equal, the magnifying power is the same as that of the astronomical telescope, whose object and eye glasses are the same as A B and C D.

(3.)

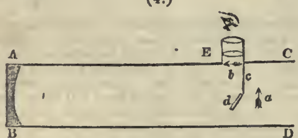


The performance of refracting telescopes depends most essentially on the goodness of the object-glass; for if the first image is bright and distinct, and perfectly achromatic, there is little difficulty in constructing eye-pieces to magnify it, without causing it to undergo any sensible alteration.

Reflecting Telescopes. — In reflecting telescopes the speculum, or mirror, performs the same office that the object-glass does in those of the refracting kind, and is therefore called the *object-mirror*. The instrument is constructed in various forms; but these differ from one another chiefly in reference to the contrivances which have been adopted for bringing the focal image into a convenient situation for being viewed by the eye-piece. The principal forms are the Newtonian, the Gregorian, the Cassegrainian, and the Herschelian.

Newtonian Telescope. — Let A B C D (fig. 4.) represent

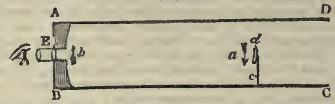
(4.)



a section of the tube of the telescope; A B the object-mirror, which would form at its focus the image a of any distant object. Now if a person attempted to view the image in its place at a by placing himself directly before the mirror, he would necessarily intercept the rays of light from the object passing down the tube to the mirror, and consequently there would be no image to view. Sir Isaac Newton overcame this difficulty by introducing a small diagonal plane speculum d between A B and a, which intercepting itself but a small portion of the light, reflects towards the side of the tube the rays converging from A B, and causes the image which would have been formed at a to be formed at b, where it can be conveniently viewed by the eye-piece E attached to the side of the tube. The small mirror is of an oval form, and is fixed on a slender arm c connected with a slide, by means of which it may be made to approach or recede from the large speculum A B, according as the image approaches to or recedes from it. In this telescope the magnifying power is equal to the focal length of the object-mirror A B divided by that of the eye-glass.

Gregorian Telescope. — In this construction the object-mirror A B (fig. 5.) is perforated in the middle, and the

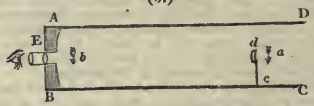
(5.)



rays of light from a distant object being reflected from the surface of A B cross each other in the focus, where they form an inverted image a, and are then intercepted by a small concave mirror d, which causes them again to converge to a focus at b, near the perforation of the object-mirror, where they form a reinverted or direct image, which is viewed by an eye-piece E screwed into the tube behind A B. The curvature of the small speculum should be elliptical, having the foci at a and b; but it is generally made spherical. In this case the great speculum should be slightly hyperbolic, to counteract the aberration of the small mirror.

Cassegrainian Telescope. — The great speculum of this instrument is perforated like the Gregorian; but the rays converging from the surface of the mirror A B (fig. 6.)

(6.)

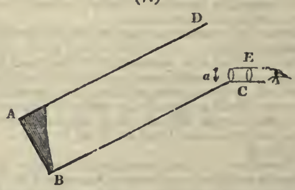


towards the focus a are intercepted before they reach that point by a small convex mirror d, not sufficiently convex to make the rays divergent, but of such a curvature as to prevent them from coming to a focus till they are thrown back to b, near the aperture in A B, where they form an inverted image which is viewed by the eye-piece E. This construction has the advantage of requiring a shorter tube than the Gregorian; but the inversion of the image is not corrected, and for this reason probably it has not been much used.

In the two last constructions the small mirror d is adjusted by means of a rod turning on a shoulder near the eye end of the tube, and connected by a screw with the apparatus which carries the arm c to which the mirror is attached.

Herschelian Telescope. — This construction differs from the others in having no second mirror. The large speculum A B (fig. 7.) is placed at the bottom of the tube

(7.)



in an inclined position, so as to bring the focal image a near the edge of the tube, where it is viewed directly by the eye-piece E without interfering with the light entering the telescope from the object observed. The magnifying power is the same as in the Newtonian.

The reflecting telescope was invented by James Gregory, and is described by him in his *Optica Promota* (1663); but the first telescope of the kind was executed by Newton. Reflecting telescopes have been made on a very large scale. The celebrated intrument of Sir William Herschel, erected at Slough in 1789, was 40 feet in length. Its great speculum had a diameter of 49½ inches; its thickness was about 3½ inches, and its weight when cast was 2118 lbs. Its focal length was 40 feet, and it admitted of a power of 6450 being applied to it. The essential advantage of large telescopes of this kind consists in the immense quantity of light which they collect, whereby the observer is enabled to perceive faint nebulæ and stars which are altogether invisible in ordinary instruments.

Reflecting telescopes are used only for observing *phenomena*, and are not, like refracting telescopes, attached to circular instruments for the purpose of measuring angles with greater precision. In order to derive full

benefit from them, they must be used in the open air; and must either be mounted equatorially (*see* EQUATORIAL), or else in such a manner as to be capable of a smooth motion both in a vertical and horizontal direction. Telescopes of this kind being generally used with a high magnifying power, and consequently having a small field of view, are always accompanied with a smaller telescope or *finder* fixed to the tube, so that the axes of the two instruments are exactly parallel.

Eye-pieces of Telescopes. — When the image formed by the object-glass or mirror is viewed with a single lens or eye-glass, whether concave or convex, it is only in the centre of the field that distinct vision is obtained, all towards the margin being hazy and distorted. To remedy this defect, Boscovich and Huygens separately proposed the construction of an eye-piece formed of two lenses, placed at a distance from each other equal to half their focal distances. Boscovich recommended two similar lenses; Huygens, that the focal length of the one should be twice that of the other; and as this construction is found to answer best in practice, it is that which is most commonly used.

The two lenses are usually plano-convex, with the convex faces towards the object-glass: the larger lens, called the field glass, is innermost, or nearest the object-glass; and a diaphragm cutting off the marginal rays is usually placed between them near the focus of the eye lens, where the image is formed. This eye-piece is usually called the *negative* eye-piece, from its having the image seen by the eye behind the field glass; and is that which is commonly supplied with telescopes intended only for the purpose of *seeing* objects, without reference to measurement.

Another modification of the two-lens eye-piece was proposed by Ramsden, and is called the *positive* eye-piece, because the image observed is before both lenses. The lenses are plano-convex, and nearly of the same focal length; but their distance from each other is less than the focal distance of the lens nearest the eye, two lenses thus placed acting as a compound simple lens. This eye-piece is the most convenient when micrometer wires are placed in the focus, because it can be taken out without injuring the wires; and it has also this advantage, that the measure of an object given by one eye-piece is not altered when it is changed for another of a different magnifying power.

In both the eye-pieces now described the image is seen inverted; and though this is of no importance in astronomical observations, it is inconvenient when the telescope is used for looking at terrestrial objects. By placing an additional pair of lenses in the tube of the eye-piece, the image is repeated and reinverted, and consequently seen erect. By this means, as explained above, the terrestrial telescope is obtained.

The name of *diagonal eye-piece* has been given to eye-pieces furnished with a diagonal reflecting mirror, the object of which is to give a more convenient direction to the rays emerging from the eye-piece when the telescope is pointed high.

Telescopes are generally supplied with eye-pieces of different powers, which are all fitted to enter the same tube; and the focal adjustment is commonly effected by a rack and pinion motion acting on the tube which carries the eye-piece.

For full information respecting the construction of telescopes, and the best modes of mounting them on stands or otherwise, to secure steadiness and allow of the requisite motion, the reader is referred to *Pearson's Practical Astronomy*, vol. ii. (See also *Smith's Optics; Coddington's Optics*.)

TELLINA. (Gr. τελλινη, *a species of muscle.*) A genus of cockles (Cardiaceous Bivalves in the Cuvierian system), characterized by the hinge of the shell having one tooth on the left and two teeth on the right valve, often bifid; in the right valve there is a plate which does not enter a cavity in the opposite valve. There is a slight fold near the posterior extremity of both valves which renders them unequal at that part, where they gape a little. The soft parts, or animal of the *Tellina*, called *peronæa* by Poli, has two long tubes for respiration and excretion, which can be withdrawn into the shell, and are concealed in a fold of the mantle.

Cuvier separated from the Linnæan *Tellinæ* the genus *Loripes*, distinguished by the feebly developed cardinal teeth, and by a long cylindrical foot. Other genera have since been detached from the Cuvierian *Tellinæ*, which now form a family, *Tellinidæ*, in the system of Lamarck.

TELL TALE. The dial plate at the wheel, showing the position of the tiller.

TELLU'RIUM. (Lat. tellus, *the earth.*) This rare metal has only been found in small quantities in the gold mines of Transylvania: it occurs in the metallic state, combined with gold or silver. It is white, brilliant, brittle, and easily fusible. Its specific gravity is about 6·25. It is combustible, and often exhales a peculiar odour, like horse-radish, which Berzelius ascribes to the presence of minute portions of selenium. It forms a protoxide and a peroxide, often called *tellurous* and *telluric acids*. Its equivalent is either 32 or 64. In the former case, the protoxide consists of 1 atom of tellurium and 1 of oxygen (32 + 8), and the peroxide of 1 atom of tellurium and 1½ of oxygen (32 + 12); in the latter the numbers are doubled. Tellurium forms a gaseous compound with hydrogen, which has been called *hydrotelluric acid.*

TE'MPERAMENT. (Lat. temperare, *to moderate.*) In Music, the adjustment of the imperfect concords, in musical instruments whose sounds are fixed, such as organs, piano-fortes, &c., so as to transfer to them part of the beauty of the perfect concords. The defect to be remedied arises from the single short keys between the two larger ones serving for flats as well as sharps. It is necessary to observe, that in the theory of harmonies the interval of a tone is not always the same; for instance, that lying between the fourth and fifth of the scale contains nine small parts, called commas, whereas that between the fifth and sixth of the major scale contains only eight commas. Again, the diatonic semitone contains five commas, and the chromatic semitone three or four, according to the magnitude of the tone. Hence it is that the different situation of these elements with regard to each other, causes intervals of the same names to consist of different degrees or elements. To improve them, therefore, musicians *temper* them so as to reduce the whole more to mean distances from each other, necessarily producing a new division of the octave.

TEMPERAMENT, in Physiology, has been defined as that peculiarity of organization which to a certain extent influences our thoughts and actions. The ancient physicians enumerated four temperaments; namely, the bilious, the choleric, the phlegmatic, the sanguine, the melancholic. To these some have added the nervous; and these terms are still in use among medical writers.

TEMPERATE ZONES, in Geography, are two of the five zones into which the terrestrial globe is divided. The *north temperate zone* is included between the tropic of Cancer and the arctic circle; and the *south temperate zone* between the tropic of Capricorn and the antarctic circle.

TE'MPERATURE. A definite degree of sensible heat, as measured by the thermometer.

TE'MPLARS, or KNIGHTS OF THE TEMPLE. A military order of religious persons. It was founded by an association of knights, in the beginning of the 12th century, for the protection of pilgrims on the roads in Palestine: afterwards, it took for its chief object the protection of the Holy Sepulchre at Jerusalem against the Saracens. Knights were fixed at Jerusalem by King Baldwin II., who gave them the ground on the east of the Temple. Their rules were taken from those of the Benedictine monks: they took the vows of chastity, obedience, and poverty. The classes of the order were, knights, esquires, servitors, and chaplains; the universal badge of the order was a girdle of linen thread. The officers of the order were chosen by the chapter from among the knights: they were, for military affairs, marshals and bannerets; for purposes of government, priors, who superintended single priories or preceptories; abbots, commanders, and grand priors, who governed the possessions of the order within separate provinces; and the grand master, who, in some respects, assumed the dignity of a sovereign prince, being independent in secular matters, and depending solely on the pope in spiritual. The chief part of the 9000 estates, lordships, &c. which the society possessed in the 13th century, was situated in France; and the grand master was usually of that nation. The Templars were driven from Palestine by the Saracens, with the rest of the Christians, and then fixed the chief seat of their order in Cyprus. Their exorbitant power and wealth, and the haughty manner in which they endeavoured to keep aloof from the control of European sovereigns, and act as a military republic independent of their authority, were probably the principal reasons which induced Pope Clement V. and Philip the Fair of France to concert their overthrow. The charges of heresy and idolatry, which were preferred against them, were at least unsupported by evidence. In 1307, Jacques de Molay, the grand master, having been enticed into France, was arrested by Philip; the Templars' estates were seized; many of them burnt alive, after the mockery of a trial; and, in 1312, the order was abolished by a bull of Clement V. Its vast estates fell partly into the hands of the sovereigns of the countries in which they were situated, partly into those of the Hospitallers and other military orders. Detached bodies of the order, however, continued to subsist for some time in different countries. See, among numerous authorities, Raynouard's tragedy of *Les Templiers*, with the notes; *Turner's England in the Middle Ages*, vol. ii.; *Mem. de l'Ac. des Inscr.* vol. xxxvii.; *Addison's History of the Knights Templars and the Temple Church*, 1842. For a notice of the strange irreligious doctrines attributed to them, see the article BAPHOMET.

TE'MPLE. A building dedicated to the service o

some deity. Derived from the Lat. templum, Gr. τέμενος, signifying *separation* and *consecration*. The term is generally confined to heathen edifices; excepting in the case of the building erected for the worship of God by Solomon at Jerusalem, which is emphatically denominated *the Temple*. This edifice was similar in its plan to the Tabernacle, consisting of the holy of holies, the sanctuary, and a portico. It is minutely described in 1 Kings, vi.

The Temple of Solomon was begun B. C. 1012, and destroyed by Nebuchadnezzar B. C. 586. It was rebuilt after the return of the Jews from captivity, and after a period of nearly 500 years repaired and beautified by Herod the Great. The restoration contemplated by this prince must have been extensive. When the Jews say to Christ, "Forty years was this temple in building," they are generally supposed to allude to the time during which the repairs had been in progress; nor, according to Josephus, were they brought to a completion when the temple itself, together with the entire city, were demolished by the army of Titus, A. D. 70.

The structure to which this term is applied is of comparatively modern date, for the earliest temples were an open spot with a rude altar of earth and stones; indeed, the Persian religion forbade the worship of the Deity except in the open air, and the earliest Greek temples give us some notion of the same sort of practice. The oracle at Delphi, according to Pausanias, was merely an arbour of laurels; and from Herodotus we learn that the oracles at Dodona were delivered from an old oak. The remarkable features of the Egyptian temple are the massive dimensions, and the number and arrangement of the columns; the cell being always of diminutive size. In Greece, at the period when they had advanced in art, every city exhibited structures of the most elaborate and splendid description dedicated to the service of their divinities; and the Romans long after emulated their masters in the care and riches bestowed upon these edifices. Some of the most celebrated were those of the Parthenon (to Minerva) at Athens, of Diana at Ephesus, of Apollo at Delphi, of Jupiter at Olympia, of Venus at Paphos and Cythera, and that of the Capitoline Jupiter at Rome. Asia Minor abounded with them; and in the other direction we find them as far west as Nismes. Vitruvius has classed temples under seven heads; viz. those *in antis*, the *prostyle*, the *amphiprostyle*, the *peripteral*, the *dipteral*, the *pseudodipteral*, and the *hypæthral*, all of which are defined under these names in this work.

TE'MPLET. (Etym. doubtful.) In Architecture, a short piece of timber laid under a girder or beam to distribute the weight. Also a mould used by bricklayers for cutting or setting out work, and by millwrights for shaping the teeth of wheels.

TEMPO. (It. *time*.) In Music, the Italian word constantly used to express time.

TE'MPO D'IMBROGLIO. (It. *time of trouble*.) In Music, a term applied to a composition written in one measure, but really performed in another.

TE'MPORAL or TEMPLE BONES. Two irregular bones, one on each side of the head. They are connected with the occipital, parietal, and sphenoid bones, and are articulated with the lower jaw. Comparative anatomy shows that the so-called "temporal bone," in man, is essentially an assemblage of five bones, called squamous, zygomatic, tympanic, petrous, and mastoid; having distinct functions developed in different proportions, and continuing permanently detached in the cold-blooded classes, but soon coalescing in the warm-blooded classes. The tympanic element, however, continues permanently detached in birds.

TENA'CITY OF THE METALS. The power which metallic wires possess of sustaining, without breaking, the action of a suspended weight. *See* COHESION, STRENGTH OF MATERIALS.

TENA'CULUM. A surgical instrument, consisting of a fine sharp-pointed hook, by which the mouths of bleeding arteries are seized and drawn out, so that in operations they may be secured by ligaments.

TENAILLON. In Fortification, a kind of outwork made on each side of a small ravelin to increase its strength, and to cover the shoulders of the bastion. Works of this kind are, however, so decidedly inferior to large ravelins, that they are seldom adopted.

TENANT, TENEMENT. In Law. These words are derived from the principles of the feudal system, according to which (as it prevailed in England) no land was without a lord; and every one who enjoyed land *held* it either of a mesne tenant, or of the crown. The party holding the land is called *tenant*, the thing holden *tenement*, the mode of holding *tenure*. Thus tenants are said to be in fee-simple, in tail, for life, for years, &c. Tenement, in the largest sense of the word, is every thing which may be holden; viz. all corporeal hereditaments, and incorporeal hereditaments of a permanent nature issuing out of the same. Thus lands, houses, rights of common, &c., franchises, offices, are all tenements in the larger sense. In the more narrow acceptation in which the word is popularly applied, it describes a house with the homestall or immediate appurtenances.

TENCH. The name of a species of Cyprinoid fishes (*Tinca vulgaris*, Cuv.), and the type of a subgenus of that family. It is generally more or less abundant in ornamental waters and ponds, but is seldom found in rivers in this country. It is common in most of the lakes of the European continent, whence it is supposed to have been imported into England. The tench is remarkable for its tenacity of life; it spawns about the middle of June, at which time the female is attended by two males. Their food consists of the smaller soft-bodied aquatic animals, and vegetable matter. In stocking a pond with tench, the large-sized fish should be selected, and two males to one female should be the proportion of the sexes. *See* TINCA.

TE'NDER. In Law, the legal tender of a debt is by the actual production and offer of the sum due, unless the creditor dispense with it by a declaration that he will not accept it. The tender must be of money: if beyond the sum of 40*s*., in gold, or in what has been rendered by act of parliament equivalent for that purpose, viz. Bank of England notes, which are a legal tender for every sum above 5*l*., except at the Bank of England or its branches. A tender of country bank notes, if not objected to on that ground, is sufficient. The tender of a larger sum than that due is legal, unless it be of a sum requiring change.

TENDO ACHILLIS. The large tendon which passes from the muscles of the calf of the leg to the heel. Its name has reference to the fable of the dipping of Achilles in the Styx; his mother, Thetis, having, as it is said, held him by that part.

TE'NDRIL, is any slender twining part by which one plant attaches itself to another. It is often a transformation of a leaf which has no lamina, or which has the midrib elongated beyond it, retaining its usual tapering figure, and becoming long and twisted spirally. In the vine it is an abortive bunch of flowers; in the passion flower, a metamorphosed branch; in some petals a thin extended point, as in *Strophanthus*.

TENE'SMUS. (Gr. τειν, *I stretch or constringe*.) A straining and ineffectual inclination to void the contents of the bowels.

TE'NNANTITE. A mineral named in honour of the late Mr. Tennant. It is an arsenical sulphuret of copper and iron. It occurs in the copper veins of some of the Cornish mines, both massive and crystallized.

TE'NON. (Lat. teneo, *I hold*.) In Architecture, the end of a piece of wood or timber, diminished usually by one third of its thickness, which is received into a hole corresponding to it in size, called a mortise, by which expedient the two are held jointed or fastened together.

TENO'RE, or TENOR. (It.) In Music, the mean or middle part of a composition, being the ordinary compass of the human voice when neither raised to a treble or lowered to a bass. What is called counter-tenor is only a higher tenor.

TE'NREC. The name of a small Insectivorous quadruped of Madagascar, allied to the hedgehog: it forms the type of the genus *Centetes*.

TENSE. (Lat. tempus, *time*.) In Grammar, that modification of the verb which defines the time at which the action is conceived as taking place. *See* GRAMMAR.

TENSOR MUSCLES, in Anatomy, are those which tighten the part to which they are fixed; as the tensor vaginæ femoris, tensor palati, &c.

TENT, *Tinta*. A Spanish red wine, chiefly from Malaga and Gallicia.

TENT, in Surgery, is a plug of lint used for dilating wounds: a piece of sponge which has been imbued with wax is termed *sponge-tent*.

TE'NTACLE. (Lat. tentaculum, *a holder*.) This term is used by Savigny in a restricted sense to signify the elongated, filiform, inarticulate appendages of the mouth of Annellides; but is also applied to all appendages, whether jointed or not, which are used as instruments of exploration and prehension. Thus the oral arms of the Polyps, the prehensile processes of Cirripeds and Annellides, the cephalic feet of the Cephalopods, the barbs of fishes, are termed tentacles.

TENTH. In Music, an interval containing nine degrees and five spaces.

TENTHS. The tenth part of the yearly value of al benefices, which was anciently paid, with the first fruits, to the pope. *See* FIRST FRUITS.

TENTO'RIUM. The process of the *dura mater* which separates the cerebrum from the cerebellum.

TE'NUES. (Lat. *thin*; Gr. ψιλαι.) The three letters *k*, *p*, *t* in the Greek alphabet are so called, in relation to their respective middle letters *g*, *b*, and *d*, and their aspirates *ch*, *ph*, and *th*.

TE'NUIRO'STERS, *Tenuirostres*. (Lat. tenuis, *slender*, and rostrum, *a beak*.) The name of a tribe of Insessorial birds, including those which have a long and slender bill.

TE'NURE. The feudal relation between lord and vassal in respect of lands. Tenures in capite, or in chief,

were those by which land was held immediately of the crown; mesne tenures, of mesne or inferior lords. English tenures under the feudal system are reduced by Blackstone to four: knight-service, or chivalry; free socage; pure villenage; and villein-socage. *See* FEUDAL SYSTEM, SOCAGE, VILLENAGE.

TENURES, SCOTTISH, were five: viz. 1. Military, or *ward-holding;* abolished, with all its *casualties* or incidents, by 20 G. 2. c. 50. 2. By *mortification*, or *mortmain;* which now only applies to manses and glebes, retained by the act of 1587 as mortified to the church. 3. *Burgage holding*, by which the burgesses of royal burghs hold lands and houses within the burgh of the sovereign by service of watching and warding, &c. 4. *Blanch tenures*, by which the grantee or vassal is bound to pay to the superior annually a species of quit-rent or acknowledgment. 5. *Feu-holding*, by grant, with reservation of pecuniary services. *See* FEU.

TEPHROMANTI'A. (Gr. τεφρα, *ashes*, and μαντεια, *prophecy*.) Divination from the figures assumed by red-hot embers. (See Potter, *Arch. Gr.* i. 353.)

TE'RAPHIM. A word used thirteen or fourteen times in the Old Testament, and commonly rendered by our translators "idols." Bryant explains them as "lunar amulets, or types of the ark in the form of crescents, supposed to have been invented by the patriarch Terah." (*Antiq.* iii. 321.) In later times, strange and horrible practices of witchcraft are described by Rabbinical writers in explaining this word. The teraph, according to Rabbi Eliezer, was made by killing a first-born child, opening the head, putting a gold plate with the name of the impure spirit under the tongue, &c. (See also the notes to *Southey's Thalaba*, book i.)

TERATO'LOGY. (Gr. τερας, *a monster*, and λογος, *a discourse*.) That branch of physiological science which treats of the various malformations and monstrosities of the organic kingdoms of nature.

TEREBE'LLUM. (Lat. terebro, *I bore*.) The name of a genus of Buccinoid Pectinibranchiate Gastropods, having an oblong shell with a narrow aperture, destitute of folds and ridges, and gradually enlarging to the extremity opposite to the spire.

TEREBRA'NTIA. (Lat. terebro, *I bore*.) The name of a section of Hymenopterous insects, characterized by the possession of an anal instrument organized for the perforation of the bodies of animals, or the substance of plants. The borer (*terebra*) is peculiar to the female, and is composed of three long and slender pieces, of which two serve as a sheath for the third; it is placed at the anal extremity of the abdomen, and the oviduct is continued into it. The females instinctively use this weapon to prepare a place for the deposition of their eggs, where the maggot may be incubated in safety, and upon its exclusion be surrounded by already organized matter adapted for its sustenance. Some genera select vegetables for the parasitic support of their young, as *Sirex* (Linn.), which infests the pine-tree; and *Cephus* (Latr.), which perforates the stalks of corn for the purpose of oviposition. Others, as the ichneumons, pierce the skins of insects, and deposit their eggs in the subcutaneous fatty and nutrient material. Some ichneumons are provided with long and extensible anal borers, which they insinuate beneath the bark of trees, and into crevices and fissures, where their instinct and peculiar antennal organs of sensation teach them that the insect resides that may form a fitting nidus for the parasitic and carnivorous larvæ. Other ichneumons, with short terebræ, place their ova in the bodies of Lepidopterous larvæ, or in those pupæ which are readily accessible to their attacks.

The female ichneumons manifest a wonderful instinct at the season of oviposition in discovering the insects, as well mature as in their different stages of egg, maggot, caterpillar, and chrysalis, which are obnoxious to the wounds, with all the fatal consequences, of the instrument from which the present section of *Hymenoptera* takes its name.

TEREBRA'TULA. (Lat. terebro, *I bore*.) The name of a genus of Palliobranchiate Acephalous Bivalve Mollusks, in which one of the valves is perforated for the transmission of a peduncle: the hole through which the peduncle passes is completed by a small detached calcareous piece.

TERE'DO. (Lat. teredo, *the ship-worm*.) The name of a genus of Acephalous Mollusks which bore their habitations in submerged timber, and occasion destructive ravages in sunken piles, ships' bottoms, &c.

TE'RGUM (Lat. tergum, *the back*), in Entomology, signifies the upper or supine surface of the abdomen.

TERM (Lat. terminus, *a boundary*), in Logic, is the expression in language of the notion obtained in an act of apprehension. (*See* APPREHENSION.) A term may consist of one word, or of several; but every word is not capable of being employed by itself as a term, or, in logical language, *categorematic*. Adverbs, prepositions, &c., and also nouns in any other case besides the nominative, are syncategorematic, *i.e.* can only form part of a term; while a verb is a mixed word, being resolvable into the copula (or auxiliary verb) and the term, to which the copula gives tense, mood, and position; but an infinitive mood is a term by itself. Simple terms, or categorematics, are divided into *singular* and *common*. A singular term stands for one individual; as "Cæsar," "the king." It is obvious that these terms cannot be affirmed or denied (in logical phrase, predicated affirmatively or negatively) of any thing but themselves. A common term stands for many individuals (which are called its significates), as "man," "king." These, it is evident, can be said (or predicated) of others; *e.g.* "Cæsar is a man," "Frederick is a king." The subject of a proposition, therefore (*see* PROPOSITION), may be either a singular or a common term; the predicate must be a common term. Terms are said to be univocal, equivocal, analogous, &c.; but these are rather distinctions of language than of logic. They are also said to be "of the first intention," and "of the second intention;" the first appearing to be words used in a vague and general sense; the latter words used in a limited and specific sense, which they bear in some particular art or science.

TERMI'NALIA. Annual festivals celebrated by the Romans in the month of February, in honour of Terminus, the god of boundaries. On such occasions the peasants assembled at the different landmarks or *termini* that divided their property, and offered up libations of milk and wine. *See* TERMINUS.

The word *terminus* is now employed chiefly to designate the extreme points of a railroad.

TE'RMINISTS. In Ecclesiastical History, a name given to a class among the Calvinists, whose tenet it is (or was, for such opinions hardly exist at the present day), that there are persons to whom God has fixed, by a secret decree, a certain *term* before their death, after which he no longer wills their salvation, however long they may live. They instanced the cases of Pharaoh, Saul, and Judas, among others.

TERMINO'LOGY. (Lat. terminus.) In every science or art, that preliminary knowledge which teaches us to define the words and phrases peculiarly employed in it (in other words, its technical terms) is called its terminology.

TERMINTHUS. A black pustule chiefly attacking the legs. It is not, however, clear what the disease was which the Greek writers describe under this name. (*Med. Dict.*)

TE'RMINUS. (Lat.) In Ancient Architecture, a stone raised for the purpose of marking the boundary of a property. Also a pedestal increasing in size as it rises, or a parallelopiped for the reception of a bust. Terminus was the name of the god of boundaries among the Romans. Terminus, in more recent times, is applied to the beginning or the end; *i.e.* to the first and last station of a railroad.

TERMITES. (Lat. termes, *the branch of a tree*.) These insects constitute an extensive and important tribe of the Neuropterous order, confined to the warmer latitudes of the globe, and performing a considerable share in the essential labour of completing the comminution and destruction of dead and decomposing organized matter. The termites are all social, terrestrial; and are active, carnivorous or omnivorous, in all the stages of their existence, save that of the ovum, after which they undergo only a semimetamorphosis. The mandibles are always strong and hard, but differ in relative size in different classes of individuals of the same community.

The tribe *Termetinæ* includes the genera *Mantispa*, *Raphidia*, *Psocus*, *Perla*, and *Termes* proper (now the type also of a family, *Termitidæ*, or white ants, as they are commonly called). These are characterized by four-jointed tarsi; but the wings are carried horizontally on the body, and very long: the head rounded, and the prothorax short and square. The body is depressed, with the antennæ short; the mouth very similar to that of the *Orthoptera*, with the four-cleft lower lip; three occelli, one rather indistinct; the wings generally but slightly transparent, coloured, with the nervures not forming a close network; and the legs short.

The termites peculiar to the tropical and adjacent countries are known under the name of white ants, and commit most extraordinary ravages, especially in the larva state, in which they are called *workers;* these are like the perfect insect, but with the body softer, and without wings, and the head generally larger and destitute of eyes, or nearly so. They are united into colonies of incalculable numbers, and live concealed in the interior of the earth, trees, and other wooden matters, such as furniture, shelves, &c., in which they form galleries, forming routes conducting to the centre of their nests; so that these objects, of which the outer surface is (with surprising instinct) left untouched, fall to pieces on the slightest touch. The nests of some species are external, but without any evident exit. Sometimes they are elevated to a great height above the surface, like pyramids, occasionally surmounted by a solid roof, which,

by their height and number, appear at a distance like a small village. Sometimes these insects affix their nests to the branches of trees. Another sort of individual, termed *neuters* or *soldiers*, and which Fabricius mistook for pupæ, defend the nest. They have a head much larger and longer; and the mandibles are very long, and cross over each other. They are far less numerous than the larvæ, and live near the outer surface of the nest, so that they make their appearance just when it is attacked: they are also stated to compel the workers to labour. The demi-nymphs have the rudiments of wings, and in other respects resemble the larvæ.

When arrived at the perfect state the termites quit their habitation; fly abroad during the evening and night in great numbers: they lose their wings before morning, which dry; and falling to the earth, they become the prey of birds, lizards, &c. The couples are then collected by the larvæ, which inclose each of them in a large cell; but Latreille conjectures that the act of coupling takes place in the air, as in the ants, and that the females alone occupy the attention of the larvæ in order to the establishment of fresh colonies. The abdomen of the female subsequently acquires an enormous size, from the innumerable eggs which it contains. The royal chamber occupies the centre of the habitation, and around it are distributed those which contain the eggs and provisions.

Some larvæ of *Termes varium* have eyes, and appear to have habits somewhat different to the rest, and to approach our ants.

Negroes and Hottentots are very fond of these insects.

TERMS, in Law, are four sections of the year appropriated to the transaction of particular business in the superior courts of common law and equity. They are now regulated by 11 G. 4. and 1 W. 4. c. 70.

Hilary Term begins the 11th, and ends the 31st of January.

Easter Term begins 15th of April, and ends the 8th of May.

Trinity Term begins 22d of May, and ends the 12th of June.

Michaelmas Term begins the 2d, and ends the 25th of November.

Whenever any one of these days falls on a Sunday, the following Monday is substituted for it; and if the days from Thursday before to Wednesday after Easter Sunday inclusive, or any part of them, fall within Easter term, such days are regarded as holydays, and the term is increased by an additional number of days at the end, and Trinity term proportionably postponed. During term the three superior common law courts sit *in banc;* and all their business, with the exception of the trial of issues in fact, and such preliminary or other matters of minor importance as can be transacted before a judge at chambers, is performed. The power of the courts has, however, been increased by a recent statute, enabling them to transact certain term business in vacation time. The rest of the year is termed Vacation. During the vacation, one judge of each court sits at Nisi Prius for the trial of causes in London and Middlesex, through the periods called Sittings; which are fixed by the same act to last not more than twenty-four days after Hilary, Trinity, and Michaelmas terms respectively, nor more than six days after Easter term. During the vacation also the circuits are held, in which causes are tried and the gaols delivered in other parts of England and Wales.

TERMS OF EQUATIONS, are the several parts of which they are composed, connected by the signs of addition or subtraction. Thus, $2ax-bc$, has for its terms $2ax$ and bc. Generally all terms containing the same power of the unknown quantity are considered as one compound term; the coefficients, with their proper signs, being connected with that power of the unknown quantity.

TERPSI'CHORE. (Gr. τερπω, *I delight*, and χορος, *a dance*.) The muse who presided over dancing, usually represented with a seven-stringed lyre or a plectrum in the hand, and in the act of dancing.

TERRACE. (Fr. terrasse.) In Architecture, a raised natural or artificial bank for the purpose of affording a promenade.

TERRA COTTA, literally baked clay, is the name given to statues, architectural decorations, figures, vases, &c., modelled or cast in a paste made of pipe or potter's clay and a fine-grained colourless sand from Ryegate, with pulverized potsherds, slowly dried in the air, and afterwards fired to a stony hardness in a proper kiln.

TERRÆ FILIUS. In Classical Latinity, a humorous designation of persons of low origin or obscure birth: terræ filii, *sons of the earth*. (See *Persius*, Satire 6.) In the university of Oxford, by an ancient custom, abolished a century ago, a satirical Latin oration was read at the commemoration annually by an undergraduate, who assumed the title of Terræ Filius, and often indulged in considerable license in his treatment of the authorities of the place.

TERRA JAPONICA. The old pharmaceutical designation of the substance now called *catechu*. It was formerly regarded as an earthy mineral.

TERRA PONDEROSA. The old mineralogical name of carbonate and sulphate of baryta.

TERRA SIENNA. A brown ochreous clay brought from Sienna, and sometimes used as a pigment.

TERRE-PLEIN. In Fortification, the horizontal surface of the rampart where the guns are placed and worked. Its breadth may be from 24 to 40 feet; and it is bounded outside by the parapet, and inside by the inner slope of the rampart. *See* FORTIFICATION.

TERRE'STRIALS, *Terrestres.* (Lat. terra, *the earth.*) The name of a section of the class *Aves*, corresponding to the orders *Rasores* and *Cursores;* also of a family of Pulmonated Gastropods, and of a division of Isopodous Crustaceans.

TERRE-VERTE. Green earth. A species of chlorite of a green or olive colour, found in Germany, France, Italy, and North America. According to Klaproth, it is a hydrated silicate of oxide of iron and potash, with a little magnesia and alumina. The green earth of Verona, once used as a pigment, is a sub-species of this mineral.

TE'RROR, REIGN OF. In the History of the French Revolution. This term has been generally applied to the period during which the executions were most numerous, and the country under the sway of the actual terror inspired by the ferocious measures of its governors, who had established it avowedly as the principle of their authority. It seems to be most properly confined to the period between October, 1793, when the revolutionary tribunal, although constituted at an earlier time, was first put in permanent action on the fall of the party of the Gironde, and the overthrow of Robespierre and his accomplices in Thermidor (July), 1794. The agents and partisans of the system have been termed Terrorists.

TE'RTIALS, *Tertiariæ*. (Lat. tres, *three.*) These are the large feathers which take their rise from the proximal extremity of the bones of the wing, corresponding to those of the forearm near the elbow joint, forming a continuation of the secondaries. They are so long in some birds of the snipe and lapwing kind, that when the bird is flying they give it the appearance of having four wings.

TERTIAN FEVER. An intermittent fever or ague, the paroxysms of which return every other day. *See* AGUE.

TE'RTIARIES. In Ecclesiastical History, a religious body, a kind of associates of the Franciscans, who acknowledged the *third* rule of Saint Francis, and seem connected with the Fraticelli and Beghardi of the 13th century. (See *Mosheim*, 13th cent. part ii. chap. ii.)

TE'RTIARY STRATA. A series of sedimentary rocks which lie above the primary and secondary strata, and are distinguished from them by their *organic remains*. *See* GEOLOGY.

TERTIUM SAL. An obsolete chemical term formerly applied to neutral salts, as being a third substance, or *tertium quod*, resulting from the union of an acid and alkali.

TERTU'LLIANISTS. In Ecclesiastical History, a branch of the African Montanists; so named from the father Tertullian, who embraced Montanist opinions. (See *Burton's Lectures*, vol. ii. p. 234.)

TERU'NCIUS. A coin of ancient Rome, the same as the quadrans or triuncis, being the 4th part of the *as*, and consequently containing three ounces before the value was diminished.

TE'RZA RI'MA (*third or triple rhyme*). A peculiar and complicated system of versification, borrowed by the early Italian poets from the Troubadours. The verses are the ordinary Italian heroic lines of eleven syllables (interspersed very rarely with ten-syllable lines). The rhyme is thus arranged: — At the commencement of a poem or portion of a poem, verses 1 and 3 rhyme together; as do verses 2, 4, and 6; the third rhyme begins with verse 5, which rhymes to 7 and 9; the fourth is formed by 8, 10, and 12, and so on; and the poem or canto ends abruptly, the last rhyme, like the first, being on a couplet instead of a triplet. It is obvious that the rhyme is interlaced throughout, and continually in suspense, so that no pause can be found until the end of the poem or canto; as, at the end of every line, there must still be a rhyme incomplete. This continuity gives a very peculiar character to the metre, and renders it highly expressive of sustained narrative or passion, and the abruptness of the conclusion is often turned to good effect by masters of versification. This metre has been rendered celebrated by Dante, who wrote in it his *Divina Commedia*. It has been adopted by his imitators, of whom the latest, Vincenzo Monti, has used it to much advantage; and by Ariosto and other poets for their satires. Byron has adopted it in English, with indifferent success, in his *Prophecy of Dante;* and it has been attempted by various translators.

TERZE'TTO. (It.) In Music, a composition in three parts.

TE'SSELATED PAVEMENT. (Lat. tessela, di-

min. of tessera.) In ancient Architecture, a pavement formed of small square pieces of stone called *tesseræ* or *dies*. They are frequently, indeed mostly, found inlaid in different colours and patterns, and with a central subject. They are embedded in cement, and rest on prepared hard strata.

TE'SSERA. In Roman Antiquities, a die six-sided, like the modern dice; and thus to be distinguished from the talus, which had only three sides. Tickets or tallies used for various purposes were called tesseræ. Thus guards were set at night in their camps by means of a tessera with a particular inscription, given from one centurion to another through the army; and in this way the word tessera seems to have come to signify the watchword or password delivered to the guard. (See *Mém. de l'Acad. des Inscr.* vol. xxxvii.)

TESSERA. In Architecture. *See* TESSELATED PAVEMENT.

TE'SSERACONTE'RIS. (Gr. τεσσεϱακοντα, *forty*, and εϱεσσω, *I row*.) A galley with forty banks of oars; one of the largest of monstrous vessels mentioned by ancient writers. Great doubts have been entertained as to the possibility of the construction of a vessel which, according to the received notions respecting classical shipbuilding, must have required about *four thousand* rowers; but it is seriously recorded that one was built for Ptolemy Philopater, probably for purposes of show only. *See* TRIREME, GALLEY.

TESSULAR. A term applied in Crystallography to a system of crystals, including the cube, tetraedron, &c.

TEST. In Chemistry, any thing by which we distinguish the chemical nature of substances from each other: thus infusion of galls is a *test* of the presence of iron, which it renders evident by the production of a black colour in water and other liquids containing that metal; in the same way sulphuretted hydrogen is a test of the presence of lead, and nitrate of baryta of sulphuric acid. In Metallurgy and Assaying, the porous crucible which absorbs the liquid vitrifiable oxide of lead and other metals combined with it is sometimes called the *test*.

TE'STA. In Botany, the integuments of a seed.

TESTA'CEANS, *Testacea*. (Lat. testa, *a shell*.) This term was employed by Linné to signify an order of the class *Vermes*. It is applied by Cuvier to an order of his class *Acephala*, comprehending those which are provided with a calcareous shell.

TESTACE'LLUS. (Lat. testa.) A genus of slugs; so called from their being furnished with a diminutive shell, which forms a shield or protection to the heart. Of this destructive genus the following species are British, and occasionally infest our gardens and nursery grounds: — *Test. scutellum*, Sowerby; *Test. halyotideus; Test. maugei*.

TESTAMENT, OLD AND NEW. *See* BIBLE.

TEST AND CORPORATION ACT. The popular names of the statutes 13 Car. 2. st. 2. c. 1. and 25 Car. 2. ch. 2.: by the first of which it was provided that all magistrates in corporations should take the oaths of allegiance and supremacy, and another renouncing the doctrine that it is lawful to take arms against the king; and should have received the sacrament within a year before their election, according to the rites of the church of England. The latter extended these provisions to "all persons that shall bear any office or offices, civil or military," &c.; and introduced a new declaration against transubstantiation. These acts, long esteemed the great bulwarks of the Protestant church, were nevertheless evaded by means of acts of indemnity annually passed for the relief of those who had neglected to take the oaths. They were finally repealed 1828 (9 G. 4. c. 17.), as far as regarded the administration of the sacrament, and a declaration set forth in the act substituted. Locke, as well as many other eminent men, has strongly objected to the principle of making a religious solemnity a test of conformity: it is defended by Dean Swift.

TESTIMONY. *See* EVIDENCE.

TE'STING. In Metallurgy, the operation of refining gold and silver by means of lead upon a vessel called a *test* or cupel. *See* CUPELLATION.

TESTUDINA'TA. (Lat. testa.) The name of a tribe of Chelonian reptiles, of which the tortoise (*Testudo*) is the type. It has been sometimes used as synonymous with *Chelonia*, and as a name for the whole order.

TESTU'DO. A military contrivance adopted by the Greeks and Romans principally in attacking walls and fortified places. It was formed by a body of troops holding their shields above their heads, so as to overlap one another and form a kind of penthouse, which threw off the missiles of the enemy while the assailants were approaching the walls. The word properly means a tortoise, from the similitude of whose shell to this contrivance the name was borrowed.

TE'TANUS. (Gr. τεινω, *I stretch*.) A spasm of the whole of the muscles. It is frequently caused by lacerated wounds, and affecting the jaw is termed *lockjaw*. In hot climates this disease is sometimes produced by exposure to cold, or by suppressed perspiration, and it then often admits of relief and cure; but when it is the consequence of a wound it is usually fatal.

TETHY'DANS, *Tethydes*. The name of a tribe of Tunicated Acephalous Mollusks, of which the genus *Ascidia* (*Tethys* of the ancients) is the type.

TE'THYS. (Gr. τηθυον, *an ascidian*.) A name applied by Linnæus to a genus of Vermes Testacea; and by Cuvier to a genus of Nudibranchiate Gastropods, characterized by having two rows of branchiæ along the back in the form of tufts.

TETHYS. In Greek Mythology, the daughter of Uranus and Gaia, and wife of her brother Oceanus. The symbol of the sea, and of the element of water; in which character she is sometimes confounded with Thetis, unless indeed the name of the latter goddess be only another form of hers.

TETRA'CERAS. (Gr. τετταϱες, *four*, and κεϱας, *a horn*.) The generic name proposed by Dr. Leach for the four-horned antelope.

TE'TRACHORD. (Gr. τετταϱες, and χοϱδη, *a string*.) In Music, a concord consisting of, three degrees or intervals, and four terms or sounds; in modern music it is commonly called *a fourth*. The word, in its strictly literal sense, signifies any instrument with four strings, and was applied to the lyre in its primitive state.

TE'TRADITES. A word used in several senses, all of them, however, bearing upon its original derivation from Gr. τετταϱες, *four*. 1. Among the ancients children were so called who were born in the fourth month; and such were believed to be unlucky. 2. The Manichees and others, who believed the Godhead to consist of four instead of three persons, bore this name. And 3. In Ecclesiastical History different sects of heretics were so called, in consequence of the respect with which they regarded the number four.

TETRA'DORON. (Gr.) In ancient Architecture, a species of brick used by Greek builders in the private dwellings, four palms in length.

TE'TRADRACHM. A common silver coin of the ancient Greeks, of the value of four drachms.

TETRADY'NAMOUS. (Gr. τετταϱες, and δυναμις, *power*.) A flower having six stamens, of which two are short, and separated by two pairs of longer ones.

TETRAE'DRON, or TETRAHEDRON. (Gr. τετταϱες, and εδϱον, *side*.) In Geometry, one of the five Platonic bodies, or regular solids. It is bounded by four equilateral and equal triangles, or it is a triangular pyramid having four equal and equilateral faces. If we assume $a =$ the linear edge, $b =$ the whole superficies, $c =$ the solid content, $r =$ the radius of the inscribed sphere, $R =$ the radius of the circumscribed sphere, then the following relations hold true: —

$$a = 2r\sqrt{6},\ b = 24r^2\sqrt{3},\ c = 8r^3\sqrt{3},\ R = 3r.$$

See PLATONIC BODIES.

TETRAETE'RIS. (Gr. τετταϱες, and ετος, *a year*.) In Grecian Chronology, a cycle of four years, invented by Solon, to make the lunar year equal to the solar. This he effected by intercalating a month of twenty-two days at the end of two years, and at the lapse of other two years another month of twenty-three days, making in all forty-five days, which will be found to be the difference between the lunar and solar year after an interval of four years.

TE'TRAGON. (Gr. τετταϱες, and γωνια, *angle*.) In Geometry, a figure having four angles.

TE'TRAGO'NIA (Gr. τετταϱες, and γωνια), is a genus of herbaceous plants of the Portulacaceous order, with four-cornered fruit; one species of which, native of New Zealand, is cultivated as an esculent under the name of New Zealand spinach. Although inferior to genuine spinach, it is valuable on account of its resistance to drought and the great quantity of foliage that may be gathered from a single plant. It is an annual of the easiest culture.

TETRAGRA'MMATION. Among several ancient nations, the name of the mystic number four, which was often symbolised to represent the Deity, whose name was expressed in several languages by four letters: thus the Heb. יהוה; the Assyrian Adad; the Egyptian Amon; the Persian Syre; the Greek Θεος; the Lat. Deus. By a curious coincidence, the same peculiarity prevails in many modern languages, as will be seen in the Germ. *Gott*, the French *Dieu*, &c.

TETRA'LOGY. (Gr. τετταϱες, and λογος, *discourse*.) The name given to the collection of four dramatic compositions which was brought forward for exhibition at Athens by competitors for scenic honour. It consisted of three tragedies and a "satyrus" (*see* SATIRE), of which the only example left is the *Cyclops* of Euripides.

TETRA'METER. (Gr. τετταϱες, and μετϱον, *measure*.) A verse consisting of four measures; that is, according to the Greek prosody, of eight iambic, trochaic, or anapæstic feet, or four feet exceeding three times.

TETRA'NDROUS. (Gr. τετταϱες, *four*, and ανηϱ, *a man*.) A flower having four stamens.

TE'TRAO. (Lat. tetrao, *a bustard*.) A name selected

by Linnæus for an extensive genus of gallinaceous birds, characterised by a naked and generally red band, which occupies the place of the eyebrow. This genus comprehended all the various species of grouse, partridges, francolins, quails, and tinamous; and the necessity for subdividing it was consequently soon recognised. Latham restricts the genus *Tetrao* to those species of which the feet are covered by feathers, and are without spurs, with naked toes, and a round or forked tail: these are the true grouse. The species in which the toes are feathered as well as the legs, called ptarmigan, form the genus *Lagopus*. Brisson separated from the Linnæan *Tetraones*, the partridges, francolins, and quails, under the generic title *Perdix;* and the obvious characters indicated by the common names of these tribes, have been made by later zoologists the grounds for as many distinct genera. The quails of the New World form the distinct genus *Ortyx*, The long-necked tinamous of America, constitute the last genus (*Tinamus*, Latham) of the family *Tetraonidæ*.

TETRAPHA'RMACON. An ointment composed of four remedies; namely, wax, resin, lard, and pitch.

TE'TRAPLA. (Gr. *τετταρες*.) In Ecclesiastical History, the name of a Bible arranged by Origen in four columns, consisting of four different Greek versions; viz. that of the Septuagint, that of Aquila, that of Symmachus, and that of Theodosian. This work must not be confounded with the *Hexapla*, which see.

TETRAPNEUMO'NIANS, *Tetrapneumones*. (Gr. *τετταρες*, and *πνευμων*, *a lung*.) The name of a section of spiders (*Araneidæ*), comprehending those which have four pulmonary sacs.

TETRA'PTERANS, *Tetraptera*. (Gr. *τετταρες*, and *πτερον*, *a wing*.) A name applied by some entomologists to the insects which have four wings, and which thus constitute an extensive primary division of the class.

TE'TRARCH. (Gr. *τετράρχης*.) The governor of a fourth part of a country. This was a title granted by the Romans to some tributary princes, whom they did not dignify with the style of king. It seems to have originated among the Galatians. Such were the sons of Herod the Great, amongst whom his dominions were divided after his death. (See *Mém. de l'Acad. des Inscr.* vol. xxviii.)

TETRASPASTON. (Gr. *τετταρες*, and *σπαω*, *I pull*.) In Mechanics, a machine in which four pulleys all act together.

TETRA'STICH. (Gr. *τετταρες*, and *στιχος*, *verse*.) In Poetry, a stanza of four verses.

TE'TRASTYLE. (Gr. *τετταρες*, and *στυλος*, *a column*.) In Architecture, a building having four columns in front.

TE'TTER. An eruptive disease of the cuticle. *See* PSORIASIS.

TETTI'GES. (Gr. *grasshoppers*.) An appellation assumed by the ancient Athenians in allusion to the boast that they were produced from the soil which they inhabited. In conformity with this belief they were often styled *αυτοχθονες*, or earthborn, and wore golden grasshoppers in their hair.

TETTIGO'NIANS, *Tettigonides*. (Lat. tettigonia, *a kind of grasshopper*.) A section of Hemipterous insects, of which the genus *Tettigonia* is the type. It is synonymous with Cicadarians. *See* CICADA.

TEUTA'TES. In Mythology, a Celtic divinity, to whom Roman writers have given some of the attributes of their Mercury (*Mem. de l'Ac. des Inscr.* xxiv. 349.), enumerated by Lucan among the gods of the Gauls: Quibus immitis placatur sanguine diro Teutates.

TEUTHIDANS, *Teuthidæ*. (Gr. *τευθος*, *a calamary*.) The family of Dibranchiate Cephalods of which the calamary (*Loligo vulgaris*) is the type.

TEUTO'NIC ORDER. One of the principal military orders of religious persons. It was founded in 1190, by Frederic duke of Swabia, and intended for Germans of noble rank only: its rules were the same with those of the Templars. Like the other orders (*see* SAINT JOHN, TEMPLARS), its original object was the performance of service against the infidels in Palestine. It was dedicated to the Virgin Mary. After the conquest of Jerusalem by the Saracens, the grand master removed to Venice, and afterwards to Marburg. By degrees it made extensive conquests from the various heathen nations on the southern shores of the Baltic. The Prussians were subdued by it, and forced to embrace Christianity, after a struggle of more than half a century. In 1237, it was united with the order of the Brethren of the Sword in Livonia. Its conquests elevated it to the rank of a sovereign power in Europe. The grand master, during the epoch of its domination, had his seat at Marienburg, in Prussia. Its territory extended from the Oder to the Gulf of Finland, and the population under its government is supposed to have amounted in the 15th century to two millions and a half of souls. Its dominions, however, were gradually lost by revolt or foreign conquest. West Prussia fell to Poland, East Prussia to the house of Brandenburg. Afterwards the seat of the grand master was at Mergentheim in Swabia; and he became a spiritual prince of the empire. By the peace of Presburg, in 1805, the rights and revenue of the grand mastership was obtained by the emperor of Austria: but the order was abolished by Napoleon in 1809; and its lands having passed to the sovereigns of the various districts in which they were situate, it now retains a titular existence only in Austria.

TE'XTUARIES. Among the Jews, the sect of Caraites, or Karaites, has been so called (see that word), from its adherence to the text of the Jewish scriptures.

THABORITES. *See* TABORITES.

THALAMUS. (Gr. *θαλαμος*, *a bed*.) In Anatomy, the part of the brain from which the optic nerves have part of their origin.

THALAMUS, in Botany, is the part on which the ovary is seated. The succulent red centre of a strawberry, the core in the fruit of a raspberry, are the thalami of these plants. Some botanists call it the receptacle of the fruit.

THALI'A. (Gr. *θαλεια*, *the blooming one*.) The muse who is generally regarded as the patroness of pastoral and comic poetry. She is also supposed to preside over husbandry and planting. She is represented leaning on a column with a mask in her right hand and a shepherd's crook in her left.

THALI'DANS, *Thalides*. (Gr. Θαλεια, one of the Muses.) The name of a tribe of Tunicaries, of which the genus *Salpa* or *Thalia* is the type. *See* SALPA.

THA'LLUS. In Botany, a term given to the organs of vegetation of liverworts, lichens, and seaweed, and to the bed of fibres from which many species of fungi arise. It is regarded as a fusion or blending together of leaf and stem. Hence plants consisting of thalli only are called Thallophytes or Thallogens. The spawn of the mushroom shows the appearance of the thallus in fungi.

THAMMUZ. The tenth month of the Jewish civil year, answering to part of June and July, and including twenty-nine days. In Mythology, the name under which the Phœnicians worshipped Osiris or Adonis. *See* ADONIS.

THANE. (Sax. thegn.) In early English History, a title of honour among the Anglo-Saxons. In its original meaning it signified a minister or servant, and was applied to the followers of kings and chieftains. Thus the king's thanes were at an early period a distinct and elevated class. In a later age of the Anglo-Saxon power, the term had become more extensive in its signification, and seems to have been appropriated to all landed proprietors who were below the rank of earl and above that of alderman, and had the privilege of assisting in framing the laws. In Latin charters the word *miles* is the equivalent of thane. There were superior and subordinate thanes, standing in the same relative situation as mesne lords and vassals under the feudal system of France and Normandy. (See *Turner's Anglo-Saxons; Palgrave's Commonwealth*.)

THA'TCHING. Covering houses, stacks, or ricks with straw or reeds, in such a manner as to throw off the rain, and exclude excessive heat, or prevent its escape from within. The straw generally used in thatching is that of the wheat, as being the longest and thickest, and the most durable. Next to wheat, rye straw is preferred, or, in default of that, the straw of oats; but the most durable of all thatch in cold countries is that formed of the reed (*Arundo donax*, Linn.), or of the common heath or ling (*Calluna vulgaris*, Sal.). A very durable covering of the thatch kind is also formed of the spray of birch, of the bark of that tree, or of oak or pine, and of the chips and shavings made by hurdle-makers from the poles and shoots supplied by copse woods. Thatched roofs were formerly almost universal in cottage architecture; but they are now being supplanted by roofs covered with tiles or slates, which are much more durable, and not subject to catch fire; while the straw formerly used for roofs is much more profitably employed as litter for cattle, and thus turned into manure, and employed in reproduction, — a process which, in agriculture at least, ought not to be deprived of any material contributing so essentially to its aid as manure.

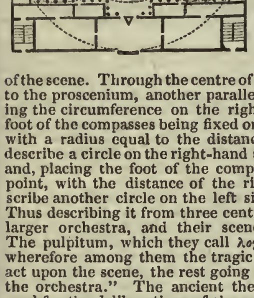
THAU'MATROPE. (Gr. *θαῦμα*, *a wonder; τρεπω*, *I turn*.) The name given by Dr. Paris to an optical toy, the principle of which depends on the *persistence* of vision. A circle is cut out of a piece of card, to opposite edges of which two silk strings are fixed, by twisting which between the finger and thumb of each hand the disc is turned round with considerable velocity. On one side of the disc is drawn any object, as a chariot; on the other side, the charioteer in the attitude of driving; so that when the card is twirled round, we see the charioteer driving the chariot; or, in consequence of the duration of the impressions of light on the retina, we see at once what is drawn on both sides of the card. (*Library of Useful Knowledge*, "Optics.")

THEA (Chinese tcha), is the botanical name of the genus which includes the plants yielding tea. They are found in China and the bordering countries in various situations, either in warm and damp valleys by the sides

of rivers, as in Assam, or on mountain sides, and on cool hills; occurring in the latter situations as far northward as Chusan. Some botanists assert that there is but one kind of tea tree, the difference in the samples of commerce depending upon the mode of preparation; others say that genuine black and green teas are the produce of different species, but that both kinds may be made artificially from the former sort. The latter appears to be the truth. The cultivation of tea for commercial purposes has been attempted successfully in the Himalayas, Java, Brazil, and Madeira; but unprofitably in the two latter countries, on account of the high price of labour. *See* TEA.

THE'ATINES. A religious order in the Roman Catholic church, the earliest in point of date of the communities of "regular clerks:" it was founded in 1524 by St. Cajetan of Thiene. The members, besides the ordinary monastic vows, bound themselves to the duties of the cure of souls, preaching against heresies, tending the sick and convicts, and to abstain from possessing property or asking for alms. This order does not appear to have met with much success, except in Italy, where (it is said in the *Conv. Lexicon*) the bishops are very generally chosen from it. (See *Mosheim*, cent. xvi.)

THE'ATRE. (Gr. θεατρον, from θεαομαι, *I behold.*) In Architecture, a building appropriated to the representation of dramatic spectacles. The theatres of the Greeks and Romans display some of the most extraordinary specimens of their power in the arts. Bacchus has the reputation of being the inventor of them, which, after their temples, appear to have been the most important public edifices of those people. They seem to have been carried to perfection in the Grecian colonies at an earlier period than they were in the mother country. The first theatre of *stone* at Athens, called the theatre of Bacchus, was built in the time of Themistocles; and as there seems little doubt that the Athenians were the inventors of the drama as a regular scenic action, it is fair to presume that they were the first to regulate the form and proportions which necessity and pleasure dictated in their arrangement. The subjoined diagram shows the general form of the Greek theatre, which differed but little from that of the Romans; and the instructions given by Vitruvius in the eighth chapter of his fifth book, as to the general outline of the plan, are as follows: — "Whereas in the Latin theatre the points of four triangles touch the circumference, in the theatres of the Greeks the angles of three squares are substituted; and the side of that square which is nearest to the place of the scene, at the points where it touches the circumference of the circle, is the boundary of the proscenium. A line drawn parallel to this, at the extremity of the circle, will give the front of the scene. Through the centre of the orchestra, opposite to the proscenium, another parallel line is drawn touching the circumference on the right and left; then, one foot of the compasses being fixed on the right-hand point, with a radius equal to the distance from the left point describe a circle on the right-hand side of the proscenium, and, placing the foot of the compasses on the left-hand point, with the distance of the right-hand interval describe another circle on the left side of the proscenium. Thus describing it from three centres, the Greeks have a larger orchestra, and their scene is further recessed. The pulpitum, which they call λογειον, is less in width; wherefore among them the tragic and comic performers act upon the scene, the rest going through their parts in the orchestra." The ancient theatres were frequently used for the deliberations of the general assembly of the people on political matters, as we find from Tacitus and Ausonius in respect of the theatres at Antioch and Athens. Notwithstanding the use of those buildings in later times as quarries freely used by the inhabitants of the cities in which they stood, there are still considerable ruins at Ephesus, Alabanda, Teos, Smyrna, Hierapolis, Cyzicus, Alinda, Magnesia, Laodicea, Mylassa, Sardis, Miletus, Stratonicea, Telmessus, Jasus, and Patara, all in Asia Minor; in Sicily, at Catana, Taurominium, Syracuse, Argyrium, and Segesta. In Greece, ruins are still extant at Athens, Sparta, in the island of Egina, at Epidaurus, and Megalopolis. According to Pausanias, that at Epidaurus, built by Polycletus, surpassed all the other theatres of Greece in its beauty and proportions; but in grandeur and magnificence the Roman theatres far surpassed those of the Greeks; nor is this surprising, considering the population the former had to accommodate compared with that of the latter. For a very considerable period the theatres of Rome, like those of the Etruscans, were of wood; and Pompey, on his return from the war against Mithridates, was the first who constructed one of stone. This must have been of large dimensions, inasmuch as it would contain 40,000 spectators. The remains of it at some stables of a palace are still visible. There were two other considerable theatres in Rome; the first built in the year 741 of the city, by Cornelius Balbus; and the second, which was begun by Julius Cæsar, but not finished till the time of Augustus, who dedicated it to his friend Marcellus. From the remains it appears that it was a specimen of great beauty and purity, as far as relates to the profiles of two of its orders, there being no vestiges of the upper order. The only other remains of Roman theatres are at Saguntum and Oranges, though the Romans usually erected theatres in their newly conquered cities, or at least embellished and improved those they found on the spot.



The modern theatres of Rome are, perhaps, the worst in Europe. Italy, however, boasts some beautiful examples; the principal whereof are those at Parma, now in a very dilapidated state, Milan, Verona, Turin, Naples, and Bologna. In France, a very fine theatre at Bourdeaux; the theatre at Versailles; and some elegant theatres in Paris. Till recently this country has been unsuccessful in the design of theatres; but a taste seems rising, which we doubt not, if opportunity occurred, would tend to raise its character in that respect in the eyes of foreigners. We subjoin a short table of the width of the stage in a few European theatres: —

Milan	40 feet.
San Benedetto, Venice	40
Theatre Français, Paris	40
Parma	40
Bourdeaux	39
Turin	39
Covent Garden	37
Argentino at Rome	36
Theatre Italien, Paris	33

THE'BAID. The name given to the heroic poem of Statius, which celebrates the civil war of Thebes waged between the two brothers Eteocles and Polynices. It consists of twelve books. The poet Gray has translated book ii.

THEBAN YEAR. In Chronology, the Egyptian year of 365 days 6 hours was so called. (See Bryant, *Ancient Mythology*, iv. 437.)

THE'CA. (Gr. θηκη, *a case or receptacle.*) This term is used in Botany in various senses. It is applied to one of the lobes of an anther; to the case or urn containing the spores of mosses; to delicate tubes sunk in the shields of some lichens; and to certain simple kinds of fruit. In all cases it expresses a hollow case. It is now seldom used, except for the spore-vessel of a moss.

THE'CAPHONE. The long stalk upon which the ovarium of some plants is seated; as in *Cleome*, and the caper bush.

THECODA'CTYLUS. (Gr. θηκη, and δακτυλος, *a digit.*) A subgenus of night-lizards or geckoes, distinguished by having the subdigital scales divided by a median groove into which the claw can be retracted.

THE'CODONTS. (Gr. θηκη, and οδους, *a tooth.*) A tribe of extinct Lacertian reptiles, distinguished by having their teeth implanted in distinct sockets. One of the genera of this tribe, from the magnesian conglomerate near Bristol, has been called *Thecodontosaurus*.

THE'COSTOMES, *Thecostoma*. (Gr. θηκη, and στομα, *a mouth.*) The name given by Latreille to those insects which have a suctorious mouth enveloped in a sheath.

THEFT. In Jurisprudence, the general name for the most ordinary class of offences against property; for which English law uses the peculiar designation of larceny. The difficulty of distinguishing between theft, those other species of fraudulent appropriation which are regarded by the laws of most countries as criminal offences, and, finally, that class which is only the subject of civil action, has given rise to a variety of definitions. By the French Code, art. 379., "Whoever has fraudulently abstracted a thing which does not belong to him is guilty of theft." By that of Bavaria, art. 209., "Whoever knowingly of his own accord takes possession of moveables not his, without consent of the person entitled thereto, but without violence to any one, with intent unlawfully to hold the same as his property, is a thief." The principal characteristics of English law on the subject are, that it requires an actual taking, and an actual carrying away for some distance, however small, to constitute the offence. The Commissioners of Criminal Law, in their Third Report (1839), recommend the following definition: "Whosoever shall, without such consent as is hereinafter specified, take and remove anything, being the property of any other person, and, unless when it shall be otherwise provided, of some value, with intent to despoil the owner, and fraudulently appropriate the same, shall be guilty of theft."

THEISM. *See* Deism.

THEME. (Gr. θεμα.) A subject proposed for discussion, whether orally or in writing.

THE'MIS. (Gr. Θεμις.) In Grecian Mythology, the goddess of law. She was one of the Titans, and bore to Jupiter Peace, Order, Justice, the Fates, and Seasons.

THEO'CRACY. (Gr. Θεος, *God*; κρατεω, *I rule*.) A term expressing the government of a state immediately by God. The constitution of the Israelites, previous to the appointment of kings, was emphatically a theocracy; their chief magistrates or judges being for the most part occasional officers appointed by the express direction of God. The kingly government may still be considered in a secondary sense as a theocracy, from the general superintendence which Jehovah continued to exercise over it. All polities may in this sense be called theocratic in which the final appeal in matters of moment is made to the will of God, as expressed in oracles, by auguries, or the mouth of the priesthood.

THEOCRA'SY. (Gr. Θεος, and κρασις, *mixture*.) In ancient Philosophy, a term invented to signify the intimate union of the soul with God in contemplation, which was considered attainable by the newer Platonists. Similar ideas are entertained by the philosophers of India, and by many religious sects. *See* Quietism.

THEODICÆ'A. (Gr. Θεος, *God*; δικαιος, *just*.) A justification of the dealings of Divine Providence with man. A work under this title was published by Leibnitz in the year 1710, in which he endeavours to prove that of all the possible schemes of government which God might have adopted, the one which actually exists in the world is the best. This is commonly known under the name of Optimism.

THEO'DOLITE. (Gr. θεαομαι, *I view*, and δολος, *stratagem*.) A surveying instrument for measuring the angular distances between objects projected on the plane of the horizon.

In accurate surveying, when the instrument used for observing the angles is a sextant or reflecting circle, or such that its plane must be brought into the plane of the three objects which form the angular points of the triangle to be measured, the altitudes of the two distant objects above the horizon of the observer must be determined, and a calculation is then necessary to reduce the observed angles to the plane of the horizon. The object of the theodolite is to measure the horizontal angles at once, and thereby render the previous calculation, and even the observation of the altitudes, unnecessary.

It is easy to conceive, in a general way, how this object may be effected. A telescope with cross wires in its focus must be mounted so as to be moveable both about a vertical and horizontal axis, in order that it may be brought to bear upon any object, whether in the horizon, or above or below it; and the proper means applied for measuring, with the utmost accuracy, the angle described about the vertical axis (which is the horizontal angle) in turning the telescope round from one object to another. It is consequently necessary to fix a graduated circle to the vertical axis, so that its plane may be exactly horizontal, and its centre coincident with the vertical axis; and about the same axis a radial bar, firmly connected with the telescope, must revolve parallel to the plane of the circle, for the purpose of indicating the divisions passed over on the limb of the circle when the telescope is turned from the first object to the second. And in order to render the instrument subservient to the purpose of measuring altitudes, a graduated vertical arch is attached to the telescope; but as it seldom happens, in the practice of surveying, that the objects observed are very much elevated above or depressed below the horizon, or that the vertical angles are required to be taken with the same degree of accuracy as the horizontal angles, the vertical arch is generally only a portion of a circle of smaller radius, and less minutely divided than the horizontal circle.

The theodolite, as now generally constructed for the purposes of ordinary surveying, may be described as follows: —The horizontal limb or circle consists of two circular plates, which turn freely on each other. The lower or graduated plate receives the divisions of the circle, and the upper or vernier plate has two vernier divisions diametrically opposite. The vertical axis consists of two conical parts, one working within the other. The external part is attached to the graduated plate, and the internal to the vernier plate. The diameter of the under plate is somewhat larger than that of the vernier plate, and its edge is sloped off to receive the graduation; and portions of the opposite edges of the vernier plate are sloped off in like manner to receive the vernier divisions. The graduation is usually to thirty minutes of a degree, but is subdivided by the verniers into single minutes; and in a well-made instrument quarter minutes may be estimated by the eye. For the purpose of adjusting the plane of the circle to the horizon, the external axis is fitted into a ball, which works in a socket between two parallel plates held firmly together by the ball and socket, the under plate being connected with the staff-head supporting the instrument. But this adjustment may also be made (and in larger instruments is usually made) by a tripod support, having a foot screw at each extremity acting against a plate of metal supported by the staff. Upon the plane of the vernier plate are placed two spirit levels at right angles to each other, with their proper adjusting screws, by which the circle is brought accurately into the horizontal plane indicated by the levels. The centre of the circle is adjusted over the point which forms the centre of the station from which the observation is to be made by means of a plummet.

Instead of the vernier plate described above, the index is sometimes formed by three radial bars connected with the internal vertical axis, each carrying a vernier at its extremity; and a fourth bar carries the clamp, by which the system is secured to the graduated limb.

The horizontal axis of the vertical limb (which is usually a semicircle) is supported by a frame firmly imbedded in the vernier plate, and turning along with it about the vertical axis. The telescope has two collars or rings of bell metal, ground truly cylindrical, on which it rests in supports permanently attached to the vertical limb, so that both move together in the vertical plane. The divisions on this limb are read off to single minutes by means of a fixed vernier connected with the frame, and so adjusted that the index points to the zero of the graduated arc when the optical axis of the telescope is truly horizontal. For effecting this adjustment, or determining its index error, a spirit level is attached to the telescope, at one end by a joint, and at the other by a screw, whereby the end is raised or depressed until the air bubble stands at the middle of the glass tube. The telescope is then reversed; and if the air bubble of the level still stands at zero, the adjustment is perfect; if not, the index error becomes known by bringing the level to the proper position, and may either be corrected or allowed for in the observations.

In some theodolites the telescope is supported in the manner of a transit instrument; that is to say, the telescope and the horizontal axis on which it turns form one piece, and the vertical limb is a complete circle. By this construction the instrument becomes better adapted for determining the altitudes of stars, and consequently for finding the direction of the meridian and the azimuths of objects, or for other astronomical purposes. In fact, it becomes an altitude and azimuth instrument.

In theodolites for common topographical purposes the horizontal circle is seldom more than five inches in diameter; but as the double vertical axis gives the means of carrying round the telescope from the first object to the second without disturbing the graduated circle, and then, by clamping the vernier and graduated plates, of bringing it back, and the graduated circle along with it, to the first object, the measure of the angle may be repeated any number of times, exactly as with the repeating circle, and a very considerable degree of accuracy obtained even with a circle of this small size. (*See* Repeating Circle.) But the principle of repetition is better carried into effect by means of a particular kind of stand or tripod, called a *repeating stand*, which turns round concentrically with the vertical axis of the theodolite; and this apparatus is usually had recourse to when the instrument is on a large scale.

As the accuracy of the observation must depend on the horizontal circle remaining perfectly fixed while the telescope and verniers are turned round, a second telescope, called a watch telescope, is sometimes attached to the horizontal circle beneath the limb, which, being directed to a fixed object, serves to detect any disturbance of the circle clamp, or accidental shifting of position while the upper telescope with the verniers is turned from the first object to the second. But this can scarcely be applied to the repeating theodolite.

The principal adjustments of the theodolite are, first, to rectify the line of collimation of the telescope; secondly, to make the axis of the horizontal limb truly vertical; and, thirdly, to adjust the zero of altitude. For the practical methods of making these adjustments in the case of the common surveying theodolite, and instructions as to the mode of observing, the reader may be referred to *Simms's Treatise on Mathematical Instruments*, 1834.

In geodetical operations, where very great accuracy is indispensable, as, for example, in measuring an arc of the meridian, the instrument is constructed on a much larger scale. The great theodolite by Ramsden, belonging to the Board of Ordnance, which has been used for measuring most of the principal angles of the British Trigonometrical Survey, has a horizontal circle of three feet in diameter, and two telescopes of thirty-six inches focal length. A similar one of equal dimensions had formerly been constructed by the same excellent artist for the Royal Society, and was used by General Roy in his operations for connecting the observations of Greenwich and Paris towards the end of the last century, and also by Colonel Colby and Captain Kater for the same purpose in 1821. A full description of this superb instrument is given in the *Phil. Trans.* vol. lxxx., and in the

first volume of the *Trigonometrical Survey of England and Wales*. A theodolite of equal dimensions, by Cary, has been employed in the measurement of the great meridional arc of India by Colonel Lambton and Colonel Everest. The French astronomers, in measuring their arc of meridian, used only the repeating circle; but in the more recent operations of the same kind in Germany and Russia, the geodetical angles were determined with the theodolite.

THEO'GONY. (Gr. Θεος, *God*; γονος, *birth*.) In the Religion and Literature of ancient Greece and Rome, the history of the descent and relationships of the various gods who were the objects of popular worship. These genealogies were very variously related by different writers, and originated in some instances from national superstition; while in others they had an allegorical sense, and were invented by the learned men or poets of those countries.

Theogony is also the title of a poem attributed to Hesiod, giving an account of the birth and parentage of most of the Grecian divinities.

THEOLOGIUM. A small upper stage in the ancient theatre upon which the machinery of the gods was arranged.

THEO'LOGY. (Gr. Θεος, and λογος, *discourse*.) The science which treats of the nature and attributes of God, of his relations to man, and of the manner in which they may be discovered. Lord Bacon divides the science under the following heads: — 1. Inspired. 2. Natural, which he calls the first part of philosophy. 3. Appendices Theologiæ Inspiratæ: sc. Doctrina de legitimo usu rationis humanæ in divinis; doctrina de gradibus unitatis in civitate Dei; emanationes scripturarum. 4. Theologiæ tam inspiratæ quam naturalis appendix: Doctrina de angelis et spiritibus. (*De Augm. Sci.* l. ii. ch. 1.)

Natural Theology is the inquiry into these subjects prior to the idea of revelation, and conjectures concerning them from data furnished by the constitution of nature alone. It is only by the conclusions arrived at by this process that we are put in a proper condition to examine the evidence of *revealed religion*, the basis of which is the satisfaction it affords to the demands of the human reason and affections.

A pure system of natural theology, looking no farther for the evidence of divinity than the marks of it displayed in the creation, is deism, — the belief in God as a superintending Providence, which seems to require as a corollary the idea of a future retribution. Those who can discover no design in the constitution of the world, *i. e.* no trace of God's hand therein, are atheists, or deniers of a Deity. Again, the most common form of religion deduced by the heathens from their researches in natural theology is the supposition of numerous gods, each manifesting himself to us in the various functions and qualities of the animate and inanimate world, and sometimes, according to ancient legends and traditions, by direct communication in various ways. Opposed to this is monotheism, which recognizes more distinctly than deism the unity of the godhead, and gathers up under one volition and agency the attributes which the polytheist dispersed among a vast number of divinities. Of monotheist religions the Jewish, Christian, and Mohammedan lay claim to express revelation by the word of God.

THE'OMANCY. (Gr. Θεος, and μαντεια, *prophecy*.) A name which has been given to that species of divination which was drawn from the responses of oracles among heathen nations, in which a god himself was supposed to answer the inquirer; or from the predictions of sibyls and others supposed to be immediately inspired by some divinity.

THEOPA'SCHITES. (Gr. Θεος, and πασχω, *I suffer*.) In Ecclesiastical History, a name given by the orthodox to certain heretics of the 5th century, followers of Peter the Fuller, an usurping bishop of Antioch. Being strongly attached to the Monophysite opinions, his enemies charged him and his disciples with holding that all the three persons of the Godhead were crucified. (*Mosheim*, 5th cent. part ii. ch. 51.)

THEO'PHANY. (Gr. Θεος, and φαινομαι, *I appear*.) A word invented to signify the manifestations of God to man by actual appearance. These have formed a striking feature in most systems of religion. (See, on Pagan Theophanies, the 5th Dissertation of M. Foucher on the Hellenic Religion, *Mém. de l'Acad. des Inscr.* vol. xxxvi. p. 292.)

THEOPHILA'NTHROPISTS. (Gr. Θεος, *God*, and φιλανθρωπος, *a lover of men*.) A title assumed by a society formed at Paris during the first French revolution. The object of its founders was to establish a new religion in the place of Christianity, which had been formally abolished in France by the Convention, and had lost its power over the minds of large classes of the people. The Directory granted these philosophical sectarians the use of ten parish churches in Paris, where they held meetings for religious service; at first on the Decadi, or revolutionary holyday, afterwards on the Sunday. Their system of belief was a pure deism; their service a simple liturgy, with some emblematic mummeries. The attempt to found a new sect was, however, wholly unsuccessful. In 1802 they were forbidden the use of the churches by the consuls, and then ceased to exist.

THEO'RBO. (It. tiorba.) A lute of large dimensions, sometimes called the arch-lute, and formerly used for striking the chords of the thorough bass in accompaniments.

THE'OREM. (Gr. θεωρημα, from θεαομαι, *I observe*.) In Geometry, a truth proposed to be proved; in contradistinction to a *problem*, which proposes something to be done. A theorem wants demonstration; a problem requires solution. In algebra, the term is applied to various formulæ, as the *binomial theorem*, *Taylor's theorem*, and others; for which see the respective terms.

THEO'RICON. In ancient Attic History, the name given to that portion of the revenue of the state which was exclusively reserved for the purpose of theatrical representations. (See *Boeckh's Public Economy of Athens*, i. 289. 299. &c.)

THE'ORY (Gr. θεωρια), in Science, properly expresses a connected arrangement of facts, according to their bearing on some real or hypothetical law. A *hypothesis* has been distinguished from a theory as an assumption which is conceived to afford a *support* to the discovered law. Thus some have imagined that the facts of gravitation are explained on the supposition of a subtle and all-pervading ether. Here it is evident that the *facts*, and therefore the *theory* or connected survey of them, are unaffected by the *supposition* in question.

Theory. The abstract principles of any science or art, considered without reference to practice.

THEO'SOPHISTS. (Gr. Θεος, and σοφια, *wisdom*.) The name commonly given to a sect of philosophers who pretended to derive their knowledge of God and divine matters from direct inspiration. One of the most distinguished of this class in modern times was Jacob Böhme.

THERAPE'UTÆ. (Gr. *worshippers*.) A Jewish sect of the first century after Christ, concerning whom some doubt is entertained whether or not they had embraced Christianity. They are mentioned by Philo Judæus. (See *Burton's Lecture on the Ecclesiastical History of the First Three Centuries*, vol. i. p. 300.)

THERAPEU'TICS. (Gr. θεραπευειν, *to heal*.) A branch of pathology relating to the application of remedies, and the curative treatment of disease.

THERAPHIM. *See* Teraphim.

THERI'ACA. (Gr. θηρ, *a venomous animal*.) A name given in ancient Pharmacy to certain complex remedies supposed to be antidotes to poisons: they were usually in the form of confections. Some of the more celebrated have been transferred to comparatively modern pharmacopœiæ; such as the *Theriaca* of Andromachus; *Theriaca Veneta*; *Confectio Mithridati*, &c.

THERMÆ. (Lat.) In Ancient Architecture. *See* Bath.

THE'RMIDOR. In the French Calendar, the name of the 11th month of the year in the French Republic. It commenced on the 19th of July, and ended on the 17th of August. The name is derived from the Gr. θερμος, *warm*, and was borrowed from the great heat which characterizes that period of the year. It was the month signalized by the overthrow of Robespierre and the Reign of Terror; thence commonly called the Revolution of Thermidor, and those who boasted of having participated in it called themselves Thermidorians.

THERMO-ELECTRICITY. When one part of a metallic bar is heated and another cooled an electric current is generated in its substance, which may be rendered evident and its direction ascertained by the galvanometer. When two metals of different temperatures are brought into contact similar electric currents are generated, the quantity and direction of the electricity varying with the nature of the metals and their respective temperatures. The best apparatus for exhibiting these thermo-electric currents consists of alternate bars of antimony and bismuth soldered together at their ends, so as to form a compound bar or parallelogram, the junctions of which may be alternately heated and cooled: in this case the direction of the current is from the antimony to the bismuth; so that these metals bear the same relation to each other in the thermo-electric series, as the zinc and silver in the simple voltaic circuit. The term *stereo-electric* has also been applied to these currents, implying their production in solid bodies independent of a fluid, and as opposed to the hydro-electric or voltaic current. *See* Voltaic Battery.

THERMO'METER. (Gr. θερμος, *warm*, and μετρον, *measure*.) An instrument for measuring variations of heat or temperature.

The principle upon which thermometers are constructed is the change of volume which takes place in bodies when their temperature undergoes an alteration. Generally speaking, all bodies expand when heated and contract when cooled, and in such a manner that, under

the same circumstances of temperature, they return to the same dimensions; so that the change of volume becomes the exponent of the temperature which produces it. But as it is necessary not merely that expansion and contraction take place, but that they be capable of being conveniently observed and measured, only a small number of bodies are adapted for thermometrical purposes. Solid bodies, for example, undergo so small a change of volume with moderate variations of temperature, that they are in general only used for measuring very high temperatures, as the heat of furnaces, of melting metals, &c. Instruments for such purposes are called pyrometers. (*See* PYROMETER.) The gaseous fluids, on the other hand, are extremely susceptible of the impressions of heat and cold; and as their changes of volume are great even with moderate accessions of heat, they are only adapted for indicating very minute variations, or for forming *differential* thermometers. (*See* DIFFERENTIAL THERMOMETER.) Liquids hold an intermediate place; and, by reason of their moderate but sensible expansion through the ranges of temperature within which observations have to be made for by far the greater number of purposes, are commonly used for the construction of thermometers. Various liquids have been proposed, as oils, ether, spirits of wine, and mercury; but scarcely any other than the two last are now ever used, and mercury by far the most generally.

The properties which render mercury preferable to all other liquids (unless for particular purposes) are these:—1. It supports, before it boils and is reduced to vapour, more heat than any other fluid, excepting certain oils, and endures a greater cold than would congeal most other liquids, excepting certain spirituous liquors. 2. It takes the temperature of the medium in which it is placed more quickly than any other fluid. Count Rumford found that mercury was heated from the freezing to the boiling point of water in 58 seconds, while water took 133 seconds, and air 617 seconds; the heat applied being the same in all the three cases. 3. The variations of its volume within limits which include the temperatures most frequently required to be observed are found to be perfectly regular, and proportional to the variations of temperature. The spirit thermometer is now little used excepting for observations of very low temperatures, or as a self-registering instrument for meteorological observations.

Construction of the Mercurial Thermometer.—In order to render small changes of volume sensible, a glass bulb, having a slender hollow tube attached to it, is filled with mercury, so that expansion or contraction can only take place by the rise or fall of the liquid in the tube. The diameter of the tube may be of any convenient size; but the smaller it is the larger will be the scale of the variations; and capillary tubes are usually employed. It is essential that the diameter of the bore be of a uniform width throughout; a quality which is tested by drawing up into the tube a short column of mercury, and measuring its length at the different parts with a pair of compasses. Not more than a sixth part of the tubes which come from the glass-house are found to be fit for the purpose.

Having selected a tube, the workman begins by blowing a hollow ball A upon one extremity of it, by means of an air-bag of caoutchouc (in order to avoid the introduction of watery vapour by blowing from the mouth). The length which the thermometer is to have is then marked, and above this point the tube is expanded into a second bulb B, rather larger than the first. When the tube has acquired its natural temperature one of the bulbs is warmed, in order to expel the air from it, and the open end of the tube is plunged into distilled and well-boiled mercury. During the cooling the mercury rises into the second bulb B, whence it is made to pass into A by placing this undermost, and expelling the air from it by heat, after which the mercury descends from the effect of cooling. When the bulb A has been completely filled, and also a part of B, the tube is suspended horizontally over a charcoal fire, so as to be equally heated throughout, and the enclosed mercury boiled, in order to expel every remaining particle of air or humidity. The open end is then touched with sealing-wax, and the tube withdrawn from the fire, and placed in an upright position until it is cooled, when the bulb A and the portion of the tube under B will be filled with mercury. A portion of mercury is then expelled by heat, so that the column may stand at the proper height in the tube. The tube is then carefully softened with the blow-pipe, and hermetically sealed under the bulb B, which is thus cut off.

Graduation of the Scale.—The instrument prepared in the manner now described is admirably adapted for rendering evident the expansions and contractions of the enclosed fluid, and it only remains to adapt a scale to it in order to have a complete thermometer. The graduation of the scale is in some measure arbitrary; nevertheless, in order that different thermometers may be comparable with each other, it is necessary that two points at least be taken on the scale corresponding to fixed and determinate temperatures, the distance between which will determine the graduation. The two points which are now universally chosen for this purpose are those which correspond to the temperatures of freezing and boiling water. With respect to the first of these there is no difficulty; it is only necessary to surround the bulb with ice, and to mark on the stem the point at which the mercury stands when the ice begins to melt. The boiling point is not so readily determined. As the temperature at which water boils varies to a small extent with the barometric pressure, it is necessary, in order to have instruments comparable with each other, either that the boiling point on the scale be determined when the barometer stands at a certain height which is arbitrarily assumed for the standard, or else to apply a correction when the actual height of the barometer is above or below the assumed standard. De Luc made a number of experiments on this subject, and gave a formula for the correction, which was adapted to Fahrenheit's scale and English inches by Horsley. (*Phil. Trans.* vol. lxiv.) A committee of the Royal Society, who undertook to investigate the best method of adjusting the fixed points, and whose report is contained in vol. lxvii. of the *Transactions*, laid down a set of rules which have been generally followed by English instrument makers. They recommended the adoption of 29·8 inches for the standard barometric pressure, and gave a table of the corrections for all ordinary pressures above or below this standard. Their table is very nearly represented by the following simple rule, which will be quite sufficient for the guidance of the artist in all ordinary cases:—

Supposing the thermometer placed in an atmosphere of steam immediately over the surface of boiling water, then for every tenth of an inch by which the barometer is above or below 29·8, the correction for the boiling point of the scale of the thermometer is one thousandth part of the interval between the freezing and boiling points. The corrected must be placed lower than the observed boiling point by this quantity when the pressure exceeds 29·8 inches, and higher when the pressure is less than the standard.

Several other minute circumstances must be attended to in the construction of delicate instruments. As the temperature of boiling water is different at the top and near the bottom of the vessel in which it boils, the thermometer should not be plunged into the water itself, but into the vapour which rises above it, in a close vessel with an aperture for the escape of the steam. The vessel should be of metal, because water boils at a different temperature in vessels of different substances, as metal and glass. Distilled water, or clear soft water, should be used; if mixed with saline ingredients, the temperature at which it boils would be affected, and the instrument rendered inaccurate.

The interval between the two fixed points on the stem may be divided into any number of degrees at pleasure, and the graduation continued above and below as far as may be thought requisite: the numeration may also be begun at any point whatever on the scale; but there are only three methods of division so generally adopted as to require particular notice. The first is Fahrenheit's, which is used in this country, in Holland, and North America; the second Reaumer's, which was formerly in general use in France, and is still followed in Spain and some parts of Germany; and the third that of Celsius, or the centigrade scale, now used in France, Germany, and Sweden.

Fahrenheit's Scale.—In this scale the interval between the freezing and boiling points of water is divided into 180 equal parts, or degrees, which number was chosen by Fahrenheit (or probably Röemer), from some theoretical considerations respecting the expansion of mercury; it being computed that the thermometer when plunged into melting snow contained 11,156 parts of mercury, which, at the temperature of boiling water, were expanded into 11,336 parts, being an increase of 180 parts. The zero point of the scale is placed at 32° below the freezing point of water. It has been frequently stated that this point was selected as indicating the temperature of a freezing mixture of snow and salt; but it appears from Boerhaave that it was adopted from a still more precarious supposition, namely, the greatest cold observed in Iceland, which was probably assumed to be the lowest natural temperature. The freezing point is thus marked 32°, and consequently the boiling point at $32 + 180 = 212$. It must be admitted that this scale, though it possesses some advantages in the lowness of the zero point and the smallness of the divisions, is not well adapted to philosophical purposes.

Reaumer's Scale.—Reaumer, in 1730, proposed the adoption of the temperature of melting ice as the zero of the scale, and to divide the distance between this and the boiling point of water into 80°, having observed that between those temperatures spirits of wine (which he used

for the thermometric fluid) expanded from 1000 parts to 1080. This division soon became general in France and other countries, and a great multitude of valuable observations have been recorded in terms of it; but it is now seldom used in works of science.

Centigrade Scale.—In 1742, Celsius, professor at Upsal in Sweden, proposed to divide the space between the freezing and boiling points of water into 100 equal parts, the zero point being placed (as in Reaumer's) at freezing. This division being in harmony with our decimal arithmetic, is better adapted than the two former to scientific purposes. It has been adopted by all the French writers since the Revolution, and is the best known in most parts of the north and middle of Europe.

It has been sometimes objected to this scale (and the objection applies equally to Reaumer's), that on account of the comparatively high point at which the zero is placed, meteorological observations are embarrassed with the algebraic signs of *plus* and *minus*. The inconvenience (if any) is a very trifling one, and is much more than compensated by the facilities for calculation which the scale affords.

Conversion of Degrees of one Scale into Degrees of another. — From the manner in which the three scales are graduated, it is easy to deduce formulæ expressing any temperature given according to one scale in terms of either of the others. The interval which in Fahrenheit's scale is divided into 180 parts is divided into only 100 parts in the centigrade scale, and into 80 in Reaumer's. Hence one degree of Fahrenheit's is equal to 5-9ths of a degree of the centigrade, and to 4-9ths of a degree of Reaumer. But some attention is required on account of the difference of the zero points. For the sake of perspicuity, it is convenient to adapt the expressions to three distinct cases. Let F denote degrees of Fahrenheit's scale, C degrees of the centigrade, and R degrees of Reaumer; then,

Case 1. For all temperatures above the freezing point,

$$F - 32 = \tfrac{9}{5}C = \tfrac{9}{4}R.$$

Case 2. For all temperatures between the freezing point and the zero of Fahrenheit's scale,

$$32 - F = -\tfrac{9}{5}C = -\tfrac{9}{4}R.$$

Case 3. For all temperatures below the zero of Fahrenheit,

$$-32 - F = -\tfrac{9}{5}C = -\tfrac{9}{4}R.$$

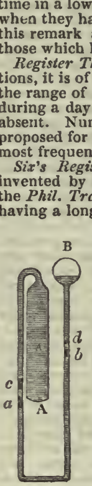
By substituting numbers in these formulæ for F, C, or R, as the case may require, the corresponding values on the other scales is immediately obtained; but if many reductions are required to be made, it is more convenient to have comparative tables, by which the correspondence of the scales is seen at a glance. Such tables are given in most treatises on chemistry.

Theory of the Graduation. — It will be evident from what has now been said that, whatever scale be adopted, the division is founded on the assumed principle that equal increments of heat produce equal expansions. This assumption may be put to the test of experiment by the mixture of fluids at different temperatures. For example, if a pound of water at 212° Fahr. be mixed with another pound of water at 32°, and the requisite precautions be used, then the temperature of the mixture will be 122°, which is the arithmetical mean between the two temperatures; and if the assumed principle be correct, a thermometer plunged into the mixture will stand at 122°. This is found to be the case with the mercurial, but not with the spirit thermometer; and, in general, thermometers formed of different fluids, when exposed to the same temperatures, do not give the same indications throughout the whole extent of the scale. An important question hence arises: what substance ought to be adopted as the standard to which, in comparing observations, all others should be reduced? It is, perhaps, not possible to determine this question with absolute certainty; but the experiments of the French chemists Dulong and Petit on the dilatation of various substances, render it probable that air and the other permanent gases (which all expand equally) afford the most accurate indications of the true variations of temperature. As compared with the air thermometer, the expansion of mercury is proportional to the increase of temperature from — 36° to + 100° of the centigrade scale. From this point to 360° (the boiling point of mercury), mercury expands more rapidly than air, and consequently the mercurial thermometer stands higher than the air thermometer in the same temperature. When the former indicates 200° and 300°, the latter indicates 197° and 292·7° respectively; and it seems to be a general law that all fluids with the same increase of heat expand more rapidly as the temperature approaches their boiling point. The more rapid expansion of the mercury at high temperatures is, however, in some measure corrected by the expansion of the bulb.

Change of the Zero Point. — There is a circumstance connected with the mercurial thermometer which requires to be attended to when very exact determinations of temperature are to be made. Bellani in Italy, and Flaugergues in France, observed that when thermometers which have been constructed for several years are placed in melting ice, the mercury stands in general higher than the zero point of the scale; and this circumstance, which renders the scale inaccurate, has been usually ascribed to the slowness with which the glass of the bulb acquires its permanent arrangement, after having been heated to a high degree in boiling the mercury. Despretz (*Traité de Physique*) observes, that in very nice experiments it is always necessary to verify the zero point; for he found that when thermometers have been kept during a certain time in a low temperature, the zero point rises, but falls when they have been kept in a high temperature: and this remark applies equally to old thermometers and to those which have been recently constructed.

Register Thermometers. — In meteorological observations, it is of great importance to ascertain the limits of the range of the thermometer in a given period of time, during a day or night, for example, while the observer is absent. Numerous contrivances have accordingly been proposed for this purpose, but the two following are those most frequently used.

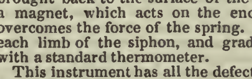
Six's Register Thermometer. — This instrument was invented by Mr. Six of Colchester, and is described in the *Phil. Trans.* vol. lxxii. It is a spirit thermometer, having a long cylindrical bulb A, with a tube bent in the form of a siphon, and terminating in a small cavity B. A part of the tube, from a to b, is filled with mercury; but the bulb A, and the remaining portion of the tube, and a small part of the cavity B, with highly rectified alcohol. The use of the mercury in the middle of the tube is to give motion to two indices, c and d, which consist each of a glass tube in which a small bit of iron wire is enclosed, the ends being capped with enamel. The indices are of such a size that they move freely within the barometric tube, and allow the spirit to pass; but a slender spring is attached to each, which presses against the side of the tube, and is just strong enough to prevent the index from falling down when it has been raised to any point and the mercury recedes. The action of the instrument will be readily apprehended from the figure.



An increase of heat expands the alcohol in the bulb A, depresses the mercury at a, and consequently raises it in the other branch of the siphon at b. The mercury while rising drives the index d before it; and when the temperature diminishes, the mercury recedes from the index, which is retained in its place by the action of the spring, and consequently marks the highest point at which the mercury has stood. In like manner, when the spirit in the bulb A is contracted by a diminution of heat, the mercury is pressed towards A by the elastic force of a portion of air purposely left in the cavity B, and drives before it the index c, which is prevented from falling back by the spring, and consequently remains at the highest point at which the mercury has stood in that branch of the siphon. When the observation has been made, the indices are brought back to the surface of the mercury by means of a magnet, which acts on the enclosed iron wire and overcomes the force of the spring. A scale is applied to each limb of the siphon, and graduated by comparison with a standard thermometer.

This instrument has all the defects which belong to the spirit thermometer, and the indications are besides in some degree deranged by the expansion and contraction of the enclosed column of mercury; probably, also, by the friction of the indices. Nevertheless, it is the best instrument we possess for determining the temperature of the sea at great depths.

Rutherford's Thermometer. — Another register thermometer, simpler in its construction, and less expensive than the former, and consequently more generally used, is the *day and night thermometer* proposed by Dr. Rutherford in the *Edinburgh Transactions*, vol. iii. It consists simply of two thermometers; a mercurial thermometer A, and a spirit thermometer B, attached horizontally to the same frame, and each provided with its own scale.



The index of A is a bit of steel, which is pushed before the mercury; but, in consequence of its horizontal position, remains in its place when the mercury recedes, and consequently indicates the highest degree of the scale to which the mercury has risen. The index of B is of glass, with a small knob at each end. This lies in the spirit, which freely passes it when the thermometer rises; but when the spirit recedes, the cohesive attraction between the fluid and the glass overcomes the friction arising from the weight of the index, and the index is consequently carried back with the spirit towards the bulb. As there is no force to move it in the opposite direction, it remains

at the point nearest the bulb to which it has been brought, and thus indicates the lowest temperature which has occurred. By inclining the instrument, the indices are brought to the surfaces of their respective fluids, and prepared for a new observation.

History of the Thermometer. — The invention of the thermometer dates from about the beginning of the 17th century, but it is not certainly known when or by whom it was first brought into use. By the Dutch authors it is ascribed to Cornelius Drebbel, a peasant of Alkmaar, and by the Italians to Sanctorio. Libri (*Annales de Chimie*, Dec. 1830) maintains, on the authority of Castelli and Viviani, that the instrument was invented by Galileo prior to 1597. The thermometer of Drebbel and Sanctorio was a very imperfect instrument. It consisted of a glass tube, having a ball blown on one of its extremities, and the other end left open. A portion of air being expelled from the ball by heat, the open end was plunged into a cup containing any liquid, when, on the cooling of the ball, the liquid would rise in the tube, and the variations of its height indicate the increase or diminution of the temperature of the bulb. The instrument had no scale, and was therefore merely an indicator of changes of temperature, or a *thermoscope;* and it was defective even in this respect, inasmuch as it is affected not merely by heat and cold, but by the varying pressure of the atmosphere. The Florentine academicians first excluded the influence of atmospheric pressure by using a spirit instead of an air thermometer, and hermetically sealing the tube. The next step in improvement was the adoption of a fixed point in the scale. Boyle proposed the thawing oil of aniseeds, which he preferred to thawing ice, because it could be readily obtained at all times of the year. Halley proposed the uniform temperature of a deep pit, which he probably considered would be the mean temperature of the earth; but he also suggested the point at which spirit boils, as well as the boiling point of water. Newton appears to have been the first who saw the advantage of having two fixed points in the scale; and in order that the instrument might be applicable to a wider range of temperature, he used linseed oil as the thermometric fluid. This, however, has not been found to answer, on account of its sluggish motion and adhesion to the sides of the tube. The astronomer Röemer proposed the substitution of mercury, which is now generally used; and the knowledge of the fluctuation of the boiling point of water, owing to atmospheric pressure, is due to Fahrenheit, about 1724. Since that time no improvement has been made in the principle of the instrument.

For further information on this subject, the reader may be referred to Deluc, *Récherches sur les Modifications de l'Atmosphère*, Genève, 1772; Biot, *Traité de Physique*, tome I.; *Nicholson's Chemistry; Library of Useful Knowledge*, "Thermometer and Pyrometer;" Muncke, in *Gehler's Physicalisches Worterbuch.*

THE'RMOSCOPE. (Gr. θερμος, and σκοπεω, *I view.*) An instrument by which changes of temperature are indicated. The modification of the air thermometer, called by Leslie a *differential thermometer*, was claimed by Count Rumford as one of his own inventions, under the name of *thermoscope*. *See* Thermometer.

THE'RMOSTAT, or HEAT GOVERNOR. (Gr. θερμος, and ιστημι, *I stand.*) A self-acting physical apparatus for regulating temperature. A thermostat, the principle of which depends on the unequal expansion of metals by heat, was proposed by Dr. Ure for regulating the safety valves of steam engines with more certainty than the common expedients. (See *Proceedings of the Royal Society* for 1830 and 1831, p. 67.)

THE'SIS (Gr. θεσις, *a position*), in a general sense, is applied to any proposition, affirmative or negative, which is laid down or advanced to be supported by argument; but it is more particularly applied to those questions which are propounded in most of the Scotch and Continental universities to the students previously to their obtaining a degree.

Thesis. In Music, the depression of the hand in marking or beating time.

THESMOPHO'RIA. (Gr. θεσμοφορια.) A festival in honour of Ceres, surnamed *the lawgiver* (θεσμοφορος), because she first taught mankind the use of laws. It was celebrated by many cities of Greece, but with most observation and ceremony by the Athenians. The worshippers were free-born women, whose husbands defrayed the expenses of the solemnity, assisted by a priest and band of virgins. The women were clothed in white garments as emblematic of purity, and were strictly enjoined to preserve the strictest chastity some days previous to and during the whole of the festival, which lasted five days.

THESMO'THETÆ. The six inferior archons at Athens, who presided at the election of the lower magistrates, received criminal informations in various matters, decided civil causes on arbitration, took the votes at elections, and performed a variety of other offices. (See *Mém. de l'Acad. des Inscr.* vol. xxxix.)

THESPIAN ART. That of tragedy or tragic acting is so termed; from Thespis, an Athenian, who lived in the first half of the 6th century before Christ, and introduced the first rudiments of a tragic stage. *See* Drama.

THE'TA. (Gr. θ.) The unlucky letter of the Greek alphabet; so called because the judges in balloting on the prisoner used it to intimate their desire for his condemnation, from its being the first letter of θανατος, *death.* Hence the verse —

O multum ante alias infelix litera Theta.

THE'TES. (Gr. θῆτες.) In ancient Attica, originally bondsmen, who were excluded from holding the chief magistracies of the state. Under the constitution of Solon they formed the lowest class of free citizens who contributed nothing to the support of the state; but in the course of the subsequent innovations which brought the state to a complete democracy all the restrictions on the thetes were removed. They served generally as light-armed soldiers, but sometimes also as regular infantry upon an emergency. (See Boeckh, *Public Economy of Athens*, ii. 258.)

THE'TIS. In Greek Mythology, one of the Nereids, daughter of Nereus and Doris: was wedded under the auspices of the gods, among whom jealousy had arisen by reason of her beauty, to Peleus, king of Thessaly. By him she became the mother of Achilles. According to the ancient cosmogonies, Thetis was an emblem of the element of water. She is best known by the verses of Homer. Her marriage with Peleus is the subject of some exquisite lines by Catullus.

THE'URGY. (Gr. Θεος, *God*, and εργον, *work.*) A name given by the ancients to their imaginary art of magic, which was, like the whole magic of the middle ages, the result of an intercourse with and influence over spiritual beings of the more exalted class, — gods, dæmons, &c. In the modern art magic, it was that species of magic which operated by celestial means: opposed to natural magic, which was effected by knowledge of the occult powers of nature; and necromancy, or magic effected by the aid of evil spirits. (See *Mém. de l'Acad. des Inscr.* vol. xxvii.)

THI'CKET. Trees or shrubs crowded together in such a manner as to form a mass not easily penetrated by men or cattle.

THI'NNING. Reducing the number of plants or trees which have been sown or planted, with a view to those which remain attaining a more mature growth. Natural woods are also thinned for the same purpose. The operation ought to be commenced as soon as the extreme leaves or branches are nearly touching one another, and continue till the plants have attained their full growth, or the required dimensions or age. On no account should the branches of any one tree in a plantation be allowed to touch the branches of any other tree; because in that case the foliage is deprived of its due proportion of sun, air, and rain, and the tree is drawn up in height at the expense of its thickness and vigour to resist storms; while the timber or fruit produced will be diminished both in quantity and quality. There is no department of planting less understood than the subject of sheltering young plantations; and it may with truth be said that in by far the greater number of cases nothing is ultimately gained by drawing up trees in masses, and afterwards thinning them out. The trees left being unprepared both by their bark and roots for the new atmospherical circumstances in which they are placed, receive a greater check than if they had been originally planted so thin as at no period of their growth to touch one another.

THIN OUT. Geologists say that strata *thin out* when they gradually diminish in thickness and disappear.

THIRD. In Music, an imperfect concord, containing two degrees or intervals, and three terms or sounds.

THIRD COAT. In Architecture, the stucco when painting is to be used, or the setting for the reception of paper.

THIRD ORDER. In Ecclesiastical History, most of the chief religious orders (Premonstrants, Carmelites, Franciscans, Augustines, &c.) have or had bodies of secular associates, not bound by vows, but conforming to a certain extent to the general designs of the order; a custom thought to have originated about A. D. 1476, when Sixtus IV. gave permission to the Carmelites to attach such persons to their body. In course of time the third order contained a mixture of secular and religious persons.

THIRST. (Germ. durst.) The sensation of a desire to drink, consisting in a sense of dryness and heat of the mouth, sometimes extending along the œsophagus to the stomach: the posterior fauces become red, and the usual mucous secretion thick and viscid, as also the saliva. A vague inquietude, troubled mind, and quick pulse ensue; and if not relieved, respiration becomes laborious, and the mouth is opened wide to admit the cool air. Some people soon suffer from thirst, and are in the habit of drinking to an excessive extent; while others hardly ever experience its sensation, and scarcely require to drink the diluting liquids or water. Thirst is a common symp-

tom of febrile and other diseases, and is most effectively relieved in such cases by mild acid and mucilaginous drinks; milk and emulsions are, however, sometimes more efficient and agreeable. Excessive exercise or perspiration are common causes of thirst, in which case the sensation seems merely to announce the deficiency of water in the system. Habitual thirst is often acquired by indulgence in drinking, especially among labourers and others who take excessive quantities of beer, and who at length can scarcely exist without unnecessary and prejudicial quantities of that or similar beverages. The thirst induced by excessive exercise in warm weather is in ordinary cases most effectually relieved by milk and water, or warm tea. In these cases indulgence in beer, cider, wine, or spirits and water, invariably induces febrile reaction, and should therefore be generally avoided.

THIRTY YEARS' WAR. In History, properly a series of wars carried on between the Protestant and Roman Catholic leagues in Germany, in the first half of the 17th century. The house of Austria was throughout at the head of the latter party. The Protestant princes of Germany were assisted by various foreign powers; in the earlier part of the war by Denmark and Sweden, and afterwards by France. It is considered to have commenced with the insurrection of the Bohemians in 1618, and ended with the peace of Westphalia in 1648. The celebrated history (incomplete) of this war, by Schiller, is rather a spirited historical essay than an accurate narrative.

THISTLE, or SAINT ANDREW. A Scottish order of knighthood, said to be of great antiquity, but revived by James V. in 1540; again by James II. of England, VII. of Scotland, in 1687; and a third time in 1703, by Queen Anne, who increased the number of knights to twelve, and placed the order on a permanent footing. The thistle as is well-known is the national emblem of Scotland; and the national motto is very appropriate, being "Nemo me impune lacesset," *nobody shall provoke me with impunity*. This is also the motto of the order of the thistle.

THMEI. The Egyptian goddess of justice, or of truth. Her figure is frequently represented in Egyptian sculptures in the hands of the kings. The Hebrew Thummim (the well-known and mysterious Urim and Thummim, Exod. xxxix. 8. 10.) is the plural or dual of the same word. (*Wilkinson's Manners and Customs of the Ancient Egyptians*, vol. v. p. 58.)

THO'LUS. (Gr. θολος.) In Architecture, a building of a circular form, but used by Vitruvius for expressing the roof of a circular building. The term was also employed to denote the laconicum of a bath, which was circular in form.

THOMÆANS, or THOMITES. In Ecclesiastical History, a name given in Europe to the ancient church of Christians established on the Malabar coast of India, and thought to have been originally founded by St. Thomas; although whether this was the apostle of that name is doubtful. The language used by them in their sacred rites, when they were first discovered by Europeans, was the Chaldee or Syriac. The Portuguese have effected a partial conversion of them to Romanism.

THO'MISTS. The followers of Thomas Aquinas, the Angelic Doctor, one of the most distinguished of the schoolmen of the 13th century. They differed from the rival sect of Scotists chiefly in the milder form under which they adopted the doctrines of realism. The Scotists regarded the universal as objectively and independently real; the Thomists sought rather to ground the objective in a spiritual or rational principle, in some degree approximating to the Platonic doctrine of ideas. The Thomists continued as a sect to the commencement of the 17th century, and numbered several eminent men in their ranks, among whom may be mentioned Algidius of Colonna and Francis Suarez.

THOMSONITE. (So called from the discoverer.) A variety of zeolite from Dumbarton: it generally occurs in radiated masses of small prismatic crystals.

THOR. In Scandinavian Mythology, the son of Odin and Freya, and the divinity who presided over all mischievous spirits that inhabited the elements. His power is represented as irresistible. Many of his deeds are preserved in the *Edda* (which see); but it is probable that the worship of this divinity under the name of Donan, or god of thunder, spread also into Germany, where traces of him are still to be found in numerous local appellations, as Donnersberg, Thorstein, &c. As the worship of this god extended, nothing was more likely than that the Germans should confound him with the Jupiter of the Romans, who were then invading their country; and hence in Germany the day sacred to Jupiter was denominated Donnerstag, while the Scandinavian equivalent of the same deity has been retained by the English in Thursday (Thor's day).

THORA'CIC DUCT. The great trunk which conveys the contents of the lacteals and absorbents into the blood. In the human body it is about the diameter of a crow-quill, and lies upon the dorsal vertebræ between the aorta and azygos vein, extending from the posterior opening of the diaphragm, in a somewhat serpentine course, to the angle formed by the union of the left subclavian and jugular veins, into which it pours its contents. *See* CHYLE and LYMPH.

THORA'CICS, *Thoracici*. (Gr. θωραξ, *the chest*.) The name given by Linnæus to those fishes which have the ventral fins placed beneath the pectorals.

THO'RAX. (Gr. θωραξ, *a shield*.) The second segment of insects is so called by Latreille and Andouin; the term is restricted to the upper surface of the trunk by Linné and Fabricius. In Arachnidans the thorax and head are confluent, and form but one segment, which is termed the cephalothorax. As a cavity appropriated to the reception of the circulating and respiratory organs, the thorax is only distinct in Mammals.

THORAX. The chest; the part of the body between the neck and the abdomen. It contains the heart and lungs, the œsophagus, the thymus gland, the thoracic duct, part of the aorta and vena cava, the vena azygos, the eighth pair of nerves, and a part of the great intercostal nerve.

THORAX. In Grecian Antiquities, a piece of defensive armour consisting of two parts, one defending the back, and the other the belly; called *lorica* by the Romans. The more ancient were made of padded linen; but they were also made of leather, brass, iron, and other metals.

THORI'NA. (From Thor, the Scandinavian deity.) An earthy substance discovered, in 1828, by Berzelius in a rare Norwegian mineral called *thorite*, which is a hydrated silicate of thorina. Like the other earths, thorina is the oxide of a heavy grey metal, which has been termed *thorium*, and which is not acted upon by water; but when heated in the air it burns with great brilliancy into a white oxide. Thorina obtained in this way is white, infusible, and very heavy, its specific gravity being 9·4. It is insoluble in all acids except sulphuric, and in that with difficulty. Its equivalent is about 68. Thorina is distinguished from alumina and glucina by its insolubility in caustic potash, and from zirconia by being precipitated by ferrocyanuret of potassium.

THO'RN APPLE. *See* STRAMMONY AND DATURIA.

THO'RNBACK. The name of a species of ray (*Raia clavata*, Linn.), distinguished by the short and strong recurved spines, rising from a broad osseous tubercular base, which are scattered over the back and tail. Two of these broad-based spines occupy the central ridge of the nose.

THOROUGH BASS. *See* BASS.

THOTH, THOUTH, TAOUT. An Egyptian divinity, considered by the Greeks as identical with Mercury. His hieroglyphic represents the beginning of the astronomical year. He was regarded as the inventor of writing and Egyptian philosophy; and is hence paralleled with Mercury by Cicero. He is represented as a human figure with the head of a lamb or ibis. (Plato, *Phædrus;* Plutarch, *De Is. et Osir.;* Wilkinson, *Ancient Egyptians*, vol. v.) Bryant says the same with Θεος (*Mythol.* i. 13.)

THOUSAND AND ONE NIGHTS; more commonly called among ourselves the *Arabian Nights' Entertainments*, from the title adopted in our first translation from Galland's version. A well-known collection of oriental tales, which has acquired in the west a popularity never attained by any other eastern composition. The history of the work has been the subject of much investigation, especially by De Sacy, Von Hammer, and our last learned translator Mr. Lane, from whom we borrow most of this article. It is the opinion of Mr. Lane that the work, in its present form, is the composition of a single author living in Egypt; and that it was most probably "not commenced earlier than the last quarter of the 15th century of our era, and completed before the termination of the first quarter of the next century, soon after the conquest of Egypt by the Osmanlee Turks in 1517." But the origin of the tales is a much more difficult subject of inquiry. It seems to be now established (from the discoveries of De Sacy and Von Hammer) that there was an ancient Persian collection of stories, known by the name of the *Hezar Afzáneh* (the "Thousand Fanciful Tales"), of unknown antiquity, but certainly older than the 9th century of our era; that the framework of this collection was the same with that of the modern, namely, the story of the cruel king Shakryar and his ingenious queen Chehrazád; and that this was very early translated into Arabic by the name of the *Thousand Nights*. But Mr. Lane differs from these learned orientalists in still believing that the early work was only a model; that the greater proportion of the modern tales are really Arabian, especially all those founded on the supposed adventures of the Khalif Haroun and his queen Zobeyde, a few only being distinctly of Persian or Indian original; *e.g.* the *Magic Horse*, the *Damsel and the Seven Wezeers*. The difference seems to reduce itself to this, whether the present work is the last of several successive editions of the old *One Thousand Nights*, or has pretensions to be considered as a new construction on an old groundwork; the latter being Mr. Lane's opinion. (See De

Sacy's Dissertation, prefixed to a late edition of Galland's version; Von Hammer's preface to that of Trébutien; Mr. Lane's Preface, and "Review" at the conclusion of his third volume; the *Athenæum*, No. 622.)

But whatever the history of the work, many of the main features of the stories are of primeval antiquity, and form, in fact, part of the popular literature of all countries. The original Persian or Arab writers were connected by habits of travelling and merchandise through India with the far East, and through Greece with the extreme West; and the superstitions, anecdotes, and pregnant sayings of all times and ages, repeated in various forms to the tired listeners of the caravan at its evening's halt, have contributed to enrich this singular collection. The *Adventures of Sindbad* have been curiously illustrated with antiquarian learning by Mr. Hole, and form one of the most singular examples of the ubiquity of good stories.

It appears that the learned Arabs hold the *Thousand and One Nights* in small esteem, as an incorrect and unclassical composition; but it is a great mistake (a very natural one for distinguished orientalists, like Mr. Lane, to fall into unconsciously) to imagine that their great charm to the people of the West consists in their faithful representation of Asiatic manners. A far greater attraction lies in the fancy which dictated the narratives — a quality belonging to all times and places. And hence it is that we are convinced Mr. Lane is wrong in his low appreciation of Galland's version. That it is very incorrect in point of costume is doubtless true; but the peculiar genius of Galland led him to detect the poetical fancy, the humour, the oddity, the picturesqueness of the composition, under the cumbrous prolixity of Arab story-telling, and to bring it out in a manner by no means strictly faithful, but sufficiently so to give an oriental quaintness to his work, without the languor of the original, — an odd but agreeable mixture of Arab simplicity with the artificial naïveté of polished France. We believe that while the versions of Mr. Lane and other learned men will always be consulted with interest, that of Galland will still be the cherished companion of all ages, but especially of youth. The numerous European imitations of the *Thousand and One Nights* are well known, and may for the most part be characterized as very unsuccessful: perhaps the best is the French *Additional Arabian Nights*, containing the history of Mangraby the Magician, &c.

THRA'NITE. The uppermost (or, according to some arrangements of the classical galley, the foremost) of the three classes of rowers in an Athenian trireme; the middle being called the zeugitæ, the lowest thalamitæ. *See* GALLEY, TRIREME.

THRA'SHING. Separating grain or seeds from the straw or haum by means of a flail or thrashing machine, or by treading with cattle. The latter was the mode employed in the ages of antiquity; and it is still practised in the south of Europe, and in Persia and India: The Romans employed oxen for this purpose; sometimes alone, and sometimes with the addition of a kind of roller studded with iron knots, which they dragged over the corn, and which was spread on a circular floor, the driver standing in the centre, and guiding the oxen around him by means of reins. It was customary to allow the oxen occasionally to breathe and take a bite of the corn, agreeably to the scripture precept. A kind of flail or rod was also sometimes used by the Romans, and is doubtless the origin of the present implement of that name. In colder and moister climates, such as that of Britain, where a floor sufficiently hard for threshing out corn could not be maintained in the open air, threshing appears to have been always performed under cover, and with the flail, till the latter end of the 18th century, when thrashing machines were introduced.

THRA'SHING MACHINE. A machine for separating corn or other seeds from the straw or haum; and either impelled by horse or cattle, wind, water, or steam. The modern thrashing machine was invented in Scotland about the year 1758 by a farmer in the parish of Dumblaine, Perthshire, and afterwards brought to nearly its present state of perfection by Mr. Meikle, a millwright of Haddingtonshire, about the year 1786. Meikle's thrashing machine consists of a cylinder furnished with beaters fixed on its circumference, to which the corn being presented by rollers the ears are beat in pieces; and while the grain drops through a grating into a winnowing machine the straw is carried forward, and delivered by itself ready to be made up into bundles. Some thrashing machines only beat out the corn, and separate it from the straw; while others beat it out, winnow it, and sift it. One of the most complete thrashing machines in Britain is that at Winstay, in Denbighshire, which not only thrashes and winnows, but measures the corn in bushels, and transports it to the granary in a fit state for being carried to market. (See *Encyc. of Agr.* p. 1311.)

The employment of thrashing machines relieves the labourers from the severest drudgery incident to agriculture; they enable the work to be done at the time there is a demand for corn; and, by doing it better, or separating the corn (particularly wheat) more completely from the straw, they add both to the wealth of the farmer and the produce of the country; enabling the former to employ, and the latter to feed, more labourers. This latter is, indeed, a most important consideration. It is calculated, by the best informed agriculturists, that 5 per cent., or one twentieth part, more produce is afforded by a crop thrashed by machinery than by the old method; and, estimating the total produce of the corn crops of Great Britain and Ireland at 50,000,000 quarters, we should, on this hypothesis, have an additional annual supply of no less than 2,500,000 quarters, were thrashing machines universally substituted for flails! So great an increase of produce in the hands of the farmers would obviously enable them to employ far more labourers than would be superseded by the use of the machine. (*Brown on Rural Affairs*, vol. i. p. 332.)

As we remarked above, thrashing machines may be driven either by horse, water, or steam power; but in all the great farms in the Lothians in Scotland, and in some parts of England, all other methods have merged in the last.

THREE-COAT WORK. In Architecture, plastering which consists of pricking-up or roughing-in, floating, and a finishing coat.

THRE'NODY. (Gr. θρῆνος, *a dirge*; ᾠδή, *song*.) A short species of occasional poem, composed on the occasion of the funeral of some distinguished personage. *See* EPICEDIUM.

THRO'MBUS. A small tumour, which sometimes ensues in consequence of the escape of blood into the cellular membrane in the operation of bleeding.

THRONE. (Gr. θρονος.) In Architecture, a chair of state raised above the level of the floor whereon it stands, usually richly ornamented and covered with a canopy.

THRUSH. In Medicine. This disease consists in small white ulcers upon the tongue, palate, and gums, and is common in infants who are ill-fed or brought up by hand. It is apt to extend through the whole course of the mucous membrane lining the alimentary canal, exciting fetid eructations and flatulency, with a troublesome diarrhœa, and sometimes proves fatal. The treatment consists in giving a gentle emetic of ipecacuanha, and keeping the bowels clear and open with castor oil, or rhubarb and magnesia. The strictest attention should be paid to the diet, which should consist of milk and light farinaceous food.

THRUSH. In Ornithology, one of the largest and most melodious of our native song birds; the type of the genus *Turdus*, Linnæus. It is not migratory, but is supposed to quit the more northern parts of England in winter for the southern provinces. It makes its nest in March; lays four or five blue eggs, spotted with black at the larger end. It feeds on berries, insects, and shell-snails; and often selects a particular kind of stone against which it breaks the shell of the snail, and near which a great quantity of fragments of the shells may be found.

THRUST. (Lat. trudo, *I push*.) In Architecture, the horizontal force of an arch, by which it acts against the piers from which it springs. Also a similar action of rafters or of a beam against the walls which bear them.

THUG. (From the Hindee verb thugna, *to deceive*.) A member of a singular association of robbers and murderers, which has excited of late years much attention in India. It appears that the existence of the system of *thuggee*, as it is called, was hardly known before the year 1810, and that no combined measures were taken to put a stop to it until about 1830. Since that time it has been fully detected, and greatly checked, chiefly through the admission of approvers from all the gangs. Capt. Meadows Taylor informs us that, between 1831 and 1837, 3266 Thugs were brought to justice, of whom 412 were hanged, 1059 transported, and 483 turned approvers. Still it is by no means supposed to be extinct. Its origin is unknown; and both Mohammedans and Hindoos belong to the society indifferently, although its tutelary goddess, Bhowanee, belongs to the latter faith. The Thugs are peculiarly superstitious in their observances. They are directed, in all their proceedings, by auguries supposed to be vouchsafed by their goddess; and particular classes are altogether exempt from their attacks: among whom are dancing girls, minstrels, sikhs, some religious mendicants, tailors, oilmen, blacksmiths, carpenters. It is stated also that they seldom destroy women unless for their own safety; and they have very seldom ventured to attack Englishmen. They usually move in large gangs, and attach themselves to travelling parties; they will journey with them for days, to find at last an opportunity to master them. When all is ready, one division of the murderers strangles the victim, while another body prepares their graves; and by means of this division of labour the fearful work is accomplished with wonderful celerity. It appears that numbers of Thugs resided together in villages, when they were prohibited by the landowners, sometimes by rajahs, to whom they paid tribute. The common

destruction of life occasioned by them may be conjectured by the fact that one Thug, admitted an approver at Saugor, confessed to Col. Taylor, who does not seem to suspect him of exaggeration, that he had been concerned in the murder of 719 persons! The existence of so strange and monstrous a system can only be explained by the condition of India; the extreme timidity and apathy of its inhabitants, and their division into castes; the number of small native governments; the habit of dwelling in villages, divided by extensive uninhabited tracts; the quantity of travelling that takes place in that commercial country, without navigable rivers or secure conveyances; and the murderous spirit of Hindoo fanaticism. (See *Col. Sleeman's Ramasccana, Vocabulary of the Thugs*, and an article on it in the *Ed. Rev.* vol. lxiv.; and *Col. Meadows Taylor's Adventures of a Thug*, 2 vols. Lond. 1839, from the Introduction to which these details are chiefly taken.)

THU'LE. The name given by the ancients to the most northern part of the habitable world; but it is almost impossible to say, from the variety of opinions entertained respecting it, whether any definite country was meant by this appellation. Some have thought that Norway, but most geographers are of opinion that Iceland, was the place alluded to. But be this as it may, it is long since the prophecy of Seneca in the following lines has been fulfilled:—

> —— Venient annis
> Sæcula seris, quibus Oceanus
> Vincula rerum laxet, et ingens
> Pateat tellus, Typhisque novos
> Deteget Orbes, nec sit terris
> Ultima Thule.

THULITE. A rare mineral of a peach-blossom colour from Norway. Its composition has not been ascertained.

THU'MERSTONE. A variety of axinite from Thum, in Saxony.

THUMMIM. *See* URIM.

THU'NDER. (Germ. donner, Lat. tonitru.) The noise produced by an explosion of lightning, or by the passage of lightning through the air from one cloud to another, or from a cloud to the ground.

The character of the sound of thunder varies with the force and the distance of the explosion, the situation of the observer, the nature of the surrounding country; and it is probably influenced also by the relative situations of the clouds.

When lightning strikes an object near us on the earth, it produces a noise resembling that of a violent crash, which is not repeated or prolonged by reflection. When the explosion is more distant, a rumbling, irregular, and recurring noise is heard, which gradually dies away in the distance, like the prolonged echo of the sound of ordnance discharged in a mountainous district.

Thunder frequently commences with an astounding rattle, which is probably occasioned by a series of explosions or discharges of electric matter in rapid succession from a highly charged thunder cloud.

We have a familiar example of this *species* of noise in the cracking which accompanies the sparks discharged from the conductor of a well-supplied electrical machine towards any adjacent conducting body; the loudness of the snaps, as well as their frequency, increasing with the electric intensity. And when we consider how trifling a portion of electric matter can be put in action by the most powerful means of artificial excitement, compared with the quantity stored up in a full-charged thunder cloud, the discrepancy between the appalling crash of the one and the insignificant snap of the other will not appear surprising, though both originate in the same cause. This cause is the vibration of the air agitated by the passage of the electric discharge with a greater or less degree of intensity; and two explanations may be given of the manner in which the vibration is produced.

The first explanation proceeds on the supposition that the electric fluid opens a passage to itself through air or other matter, in the manner of a projectile, and that the sound is caused by the rush of the air into the vacuum produced by the instantaneous passage of the fluid. But it is objected that if this explanation holds good, the passage of a cannon ball through the air ought to produce a similar sound; whereas it only produces a sort of whistling noise, which even the most timid have never thought of comparing with thunder. Another still stronger objection is, that all the experiments seem to indicate that the electric fluid is not transferred from point to point like a projectile of ponderable matter, but is conveyed along by the vibration of an elastic medium, as sound is conveyed through the atmosphere.

The second explanation, which appears more in harmony with all the facts, is founded on this vibratory propagation of the electric fluid. When the electric spark passes between two points, there is a decomposition and recomposition of electricity in all the media in which it appears, and consequently a vibration more or less violent is produced, which vibration gives rise to the sound. On this hypothesis, the continued roll is the effect of the comparatively slow propagation of sound through the air. For the sake of illustration, suppose a flash of lightning of 11250 feet in length, or that the spark is instantaneously seen from one end to the other of this line. At the same instant the flash is visible the vibration is communicated to the atmosphere through the whole extent of the line. Now suppose an observer placed in the direction of the line of the flash, and at the distance of 1125 feet from one end; then, since sound travels at the rate of about 1125 feet in a second (*see* SOUND), one second will elapse after the flash has been seen before any sound is heard. When the sound begins, the vibration communicated to the nearest stratum of air has reached his ear; and since we have supposed the line of disturbance to be 11250 in length, the vibrations of the more distant strata will continue to reach his ear in succession during the space of ten seconds. Hence the length of the flash determines the duration of the sound; and it follows that the same flash will give rise to a sound of greater or less duration, according to the position of the observer with respect to its direction. Thus, in the above instance, suppose a second observer to be placed under the line, and towards its middle, he would only hear the sound during half the time it was heard by the first observer; and if we suppose the line to be circular, and the observer to be placed near its centre, the sound would arrive from every point at the same instant in a violent crash.

Although the vibratory motion is communicated to all the strata of air along the whole length of the flash, they will not all receive the same impulsion, unless they are all at the same temperature and in the same hygrometric state, which can rarely happen. Hence the first impression of the sound is not always the most intense, although it proceeds from the nearest point.

During a thunder storm shelter should not be taken under trees or hedges, which are likely to act as conductors; but, at the same time, a person is safer when at the distance of about 30 or 40 feet from such objects than on an open plain. Water should also be carefully avoided, because it is a good conductor, and the height of a man above it may determine the course of the lightning. In a house, the safest position is near the middle of a room; and the security may be increased by sitting on a feather bed or hair mattrass, or thick woollen rug, all of which are bad conductors. It is injudicious to take refuge in a cellar, because the discharge is often from the earth to a cloud, and buildings frequently sustain the greatest injury in the basement stories. It is dangerous to be near the fireplace, because the chimney is the part most likely to be struck, and the soot is a powerful conductor. Gilt furniture, bell wires, and all large metallic surfaces, are to be avoided for the same reason. (See on this subject a highly interesting *Notice sur le Tonnerre*, by Arago, in the *Annuaire*, for 1838, translated in the *Edinburgh Philosophical Journal*.

THURLS. Short communications between the adits in mines.

THU'RSDAY. The fifth day of the week, which derives its name from Thor, the old Scandinavian god of thunder; equivalent to the Jupiter of the ancients, to whom this day was also consecrated.

THUS. (Gr. *θυω, I sacrifice*; from its use in sacrifices.) The resin of the spruce fir. The term frankincense is also applied to it, and to *olibanum*, which is the gum resin of the *Juniperus lycia*.

THWART. In Naval Affairs, used for athwart or across; also a bench for rowers.

THYMELA'CEÆ. (Thymelea, one of the genera.) A natural order of shrubby Exogens, having a calyx only, and no corolla, although the flowers of many are coloured very gaily. *Daphnes*, valued for their fragrance, *Mezereung*, the various species of the Australian genus *Pimelea*, and the *Gnidias* and *Struthiolas* of the Cape of Good Hope, are favourite subjects of cultivation. One feature of the order is the causticity of the bark, which acts upon the skin as a vesicatory, and causes excessive pain in the mouth if chewed. The berries of *Daphne laureola* (the spurge laurel) are poisonous to all animals except birds.

THY'MUS GLAND. A gland situated under the upper part of the sternum, in the anterior mediastinum. Its excretory duct has not been detected, nor is its use known. It is of great comparative size in the fœtus.

THY'NNUS. (Gr. *θυννος, a tunny*.) A genus of Scomberoid fishes, of which the highly valuable fish the tunny (*Thynnus vulgaris*, Cuv.) is the type. The form of the body in this genus of fishes is like that of the mackerel, but is less compressed; the first dorsal fin extends nearly to the second; the second dorsal and the anal fins are divided into numerous finlets; the sides of the tail are decidedly carinated; there is a single row of small pointed teeth in each jaw. The tunny is remarkable among fishes for its high temperature, its perfect respiratory organs, the quantity of nerves supplying the gills, and the general abundance of rich red blood throughout the body. It is the object of the most important fisheries in the Mediterranean sea, and when salted and dried serves the inhabitants of most Catholic countries with the fast

days' meat. The *bonito* (*Thynnus pelamys*) is a species of the present genus of fishes.

THY'RIS. (Gr. θυρις, *a window.*) A genus of butterflies.

THY'ROID. (Gr. θυρεος, *a shield*, and ειδος, *form.*) The thyroid or scutiform cartilage is placed perpendicular to the cricoid cartilage of the larynx, of which it forms the upper and anterior part. In men it is harder and more prominent than in women; it is sometimes called *Adam's apple.* The thyroid gland is situated upon the thyroid and cricoid cartilages of the trachea; its duct has not been seen, and its use is unknown. When enlarged it forms the bronchocele.

THY'RSUS. (Gr. θυρσος.) A staff entwined with ivy, which formed part of the accoutrement of a Bacchanal, or performer in the orgies of Bacchus.

THYRSUS. In Botany, a form of inflorescence, consisting of a compact panicle, the lower branches of which are shorter than those of the middle; in other words, it is composed of a primary axis developing secondary axes from its sides, which in their turn develop tertiary axes, the upper and lower branches being shorter than those of the middle, as in the common lilac.

THY'SANURANS, *Thysanura.* (Gr. θυσανοι, *fringes*, ουρα, *a tail.*) The name of an order of Ametabolian insects, comprehending those in which the abdomen is terminated by filaments, or by a forked tail adapted for leaping.

TIA'RA. The well-known ornament with which the ancient Persians adorned their heads. It was in the form of a tower, and adorned with peacocks' feathers. Xenophon says that it was sometimes encompassed with the diadem, at least in ceremonies, and had frequently the figure of a half moon embroidered upon it. This was the name also originally given to the mitre of the popes. It was nothing more than a round high cap, at first single instead of double, like that of the other bishops. Nicholas the First added the first gold circle, as the sign of the civil power. The second was added by Boniface about 1300; the third by Urban V. about 1365. (Bowden, *Life of Gregory VII.* i. 60.)

TI'BIA. (Lat.) In Anatomy, the largest of the two bones which form the second segment of the leg, or sacral extremity. In Entomology, it is the fourth joint of the leg, is very long, and usually triquetrous. Its name is said to have reference to its resemblance to the ancient pipe or flute.

TIC DOULOUREUX. A very painful affection of a nerve, coming on in sudden and excruciating attacks: it is perhaps most common in that branch of the fifth pair which comes out of the infra-orbitary foramen. Nothing is known of the cause of tic douloureux, except in one or two very rare cases, where a small spicula of bone has been found pressing on the nerves. The treatment is equally uncertain, except where it assumes an intermittent form, and then large doses of tonics, and especially carbonate of iron have proved useful.

TI'CHORRHINE. (Gr. τειχος, *a wall*; ῥιν, *a nose.*) The name of a fossil species of rhinoceros (*Rhinoceros tichorrinus*), which is so called on account of the middle vertical bony septum or wall which supports the nose.

TIDE MILLS, are such as have the ebb and flow of the tide for their first movers. As the tide rises, the water is admitted into a reservoir through a sluice, over which the mill is built, turning the water-wheel in its passage through the sluice. At high tide the sluice gates are shut till the water has fallen sufficiently outside, when they are opened, so as to allow the water to flow out again from the reservoir, and turn the wheel as it escapes through the sluice.

In some tide mills the water-wheel turns one way as the tide rises, and the contrary as it falls; but in others an arrangement is adopted by which the wheel is made to turn always in the same direction. In some, the water-wheel rises and falls with the tide; and in others, the axis is fixed, so that it can neither rise nor fall. In the latter case, the power is applied at an obvious disadvantage, though rotatory motion to a certain extent may be given even when the wheel is wholly immersed in the water, from the *difference* of the velocity of the water at the top and bottom of the sluice. (See *Gregory's Mechanics*, vol. ii.)

TIDES. The alternate rise and fall of the waters of the ocean. The moon is the principal agent in the production of the tides; but they are modified, both with respect to their height and the times at which they happen, by the action of the sun. The effect of the planets is inappreciable.

The attractive force of a body on a distant particle of matter varying inversely as the square of the distance, the particles of the earth on the side next the moon will be attracted with a greater, and those on the opposite side with a smaller force, than those which are situated intermediately. The gravitation towards the earth's centre of the particles nearest the moon will therefore be diminished, and consequently, if at liberty to move among themselves, they will rise above the general level. In like manner, the moon's attraction on the most distant particles being less than on the central ones, their relative gravitation towards the centre will also be diminished, and the waters will consequently be heaped up on the side of the earth which is turned away from the moon. Hence if the earth were at rest, the ocean would take the form of an oblong spheroid, with its longer axis passing through the attracting body; and it may be shown from theory that the spheroid would be in equilibrium under the influence of the moon's attraction, if the longer semi-axis exceeded the shorter by about 58 inches. But in consequence of the rapid rotation of the earth about its axis, the spheroid of equilibrium is never fully formed; for before the waters can take their level, the vertex of the spheroid has shifted its position on the earth's surface, in consequence of which an immensely broad and very flat wave is formed, which follows the motions of the moon at some interval of time. In the open sea the time of high water is, in general, from two to three hours after the moon's transit over the meridian either above or below the horizon. The tidal wave, it is to be observed, is entirely different from a current: the particles of water merely rise and fall; but except when the wave passes over shallows, or approaches the shore, there is little or no progressive motion.

The waters of the ocean are affected in a similar manner by the action of the sun, under the influence of which they have a tendency to assume at every instant the form of an elongated spheroid; but although the attractive force of the sun is immensely greater than that of the moon, yet, by reason of the greater distance of the sun, the *difference* of the effect on particles situated on opposite sides of the earth (on which difference the phenomena depend) is very much less. The solar tides are therefore comparatively small with respect to the lunar tides, and, in fact, are never perceived as distinct phenomena, but become sensible only from the modifications which they produce in the heights and times of those which primarily depend on the moon. At the syzygies, when the sun and moon come to the meridian together, the tides are, *ceteris paribus*, the highest; at the quadratures, or when the sun and moon are 90° distant, the tides are least. The former are called *spring tides*, the latter *neap tides.* Although we are not in possession of data to enable us to compute the exact height either of the spring or neap tides, yet their relative heights in the open ocean probably correspond very nearly to the ellipticities of the spheroids of equilibrium that would be formed under the action of the two bodies exerted separately. Now the ellipticity of the aqueous spheroid formed by the moon's action is about five feet, and the ellipticity of that formed by the sun's action about two feet; therefore, the spring and neap tides being the sum and difference of the separate effects, the average spring tide will be to the average neap in the ratio of about 7 to 3. *See* GRAVITATION.

By reason of the ellipticity of the orbits the distances of the sun and moon from the earth are continually changing; and the theory of attraction proves that the efficacy of either body in disturbing the waters of the ocean is inversely proportional to the cube of its distance. Hence it is found that if the mean efficacy of the sun be represented by 20, the influence of the sun's action will vary between the extremes of 19 and 21, and and that of the moon's between 43 and 59. The highest spring tide will therefore be to the lowest neap as $59+21$ to $43-19$; that is, as 80 to 24, or as 10 to 3.

Another effect of the solar action is observed in the times at which high water takes place from day to day. In the spring and neap tides the time of high water is not altered by the sun's action, the solar and lunar tides being synchronous in the former case, and the time of actual low water being that of solar high water in the latter; but in the intermediate tides the time of actual high water is accelerated or retarded. In the first and third quarters of the moon, the solar wave is to the westward of the lunar one; and consequently the observed tide, which is the result of the combination of the two waves, will be to the westward of the place it would occupy if the moon acted alone, and the time of high water will therefore be accelerated. In the second and fourth quarters, the general effect of the sun is to produce, for a like reason, a retardation in the time of high water. This result of the combined action of the two attracting bodies is what is usually termed the *priming and lagging* of the tides, and it is most remarkable about the time of new and full moon.

It is to be observed, however, that the effect now described is modified to some extent by the inertia of the water. The greatest and least tides do not happen exactly at the times of new and full moon; but at least two, and commonly three tides after, even at places directly exposed to the general tide of the ocean. In consequence of the greater amount of impressed force, the acceleration of the lunar tide is greater than that of the solar; whence it may happen that when the lunar tide occurs two or three hours after the transit of the moon,

the solar tide may be three or four hours after that of the sun, so as to be about an hour later at the times of conjunction and opposition. The highest spring tides will thus occur when the moon passes the meridian about an hour after the sun; while at the precise time of new and full moon the lunar tide will be retarded about a quarter of an hour by the solar tide. But the time of high water does not follow the moon's transit at the same interval at every period of the lunation. When the sun and moon are in conjunction the interval is called the *mean interval;* at other periods of the lunation the lunitidal interval is sometimes greater and sometimes less than the mean, and the difference is called the half-monthly or *semimenstrual inequality*.

The apparent time of high water at any port, in the afternoon of the day of new or full moon, is what is usually called the *establishment of the port*. Mr. Whewell calls this the *vulgar* establishment, and the mean of all the intervals of tide and transit for a half lunation he terms the *corrected* establishment. This corrected establishment is consequently the lunitidal interval corresponding to the day on which the moon passes the meridian exactly at noon or midnight.

The two tides immediately following one another, or the tides of the day and night, vary, both in height and time of high water, at any particular place with the distance of the sun and moon from the equator. As the vertex of the tide wave always tends to place itself vertically under the luminary which produces it, it is evident that, of two consecutive tides, that which happens when the moon is nearest the zenith or nadir will be greater than the other; and consequently when the moon's declination is of the same denomination as the latitude of the place, the tide which corresponds to the upper transit will be greater than the opposite one, and *vice versâ*, the differences being greatest when the sun and moon are in opposition and in opposite tropics. This is called the *diurnal inequality*, because its cycle is one day; but it varies greatly at different places, and its laws, which appear to be governed by local circumstances, are very imperfectly known.

We have now described the principal phenomena that would take place, were the earth a sphere and covered entirely with a fluid of uniform depth. But the actual phenomena of the tides are infinitely more complicated. From the interruption of the land, and the irregular form and depth of the ocean, combined with many other disturbing circumstances, among which are the inertia of the waters, the friction on the bottom and sides, the narrowness and length of the channels, the action of the wind, currents, difference of atmospheric pressure, &c. &c., great variation takes place in the mean times and height of high water at places differently situated; and the inequalities above alluded to, as depending on the parallax of the moon, her position with respect to the sun, and the declination of the two bodies, are, in many cases, altogether obliterated by the effects of the disturbing influences, or can only be detected by the calculation and comparison of long series of observations.

By reason of these disturbing causes, it becomes a matter of great difficulty to trace the propagation of the tide wave, and the connection of the tides in different parts of the world. In the *Philosophical Transactions* for 1832, Sir John Lubbock published a map of the world, in which he inserted the times of high water at new and full moon at a great number of places on the globe, collected from various sources, as works on navigation, voyages, sailing directions, &c.; and in order that the march of the tide wave might be traced more readily, the times were expressed in Greenwich time as well as the time of the place. In the same *Transactions* for 1833, Mr. Whewell prosecuted this subject at greater length; and availing himself of *à priori* considerations, as well as of a mass of information collected in the Hydrographer's office at the Admiralty, inserted in the map a series of *cotidal lines*, or lines along which high water takes place at the same instant of time. But these cotidal lines, as Sir J. Lubbock remarks, are entirely hypothetical; for we have few opportunities of determining the time of high water at a distance from the coast, though this is sometimes possible by means of a solitary island, as St. Helena. (*Lubbock's Elementary Treatise on the Tides*, 1839.)

According to Mr. Whewell's deductions, the general progress of the great tide wave may be thus described:— It is only in the Southern Ocean, between the latitudes of 30 and 70 degrees, that a zone of water exists of sufficient extent to allow of the tide wave being fully formed. Suppose, then, a line of contemporary tides, or *cotidal line*, to be formed in the Indian Ocean, as the theory supposes, that is to say, in the direction of the meridian, and at a certain distance to the eastward of the meridian in which the moon is. As this tide wave passes the Cape of Good Hope, it sends off a derivative undulation, which advances northward up the Atlantic Ocean, preserving always a certain proportion of its original magnitude and velocity. In travelling along this ocean the wave assumes a curved form, the convex part keeping near the middle of the ocean, and ahead of the branches, which, owing to the shallower water, lag behind on the American and African coasts; so that the cotidal lines have always a tendency to make very oblique angles with the shore, and, in fact, run nearly parallel to it for great distances. The main tide, Mr. Whewell conceives, after reaching the Orkneys, will move forward in the sea bounded by the shores of Norway and Siberia on the one side, and those of Greenland and America on the other, will pass the pole of the earth, and finally end its course on the shores in the neighbourhood of Behring's Straits. It may even propagate its influence through the straits, and modify the tides of the North Pacific. But a branch tide is sent off from this main tide into the German Ocean; and this, entering between the Orkneys and the coast of Norway, brings the tide to the east coast of England, and to the coasts of Holland, Denmark, and Germany. Continuing its course, part of it at least passes through the strait of Dover, and meets in the British Channel the tide from the Atlantic, which arrives on the coast of Europe twelve hours later: but in passing along the English coast another part of it is reflected from the projecting land of Norfolk upon the north coast of Germany, and again meets the tide wave on the shores of Denmark. Owing to this interference of different tide waves, the tides are almost entirely obliterated on the coast of Jutland, where their place is supplied by continual high water.

In the Pacific Ocean the tides are very small; but there are not sufficient observations to determine the forms and progress of the cotidal lines. Off Cape Horn, and round the whole shore of Terra del Fuego, from the western extremity of the Strait of Magalhaens to Staten Island, it is very remarkable that the tidal wave, instead of following the moon in its diurnal course, travels to the *eastward*. This, however, is a partial phenomenon; and a little farther to the north of the last-named places the tides set to the north and west. In the Mediterranean and Baltic seas the tides are inconsiderable, but exhibit irregularities for which it is difficult to account. The Indian Ocean appears to have high water on all sides at once, though not in the central parts at the same time.

Since the tides on our coasts are derived from the oscillations produced under the direct agency of the sun and moon in the Southern Ocean, and require a certain interval of time for their transfer, it follows that, in general, the tide is not due to the moon's transit immediately preceding; but is regulated by the position which the sun and moon had when they determined the primary tide. The time elapsed between the original formation of the tide and its appearance at any place is called the *age* of the tide, and sometimes, after Bernoulli, the *retard*. On the shores of Spain and North America the tide is a day and a half old; in the port of London, it appears to be two days and a half old when it arrives.

Velocity of the Tide Wave.— In the open ocean the crest of the tide travels with enormous velocity. If the whole surface were uniformly covered with water, the summit of the tide wave, being mainly governed by the moon, would every where follow the moon's transit at the same interval of time, and consequently travel round the earth in a little more than 24 hours. But the circumference of the earth at the equator being about 25,000 miles, the velocity of propagation would therefore be about 1000 miles per hour. The actual velocity is perhaps nowhere equal to this, and is very different at different places. In latitude 60° south, where there is no interruption from land (excepting the narrow promontory of Patagonia), the tide wave will complete a revolution in a lunar day, and consequently travel at the rate of 670 miles an hour. On examining Mr. Whewell's map of cotidal lines, it will be seen that the great tide wave from the Southern Ocean travels from the Cape of Good Hope to the Azores in about 12 hours, and from the Azores to the southernmost point of Ireland in 3 hours more. In the Atlantic the hourly velocity in some cases appears to be 10° of latitude, or near 700 miles, which is almost equal to the velocity of sound through the air. From the south point of Ireland to the north point of Scotland the time is 8 hours, and the velocity about 160 miles an hour along the shore. On the eastern coast of Britain, and in shallower water, the velocity is less. From Buchanness to Sunderland it is about 60 miles an hour; from Scarborough to Cromer 35 miles; from the North Foreland to London 30 miles; from London to Richmond 13 miles an hour in that part of the river. (Whewell, *Phil. Trans.* 1833 and 1836.) It is scarcely necessary to remind the reader that the above velocities refer to the transmission of the undulation, and are entirely different from the velocity of the current to which the tide wave gives rise in shallow water.

Range of the Tide.— The difference of level between high and low water is affected by various causes, but chiefly by the configuration of the land; and is very different at different places. In deep in-bends of the shore, open in the direction of the tide wave, and gradually contracting like a funnel, the convergence of the water causes

a very great increase of the range. Hence the very high tides in the Bristol Channel, the Bay of St. Malo, and the Bay of Fundy, where the tide is said to rise sometimes to the height of 100 feet. Promontories, under certain circumstances, exert an opposite influence, and diminish the magnitude of the tide. The observed ranges are also very anomalous. At certain places on the southeast coast of Ireland the range is not more than 3 feet, while at a little distance on each side it becomes 12 or 13 feet; and it is remarkable that these low tides occur directly opposite to the Bristol Channel, where (at Chepstow) the difference between high and low water amounts to 60 feet. In the middle of the Pacific it amounts only to 2 or 3 feet. At the London Docks the average range is about 22 feet; at Liverpool 15·5 feet; at Portsmouth 12·5 feet; at Plymouth also 12·5 feet; at Bristol 33 feet.

Theory of the Tides. — The theory of the tides, considered as a consequence of solar and lunar attraction, was first sketched by Newton in the *Principia*. In the 36th and 37th propositions of the third book, he determines the forces of the sun and moon to elevate the waters of the ocean, on the supposition that the sea is a fluid of the same density as the earth, covering the whole terrestrial surface, and which takes at every instant the figure of equilibrium. He assumes, without demonstration, that this figure is an elongated spheroid. One spheroid he supposes to be formed under the action of the sun, another under the action of the moon; and by reason of the smallness of their eccentricities they may be conceived as superposed the one on the other. From these suppositions he deduced the general phenomena of the ebb and flow of the sea; and by comparing his theory with observations of the heights of the spring tides made at the mouth of the Avon, near Bristol, he determined the ratio of the attraction of the moon to that of the sun to be nearly 4·48 to 1; whence he deduced the mass of the earth to be to that of the moon as 39·788 to 1, the density of the sun to that of the earth as 1 to 4, and the density of the moon to that of the earth as 11 to 9. Newton's theory was defective in many points of view; but fifty years elapsed before it received any improvement. In 1738, the subject of the tides was proposed as a prize question by the French Academy of Sciences, which gave occasion to the celebrated treatises of Daniel Bernoulli, Maclaurin, and Euler. Maclaurin's Essay is remarkable, as containing a demonstration of the theorem assumed by Newton, that the elliptic spheroid affords an equilibrium under the action of the disturbing forces: those of Bernoulli and Euler, though they furnish no new principle of equal or similar importance in point of theory, enter more into details, and contain many useful illustrations. That of Bernoulli, indeed, contains a table which has served as the model for all those (not purely empirical) which have since been formed. The next important step in the theory of the tides was taken by Laplace, who first treated the subject as a general question of hydrodynamics, and attempted to deduce the principal phenomena from the equations of the motions of fluids. But in order to simplify the equations, which are of a very complicated nature, he was forced to have recourse to the hypothesis of a fluid covering entirely a spheroid of a regular surface, and consequently the results were far from representing the actual observations of the tides at any port. The late Dr. Thomas Young (*Ency. Brit.*, art. "Tides") extended Laplace's method to the more general case of an ocean covering a part only of the earth's surface, and more or less irregular in its form; and attempted also to include in his calculation the effects of hydraulic friction on the times and magnitudes of the tides. It is, however, quite impossible to embrace in any calculation the whole of the accessory circumstances which influence the times and magnitudes of the tides, the greater part of which are, in fact, entirely unknown; and therefore, says Laplace, all we can do is to analyze the general phenomena which should result from the joint action of the sun and moon, and deduce from observations the data which are indispensable for completing the theory of the tides for each particular port.

A great number of observations of the tides at the port of Brest, during the last century, were discussed by Laplace in the *Mécanique Céleste;* but in order to determine the motion of the tide wave, and separate the general laws of the phenomena from local irregularities, it is necessary to have regular series of observations made at different parts of the ocean. Until very recently the theory may be said to have been in advance of the observations; but of late years the subject has received great attention, and at the present time a more perfect theory of hydrodynamics appears to be necessary for the physical explanation of the phenomena. In 1829, Sir John Lubbock undertook the discussion of the tide observations which are made at the London Docks, with the view of obtaining correct tables for predicting the time and height of the tides for the *British Almanac*. The results, which were published in the *Philosophical Transactions* for 1831, are deduced from a series of upwards of 13,000 observations, during a period of nineteen years, and are of great importance, both as affording materials for the construction of tide tables, and as pointing out the defects of the equilibrium theory, with which they were accurately compared. In some of the subsequent volumes of the *Transactions* the author has continued his investigations, and has also published, separately, an account of Bernoulli's *Traité sur le Flux et Reflux*, and an elementary treatise, which appeared in 1839. In the *Phil. Trans.* for 1833, M. Whewell gave an *Essay towards a first Aproximation to a Map of Cotidal Lines*, which has been followed by a series of interesting papers in the subsequent volumes to the present time (1842). Mr. Whewell's researches have been chiefly directed to the determination of the following points: — First, the motion of the tide wave at different parts of the ocean; secondly, the comparison of the observed laws at different places with theory; and, lastly, the laws of the diurnal inequality. In 1834, the British Association procured an extensive series of observations to be made on the coasts of Britain and Ireland at 537 stations of the coast-guard. These were repeated at the same places in June, 1835; and, at the request of our government, simultaneous observations were made by the other maritime powers of Europe and the United States. The number of stations in America was 28, extending from the mouth of the Mississippi to Nova Scotia; and the number on the continent of Europe 101, between the straits of Gibraltar and the north Cape of Norway. The results of these observations, reduced under Mr. Whewell's superintendence, were published in the *Phil. Trans.* for 1836; and they are of great importance, not only as affording a far more precise determination of the progress of the tide wave and the forms of the cotidal line on the coasts of Europe and North America than previously existed, but as furnishing more correct data for the construction of the tide tables.

Influence of Atmospheric Pressure and Winds.—Besides the numerous causes of irregularity depending on the local circumstances, the tides are also affected by the state of the atmosphere. At Brest, the height of high water varies inversely as the height of the barometer, and rises more than eight inches for a fall of about half an inch of the barometer. At Liverpool, a fall of one tenth of an inch in the barometer corresponds to a rise in the river Mersey of about an inch; and at the London Docks, a fall of one tenth of an inch corresponds to a rise in the Thames of about seven tenths of an inch. With a low barometer, the tides may therefore be expected to be high, and *vice versâ.* The tide is also liable to be disturbed by winds. Sir J. Lubbock states that, in the violent hurricane of Jan. 8. 1839, "there was no tide at Gainsborough, which is twenty-five miles up the Trent, — a circumstance unknown before. At Saltmarsh, only five miles up the Ouse, from the Humber, the tide went on ebbing, and never flowed till the river was dry in some places; while at Ostend, towards which the wind was blowing, contrary effects were observed. During strong north-westerly gales the tide marks high water earlier in the Thames than otherwise, and does not give so much water, whilst the ebb tide runs out late, and marks lower; but upon the gales abating, and the weather moderating, the tides put in, and rise much higher; whilst they also run longer before high water is marked, and with more velocity of current; nor do they run out so long or so low." (*Elementary Treatise on the Tides.*)

TIDE GAUGE. A mechanical contrivance for registering the state of the tide continuously at every instant of time. In the *Phil. Trans.* for 1838, there is a description of a very complete self-registering machine for this purpose, erected at Bristol by Mr. Bunt. The principal parts are an eight-day clock, which turns a vertical cylinder revolving once in twenty-four hours; a wheel, to which an alternate motion is communicated by a float rising and falling with the tide, and connected with the wheel by a wire passing over a pulley, and kept constantly strained by a counterpoise; and a small drum on the same axis with the wheel, which, by a suspending wire, communicates one eighteenth of the vertical motion of the float to a bar carrying a pencil, which describes a curve on the cylinder, and thereby marks the fluctuations and the time and height of high water. Various tide gauges, on similar principles, have been constructed by others, particularly by Captain Lloyd, Mr. Mitchell, and Mr. Palmer. (See the *Nautical Magazine* for October, 1832.)

TIE. In Architecture, a piece of timber or metal placed in any direction, whose office is to bind two bodies together which have a tendency to separate or diverge. *See* Roof.

Tie. In Music, a character ⌣ used in ancient music to connect syncopated notes, which were divided by a bar; thus .

TIER. A row or range of guns, casks, &c. Also the place on the orlop deck on which the cables are stowed.

TIERCE. In Heraldry, a term used for the field when divided into three parts.

TIERS E'TAT. The third branch, or commonalty, in the French estates. The origin and meaning of the word are illustrated by M. Gautier. (*Mém. de l'Acad. des Inscr.* vol. xxxvii.) The important part which the representation of the tiers état played at the commencement of the French revolution is known to all. Previously to the great French revolution, the French were divided into three distinct classes, the nobles, the clergy, and the commonalty, forming in their united capacity the states general of the kingdom; and their deliberations were separately conducted by individual vote in different chambers, in which the three classes above mentioned respectively assembled. They then met in common to deliberate together, and vote collectively. Now, as the number of the deputies was nearly equal in each order, the result of the votes taken collectively was always necessarily favourable to the privileged orders. Hence it was loudly demanded that the number of the third or tiers estate should be doubled, and the definitive resolutions decided by individual instead of collective votes. Every one knows that it was owing to the refusal of the nobles and the clergy to comply with this demand, that the crisis of the French revolution was accelerated; and to the consummation of this event a celebrated pamphlet of Siéyes, entitled *Qu'est ce que le Tiers Etat*, in a great degree contributed. *See* Assembly.

TI'GER. A species of the genus *Felis*, as large as the lion, but with a rounder head and longer body; of a bright reddish fawn colour above, a pure white below, irregularly crossed with black stripes. It is clothed with short hairs, and has no mane. The tiger is the most formidable and cruel of all quadrupeds, and the scourge of the less inhabited parts of India. It is limited to the Asiatic continent. *See* Felis.

TIGHT. The Sea term for the opposite of leaky.

TILIACEÆ (*Tilia*, the linden or lime tree), form a natural order of Exogenous plants, very nearly allied to the Malvaceous order, from which they differ in the stamens being distinct. In useful qualities they resemble that order, the bark being tough, their sap mucilaginous, and their timber light. Russia mats are made from the tough inner bark of the common lime tree; and a species of Corchorus, called *olitorius*, is employed in India as a potherb. A few have gay flowers, but the majority are plants of little interest.

TI'LLAGE LANDS. Lands kept under the plough, that is, cropped with annual or biennial plants, which require a continual change of the surface soil by stirring and turning with the plough or other agricultural implements, and by the addition of manure. The tillage plants of Britain and of analogous climates are chiefly the bread corn; leguminous or pea-flowered plants, such as the bean, pea, tares, clover, &c.; plants cultivated for their roots or tubers, such as the turnip, carrot, potato, &c.; or plants cultivated for their seeds, such as mustard, rape; or for the entire plant, such as wood, flax, hemp, and a variety of others.

TILLER. In Naval Language, the bar placed in the head of the rudder to turn it.

TI'LMUS. (Gr. τιλλω, *I pluck.*) Picking of the bed-clothes, or floccitation; a symptom of the fatal termination of some disorders.

TIMBER. In Carpentry, a word used to denote those pieces of wood that admit of being squared, or are capable of being employed in house and ship-building.

A considerable portion of the timber (oak) used in ship-building, and in the construction of machinery, is of home growth; but the greater portion of the timber (fir) used in house carpentry, and in the making of furniture, &c., is imported either from our colonial possessions or from foreign countries.

The trade in timber is one of great extent and importance. In fact, if there be one article more than another with which it is of paramount importance that a great maritime and manufacturing nation like England should be abundantly supplied on the lowest possible terms, that article is timber. But of late years, this sound principle has been most materially interfered with, partly for the sake of revenue, and partly to force a trade with our North American colonies. This forcing system has been carried to such an extreme extent, that from 1821 down to the present year (1842), a duty of 55*s.* a load has been laid on foreign timber, or timber from the N. of Europe, whereas timber from British America has been admitted at a duty of 10*s.* a load, making a discriminating or differential duty of no less than 45*s.* a load in favour of the latter! Such a preference would, under any circumstances, be most injurious; but it has been especially so from the fact of the timber of our North American possessions being, speaking generally, of very inferior quality; so that the practical operation of the system has been to compel the British public to pay a comparatively high price for a comparatively worthless article. We are glad, however, to be able to state that this pernicious system has recently been very materially modified; and that under the tariff introduced by Sir Robert Peel the duty on foreign timber is to be immediately reduced to 30*s.* a load, and that in 1843, it is to be reduced to 25*s.*, while the duty on timber from British America is to be reduced to 1*s.* the load. This reduces the differential duty or bounty in favour of Canadian timber from 45*s.* to 24*s.*, and is, in so far, a material improvement. But there neither is nor can be any good reason why the differential duty should not be still farther reduced, or rather why it should not be altogether abolished. The better plan would have been to have made the reduction only in foreign timber, and to have kept the duty on Canadian timber at its old level. Had this been done, the loss to the revenue would not have been nearly so great as it will be, at the same time that the differential duty in favour of colonial timber would have been reduced to 15*s.* a load, which, though an unpolitic, could not have been called an oppressive duty.

The consequence of this forcing system has been that of from 350 to 450 cargoes of timber annually imported into the United Kingdom, not more than from 60 to 100 are from the north of Europe. But under the new system, the proportions will be materially varied, and the balance of importation will be greatly in favour of the north of Europe. We subjoin,—

An Account of the Quantities of Timber Imported in 1838 and 1839; and of the Quantities retained for Home Consumption, and the Nett Amount of Duty derived therefrom in the same Two Years.

TIMBERS. The general term for the upright pieces of wood in a ship's frame.

TIME. In Music, that affection of sound whereby shortness or length is denominated as regards its continuity on the same degree of tune. Time may be considered either with respect to the absolute duration of the notes themselves, measured by motion foreign to music, or with respect to the proportion or quantity of notes compared with each other. The signs or characters by which the time of notes is represented are given under the article Music.

Time. A limited portion of duration, measured by certain conventional or natural periods, and often marked by particular phenomena, — as the revolution of the celestial bodies, more especially of the sun, or the rotation of the earth on its axis.

Absolute Time is time considered in itself without reference to that portion of duration to which it belongs, however noted or marked.

Relative Time is time considered with reference to the termini of some specific interval of duration.

Apparent Time is time deduced from observations of the sun, and is the same as that shown by a properly adjusted sun-dial.

Mean Time is that shown by a well-regulated clock; and would be the same as that shown by the sun, if the sun were always in the equator, and his apparent diurnal motion in the heavens were uniform.

Sidereal Time is the portion of a sidereal day which has elapsed since the transit of the first point of Aries. It represents at any moment the right ascension of whatever object is then upon the meridian.

Astronomical Time of Day is the time past *mean noon* of that day, and is reckoned on to twenty-four hours in mean time.

Civil Time is mean time adapted to the purposes of civil life. The day commences at the midnight preceding the noon of the day, and is divided into parts of twelve hours each, the first twelve marked A.M. or *ante meridiem*, and the second P.M. or *post meridiem*.

TIMO'CRACY. (Gr. τιμοκρατία.) A term made use of by some Greek writers, especially Aristotle, to signify a peculiar form of constitution; but there are two different senses in which it is thus used, corresponding to the different meanings of the word τιμη, *a price* or *honour*, from which it is derived. According to the first it represents a state in which the qualification for office is a certain amount of property; in the latter it is a kind of mean between aristocracy and oligarchy, when the ruling class, who are still the best and noblest citizens, struggle for pre-eminence amongst themselves. (See *Quart. Rev.* vol. xlv.)

TIN. (Germ. zinn.) This metal was known to the ancients, who procured it from Spain and Britain. It appears to have been in use even in the time of Moses. (Numbers, xxxvi. 22.) It is rather a scarce metal, found in few parts of the world in any quantity. Cornwall is its most productive source; it also occurs in the mountains between Gallicia and Portugal, and in those between Saxony and Bohemia. Tin has also been brought from the peninsula of Malacca in India, and from Chili and Mexico. There are only two ores of tin; the native peroxide, and the double sulphuret of tin and copper: the latter, sometimes called *bell-metal ore*, is extremely rare; and it is exclusively from the former that the commercial demands are supplied. In Cornwall, the native peroxide, or *tin stone* (which is usually blended with oxides of iron and manganese), occurs in *veins*, and in loose grains and nodules in alluvial soil: the latter is called *stream tin*, and from it the purest metal is obtained. The ore is reduced by a very simple process; it is ground, washed, and roasted in a reverberatory furnace; it is then mixed with charcoal or Welsh culm and limestone, and strongly heated, so as to bring the whole into fusion, which is kept up for eight or ten hours: the lime combines with the earthy matters of the ore into a fusible slag, whilst the coal reduces the oxide to the metallic state, and the fused metal is drawn out at the bottom of the furnace into a clay mould. In this impure state it is exposed to a heat just sufficient to melt the pure tin, which runs off into a kettle, while the less fusible impurities remain behind: in the kettle, the tin is kept in fusion, and agitated by plunging pieces of wet charcoal into it, which causes a quantity of dross to rise to the surface, where it is skimmed off, and the purified metal is then cast into blocks of about 3 cwt. each.

The stream tin is smelted by charcoal; and the mass of grain tin obtained by such reduction is heated and let fall from a height, by which it splits into masses of a columnar fracture, which characterizes the pure metal.

Pure tin is a white brilliant metal. It has a slight taste and smell when rubbed, and its hardness is intermediate between that of gold and lead. Its specific gravity is 7·2. It is very malleable; and one of its most useful forms is that of foil, which is made by beating: it is about a thousandth of an inch in thickness. Its ductility and tenacity are inferior to most of the other malleable metals. A tin wire 78-thousandths of an inch in diameter will not support more than 38 pounds without breaking. It produces a peculiar crackling noise when beat. Exposed to air, it soon becomes superficially oxidized; and when melted successive films of a gray powder form upon its surface. The temperature at which it melts is about 442°. At a white heat it takes fire, and burns with a bright flame. The equivalent of tin is 58. It forms two oxides. The protoxide is thrown down by alkaline carbonates from an aqueous solution of protochloride of tin; and when dried and heated out of the contact of air its water is expelled, and it remains in the form of a dark substance, of the specific gravity 6·6. It burns like tinder, and becomes converted into the peroxide. It is soluble in sulphuric and hydrochloric, and in dilute nitric acid, and in the pure fixed alkalies. Its salts have a strong attraction for oxygen, and easily pass into persalts; so that it is a powerful deoxidizing agent, and is often used as such in some of the chemical arts. When a solution of protochloride of tin is dropped into a solution of perchloride of gold, a purple precipitate, called, from its inventor, *purple of Cassius*, is thrown down: it appears to be a compound of peroxide of tin with protoxide of gold, and its formation depends upon the deoxidizing power of the solution of tin. When tin foil is put into nitric acid there is violent action, attended by the decomposition of the acid and the peroxidizement of the tin, which is thus converted into a white powder: this, when edulcorated and dried at a red heat, acquires a yellow tint. It does not easily form permanent compounds with the acids; but it unites with the pure alkalies, and forms soluble compounds, which have sometimes been called *stannates*, and the peroxide itself *stannic acid*. The two oxides of tin are respectively composed of 58 tin and 8 oxygen, and 58 tin and 16 oxygen: their equivalents, therefore, are 66 and 74. Tin and chlorine also combine in two proportions: the *protochloride of tin* is formed by passing hydrochloric acid gas over metallic tin gently heated in a glass tube, or by heating a mixture of equal weights of tin filings and calomel, when it remains, after driving off the mercury, in the form of a gray solid, fusible at a red heat, and volatile at higher temperatures. Its aqueous solution is commonly termed *protomuriate of tin*. When tin foil is heated in excess of gaseous chlorine, or when 1 part of tin filings is mixed with 3 of corrosive sublimate and heated, a volatile liquid distils over, which is *perchloride of tin*, and its aqueous solution forms the *permuriate*. Exposed to air, it is decomposed by the aqueous vapour of the atmosphere, and exhales dense white fumes: hence it has been called, after its discoverer, *fuming liquor of Libavius*. Both the protomuriate and permuriate of tin are used by dyers and calico-printers. The former is prepared by heating granulated tin in strong hydrochloric acid, as long as hydrogen continues to be evolved; the latter, by gradually dissolving granulated tin in a mixture of two parts by measure of hydrochloric acid, one of nitric acid, and one of water. These chlorides of tin are respectively composed of 58 tin and 36 chlorine, and 58 tin and 72 chlorine, and are therefore represented by the equivalents 94 and 130.

When melted tin and sulphur are brought together, a black *protosulphuret of tin* is formed. The *bisulphuret of tin* is a yellow glistening substance, sometimes called *Mosaic gold* (*aurum musivum*), and used in ornamental japan work. It is prepared by heating in a glass retort 2 parts of peroxide of tin, 2 of sulphur, and 1 of sal ammoniac, and maintaining a low red heat till sulphurous acid ceases to be evolved. The sulphuret and bisulphuret of tin are constituted of 58 tin and 16 sulphur, and 58 tin and 32 sulphur; and have, therefore, the equivalents 74 and 80. The total produce of the tin mines and works of Cornwall may, at present (1842), be estimated at about 4000 tons a year, worth from 65*l.* to 80*l.* a ton.

TI'NCA. (Lat. tinca, *a tench*.) A subgenus of Cyprinoid fishes, characterized by having short anal and dorsal fins; very short barbules or tentacles about the mouth; no bony serrated ray at the commencement of either the dorsal or anal fins; small scales. Like the rest of the Linnæan *Cyprini*, the *Tinci*, or tenches, have no teeth except in the pharynx; whence the name of "leather-mouthed fishes" applied to this family of *Pisces Abdominales*.

TI'NCAL. The commercial name of rough borax as imported from India.

TI'NCTURE. A pharmaceutical preparation, generally consisting of active remedies dissolved in rectified or proof spirit. Tinctures are generally made by digesting bruised or pulverized vegetable substances in the spirit, either at common temperatures or aided by heat. The term *tincture* is sometimes applied to alcoholic solutions of resins, of which tincture of myrrh, of assafœtida, &c. furnish instances. Tinctures, from the quantity of alcohol which they contain, are necessarily exhibited in small doses: the most important of them are those which contain highly active ingredients, such as tincture of opium, &c.

TI'NCTURES, in Heraldry, are of three descriptions: metals, colours, and furs. The former are or, argent; the second gules, azure, sable, vert, purpure, sanguine, and tenny. The chief furs are ermine and vair; but there are several varieties of both, distinguished by different names. Each metal and colour, in blazonry (except the two last and least honourable, sanguine and tenny), is represented by a distinct precious stone and heavenly body; and when the arms of sovereign princes or high dignities are described by old heralds, the tinctures are frequently denoted by the names of these jewels or celestial bodies. *See* OR, ARGENT, &c.

TI'NEA. The scald head. *See* RINGWORM.

TIN PLATE. White iron. The art of tinning iron originated in Saxony, and was first made known here by Mr. Andrew Yarranton, about the year 1665; but it was not till nearly a century afterwards that works were established for its production upon a large scale at Pontypool. It is made by immersing for about one hour and a half very carefully cleaned plates of rolled iron in melted tin, by which they acquire a bright surface, and are applicable to a number of purposes for which iron plate, in consequence of the extreme facility with which it rusts, could not be used. The crystalline texture of the surface of these plates is beautifully shown by washing it over with a weak acid, and then cleaning it with an alkaline ley, and varnishing with a transparent varnish. Thus modified, it forms an ornamental article called *moirée métallique*. (On the manufacture of tin plate, see *Parkes's Chemical Essays*.)

TIRO'NIAN NOTES. The short-hand of Roman

antiquity. According to the received story, they were introduced into Rome by Tiro, the freedman and favourite of Cicero: he is supposed to have imported the art from Greece. MSS., written entirely in what are called the Tironian notes, are not unfrequently of the date of the 7th century and downwards; and they are still common in marginal notes. Kopp (*Tachygraphia Veterum Exposita*, p. 1817.) thinks that they are called from the word *tiro*, a learner. His second volume contains a dictionary of these notes, which he appears to have succeeded in deciphering. Some have thought that valuable lost classics may be recovered through this key; but as yet these hopes have been nugatory. (See *Ed. Rev.* vol. xlviii. p. 357. &c.)

TI'SRI. The first Hebrew month of the civil year, and the seventh of the ecclesiastical year. It corresponds to part of September and October.

TI'SSUE, in Plants, the thin membranous organization of which every part is composed, microscopical in size, and often appearing to the naked eye homogeneous, although it consists of a great variety of forms closely compacted. Vegetable anatomists regard its primitive form as spheroidal, and that the tubes and spiral vessels are mere extensions of that form. Tissue appears to be in all plants of the same nature originally, but it soon becomes altered by the deposition of various secretions upon its sides.

TI'TAN. In Grecian Mythology, according to the more modern account, the eldest son of Uranus and Gaia, who relinquished the sovereignty of gods and men to his younger brother Saturn, the latter undertaking to destroy all his children, so that the monarchy might revert to those of Titan. He afterwards recovered the sovereignty from Saturn; but Jupiter, the son of the latter, vanquished him, and restored it to his father. This, however, is a tale altogether unknown to the original mythologists. According to them, the Titans were many in number; children of Uranus and Gaia. Hesiod makes them six. The children of the Titans, Atlas for example, retained the same appellation. The war of these Titans with Jupiter was the subject of many different and contradictory legends. Its scene was laid in Thessaly; by Homer on the mountains Olympus, Pelion, and Ossa. By some writers Titan is identified with Hyperion; but this point is involved in great obscurity.

TITANITE. Native oxide of titanium.

TITA'NIUM. A rare metal, discovered by Gregor in a mineral from Cornwall called *menachanite*. Its characters were first ascertained by Klaproth, who gave it the above name. In the year 1822, Dr. Wollaston ascertained that the minute copper-coloured crystals occasionally found in the slag of the iron smelting furnaces at Merthyr and elsewhere were pure titanium; and it is to him that we are indebted for a precise account of its properties. In this state it has a copper colour, is extremely infusible, and of a specific gravity of 5·8; it is so hard as to scratch not only glass, but crystal. It resists the action of air and acids, but is oxidized by the action of nitre at a red heat. Titanium appears susceptible of two degrees of oxidizement. The protoxide of titanium is blue or purple, and appears to constitute the mineral called *anatase*. The peroxide, or *titanic acid*, exists nearly pure in *titanite*, or *rutilite*, and is combined with the oxides of iron and manganese in *menachanite*. The equivalent of titanium has not been very satisfactorily ascertained, but it is probably about 24 upon the hydrogen scale.

TITHES. In Ecclesiastical Law, the tenth part of the produce of the land, which, in this and other Christian countries, was anciently set apart for the endowment of the church. By the Mosaical law, the Levites, by whom the public worship of the Jewish state was performed, were supported, not as the other tribes, by the allotment of a certain district of Canaan, but by the appointment of divers cities in various parts of the country for their abode, and the payment of tithes from the whole community. This ordinance has frequently been appealed to under the Christian dispensation, as establishing the divine right of the clergy to the receipt of tithes for ever; but this ground of claim has been generally abandoned in modern times; nor does the practice of the early church, at its first establishment in connection with the state, give any reason to suppose that such an idea was then entertained. Nor, in this country, do the people and their rulers appear, upon their conversion, to have felt themselves under the obligation of any strict payment of tithes. It was first enjoined, apparently, in certain ecclesiastical canons, in the year 750; and the first civil decree upon the subject is discovered in the laws of Offa, king of Mercia, in 794. In France, a similar law was enforced by Charlemagne in 778, and from that time the payment has been continued without interruption to modern times.

Of tithes there are three kinds: — 1. *Predial*, of the vegetable productions of the land, as corn, hay, &c.; 2d, *Mixed*, as of wool, pigs, &c., which, though natural products, are nurtured and preserved by the care of man; 3rd, *Personal*, as of manual occupations, trades, fisheries, and the like. Another division of tithes is into great and small, or parsonage and vicarage tithes: of these the former are chiefly corn, hay, and wood; the latter are predial tithes of other kinds, together with mixed and personal tithes. The great tithes belong to the rector; whereas only the small tithes are due to the vicar. By the original law, all the land of the country was tithable, excepting the property of the crown, and of the church itself. But when at the Reformation the monasteries were dissolved, and their estates granted for the most part to laymen, these lands would have become tithable again, but for a particular statute which was enacted for the advantage of the new possessors. It was also allowable, up to the 13 Eliz., to effect compositions between the clergy and owners of the land, by which the parish was discharged of these payments for ever, in consideration of lands made over to the parson in exchange. This practice was, however, restrained by the statute above referred to, which limited all such compositions to a period of three lives or twenty-one years. From these causes, however, it is that we find a great deal of land in the hands of lay proprietors not subject to this charge. The monasteries, however, held one third of the benefices of the kingdom, from all of which they received tithes, and appointed members of their own body, as their vicars or curates, to discharge the ordinary functions of ministers in them. To these they either gave fixed stipends, or allotted the small tithes, taking, as their own share, the great or rectorial. This is called *appropriation* of tithes; but when these benefices fell into the hands of laymen, the same practice was continued, and is distinguished by the title of *impropriation*.

Tithes are either due *de jure* or by custom: to the latter class belong all personal tithes.

The subtraction of tithes from a parson, whether a clergyman or lay impropriator (*see* IMPROPRIATION), or from a vicar, is cognizable in the ecclesiastical courts. But these courts cannot try the right to tithes, except between spiritual persons; consequently, if the defendant pleads any matter involving a question of right, it must be tried by a jury. Suits for tithes are generally instituted in the Court of Exchequer. By the 53 G. 3. c. 127. justices of the peace have jurisdiction for the recovery of small tithes to the amount of 10*l*.

Lands and their occupiers may be discharged from the payment of tithes, either in part or totally, by a real composition, or by custom or prescription. The first is where an agreement is made between the owner and the parson or vicar, with consent of the ordinary and patron, that some land, or other real recompence, be given in satisfaction of tithes. By 13 Eliz. c. 10., as we have seen, no real composition, made since that statute, is good for any longer time than three lives or twenty-one years. Compositions between a tithe-owner and parishioner cease on the death of the incumbent with whom they were made.

A discharge by custom or prescription is either, 1. *De modo decimandi*, where a *modus*, or particular manner of tithing, is shown to exist by custom, which must have existed immemorially; *i. e.* is not good, if evidence be shown of its non-existence at any time since the reign of Richard I. Or, 2. *De non decimando*, where a total exemption from tithes is shown.

Such is a general view of the law of tithe previous to the great changes introduced by the Tithe Commutation Act, 6 & 7 W. 4. c. 71.; the object of which was to convert a tax, imposed on the gross produce of the soil, and varying annually in amount as well as money value along with it, into a rent-charge, perpetual as to the amount, but varying according to the money value.

By this act the money value of the tithes in each parish was to be calculated according to the average of the seven years ending at Christmas, 1835, *minus* the expences of collecting, &c.; but without deduction on account of parochial or county rates, &c. The commissioners appointed for that purpose under the act were then to award that sum (subject to some unimportant allowances), as the amount of the rent-charge to be paid in respect of the tithes. This rent-charge was to be apportioned among the lands of the parish, having regard to their average tithable produce and productive quality. The rent-charge, being thus valued in money, was to be taken as the price of such a quantity of wheat, barley, and oats as it would have purchased (each grain in equal quantities), according to the average price at the period of the confirmation of the apportionment. That quantity of grain was therefore to remain for ever as the annual charge upon the parish. In order to regulate the money amount of the tithes, the money payment each year was to be equal to the price of that quantity at the average of the seven years immediately preceding, to be ascertained by an advertisement of the comptroller of corn returns, published in the month of January every year. The rent-charge to be paid by the occupiers of the land on which it is respectively apportioned.

It will be apparent, from this brief outline of the provisions of the act, that a very great benefit was conferred by it, for all immediate purposes, upon the tithe-owner,

and for many upon both parties. The strifes and heart-burnings between the occupiers of the soil and the clergyman, which were occasioned by the old mode of collecting the impost, have been removed. The latter has been relieved alike from the consequences of indulgence towards his debtors, and the imputation of rapacity. In point of fact, the result of the valuation has been a considerable improvement in the incomes of the clergy, who comparatively seldom received their full due. The tenant and landowner gain by the removal of a most injurious tax on improvement; for the tithe, while it increased along with the produce of the land, acted as a great discouragement to increasing that produce.

But, looking to the future, its advantages are far more questionable. The tithe-owner will gain, no doubt, by any increase which may take place in the money price of corn. But he will be a loser by any fall in the price of corn; while any increase in the quantity of commodities produced in the country, the price of corn remaining the same, will leave his condition stationary, while other classes advance. It is thought that, in the last century, the agricultural produce of England has trebled. Tithe has nearly trebled along with it. If the same progression should continue for a century more, the produce of the country will again have trebled; rents and other incomes will have increased in proportion; population will have followed the same law of advance: — tithe will remain stationary; the income of the church will be no greater than what is now deemed sufficient for her support, while the exertions required of her will have greatly augmented.

And a permanent rise in the money price of corn, which might compensate this relative loss, is probably the last thing to be anticipated. Indeed, should that price fall materially, from the introduction of foreign grain, it will, probably, be necessary to commute anew, if the income of the tithe-owners is to be maintained at all.

To those who consider the sufficient temporal maintenance of the church a matter of high national interest, this prospect is a serious one; but even those who think otherwise cannot possibly regard it with indifference. Tithes are the property of the nation; and it cannot be for the advantage of any country that state property should not partake in the advance of individual wealth — that it should, relatively speaking, continually decrease.

The Tithe Commissioners report (1841), that they have received notices that voluntary commutations have been commenced in 9197 tithe districts; have received 5906 agreements, and confirmed 5136; 821 drafts of compulsory awards (such as they are empowered to cause to be made on the non-agreement of the parties), and confirmed 560. Taking the tithe districts of England and Wales at about 12,000, they appear to have finished about half the work of valuing and awarding. They have received 3688 apportionments, and confirmed 2632. According to the returns under the property tax (1810), it appeared that about 8,000,000 acres in England and Wales were tithe-free, and 21,000,000 tithable. See *M'Culloch's Statistics of the British Empire*. The same work contains the following analysis of appropriations and impropriations of tithes: —

Belonging to the crown - - -	38
Archbishops and bishops - - -	385
Ecclesiastical corporations aggregate -	702
Dignitaries and other eccl. corporations sole -	438
Universities, colleges, and hospitals -	281
Private owners - - - -	2552
Municipal corporations (since sold) - -	43
Vicarages partly endowed - - -	121
Ditto wholly endowed - - -	132

TITHING. A territorial division, of which the origin is pretty generally attributed to Alfred. It was a district supposed to contain ten freeborn men, of whom each was pledge for the others (*see* FRANKPLEDGE). One of these was annually appointed *tithingman*, *borsholder*, or *head-borough* (from borg, *a pledge*). Ten tithings constituted (as is supposed) a hundred.

TI'TULAR. Chiefly in Ecclesiastical usage, a person invested with the title to a benefice; generally used for one who has the title only, without possession or enjoyment.

TME'SIS. (Gr. τεμνω, *I cut.*) In Grammar, a figure by which a compound word is separated into two parts by the intervention of one or more words, as in the following line of Terence, "Quæ meo cunque animo lubitum est facere," for "quæcunque meo animo." This figure is a licence in the Latin language, frequent in Terence and Lucretius, rare in later writers; in the Greek it is more common; but of all Western languages, the German lends itself most readily to the division of compound words. In English the figure is unused.

TOADSTONE. A provincial term applied to certain igneous or basaltic rocks associated with the limestone formation of Derbyshire. *See* GEOLOGY.

TOBA'CCO. The dried leaves of the *Nicotiana tabacum*, a plant indigenous to America, but which succeeds very well, and is extensively cultivated, in most parts of the Old World. The recent leaves possess very little odour or taste; but when dried, their odour is strong, narcotic, and somewhat fœtid; their taste bitter, and extremely acrid. When well cured, they are of a yellowish green colour. When distilled, they yield an essential oil, on which their virtue depends, and which is said to be a virulent poison. The leaves are used in various ways; being chewed, smoked, and ground and manufactured into snuff. It is in the last-mentioned form that tobacco is principally used in Great Britain; and, though the contrary has often been asserted, its use does not seem to have been productive of any perceptible bad consequence.

The term *tobacco* is probably derived from Tabaco, a province of Yucatan, where it was first found by the Spaniards. To Sir Francis Drake and Sir Walter Raleigh has been ascribed the honour of having introduced it into England, nearly three centuries ago. For full particulars as to the history and statistics of this important article of commerce, see the *Com. Dict.*

TO'CSIN. An old French word, of which the derivation seems not to be ascertained (Gregory of Tours uses the word "seing" for the sound of a bell (see *Encycl. Méthodique*); signifying an alarum-bell (Germ. sturmglocke). The use of the terrible tocsin, during the troubles of the Revolution, to assemble the multitude, has rendered the word almost proverbial.

TOD. A weight used in weighing wool. It contains 28 lbs. avoirdupois.

TOFT, in old English, appears to signify the ground or enclosed space on which a messuage has formerly stood.

TO'GA. The gown or mantle peculiar to the Roman people; whence it was sometimes designated as the *gens togata*, or toga-clad nation. The toga was a loose flowing woollen garment covering the whole body round, and close below, but open at the top down to the girdle. The end was drawn up and thrown over the left shoulder, leaving the right arm at liberty, as it had no sleeves. The ordinary colour of the toga was white; but this was changed for a dark colour in mourning. The chief dignitaries of the state were distinguished by a purple band affixed to the edge of the toga, which was then called *prætexta*. An embroidered toga was worn by generals when they triumphed. (See *Chambers's Dictionary* for a concise account of the different species of toga.) It was the national characteristic of the Romans in the republican age; and when Augustus thought he perceived its disuse commencing among the crowds assembled at the theatre, and the substitution of the ordinary "lacerna;" he repeated with emphasis the line of Virgil —

Romanos rerum dominos, gentemque togatam.

Among women, the toga was only worn by the disreputable; the dress of the matron was the stola.

TOISE. A French measure of length, containing six French feet, or 1·949040 metres. The French toise is equivalent to 6·3945925 English feet.

TOKAY. A wine made at Tokay in Hungary; it is luscious, and yet has an agreeable quickness of flavour. It is usually more or less turbid, and is the only wine which is preferred in that state, and consequently agitated before it is poured into the glass.

TOLERA'TION (Lat. tolero, *I bear*), is used in a general sense to express impunity and safety in the state for all dissenters from the established church, who do not maintain any doctrines inconsistent with the peace and welfare of the state. Hence toleration implies a right of enjoying the benefit of the laws and of all social privileges, without any regard to difference of religion. The first toleration act in England passed in 1689; but it was not till 1829, when the Catholic Emancipation Bill was passed, that dissenters could be said to be on equality with churchmen in every respect. The Jews are now the only sect in England precluded from the full enjoyment of civil rights in consequence of their religion.

TOLL. (Germ. zoll.) The name usually given to the duties imposed on travellers and goods passing along public roads, bridges, &c. It is also used to indicate the payment to the corporation of a town, or to the lord or owner of a market or fair, upon sale of things tollable. The right, whether to take toll, or to be exempt from its payment, rests upon prescription or grant from the king. Toll is sometimes taken by a man for every beast driven across his ground, and is then called *toll-traverse;* also by a town for beasts going through it, or over a bridge or ferry maintained at its cost, and is then called *toll-thorough*. *See* TAILLE.

TO'LMEN, or DOLMEN. In Antiquities. Borlase, in his *History of Cornwall*, gives this name to large stones with passages apparently hollowed through them, which are commonly believed to be Druidical remains. There are many such in Britanny. See also *Archæologia*, vol. ii. and vol. viii. p. 210., where there is a description and representation of a celebrated one at Primham Rocks, in

Yorkshire. It has been supposed that they were acoustic contrivances, by means of which the Druids returned oracular answers.

TOLU BALSAM. The concrete balsam of *Myroxylon peruiferum*, a tree growing in the warmest parts of South America. This substance is pale brown; brittle in cold, but tenacious in hot weather; fragrant when heated, and entirely soluble in alcohol. It appears to contain that modification of the benzoic acid which has been called *cinnamic acid*.

TOMB. (Gr. τυμβος, Lat. tumulus.) Is used to express both the grave or sepulchre in which the body of a deceased person is interred, and a monument erected in his memory. In many countries it was customary to burn the bodies of the dead, and to collect the ashes into an urn (*see* URN) which was deposited in a tomb. The tombs of the Jews were generally hollow places hewn out of a rock. The Greeks constructed their tombs outside the walls of their cities, with the exception of those raised to distinguished personages. The same distinction was observed by the Romans; their sepulchres were in the country near the high roads, and none but emperors, vestals, and great personages had the privilege of burial within the walls. In Etruria, several tombs of the ancient inhabitants have been discovered containing beautiful vases, for full particulars respecting which, the reader may consult Mrs. H. Gray's interesting *Tour to the Sepulchres of Etruria*. See for the tombs of the Egyptians, Sir G. Wilkinson's *Manners of the Ancient Egyptians*, vol. iii. p. 183.

TO'MBAC. An alloy of copper and zinc, or a species of brass with excess of zinc. When arsenic is added, it forms *white tombac*.

TOMENTO'SE. (Lat. tomentum, *sheared wool*.) Covered with short inconspicuous interwoven hairs.

TON. A denomination of weight equal to 20 cwt., or 2240 lbs. avoirdupois. *Ton* is also the name of an English measure of capacity containing 252 gallons; but when used in the latter sense, the word is usually written *tun*.

TONDI'NO. (Ital.) In Architecture, the same as *astragal*, which see.

TONE. (Gr. τονος.) In Music, a property of sound which brings it under the relation of grave or acute, or the gravity or acuteness it may have from the number of vibrations of the sonorous body producing it. It is more particularly used for expressing that degree or interval of time by which sounds may be raised or lowered from one extreme of concord to another, so as still to produce melody.

TONES, ECCLESIASTICAL. In Music, the eight modes, now generally called the Gregorian Chant, in which the service of the Catholic church is performed; four whereof are authentic, and four of them plagal. Pope Gregory has been considered the inventor of them. They are the foundation of all music, and will ever be considered stupendous monuments of composition.

TONGUE. In Architecture. *See* GROOVE.

TONGUE. In Anatomy, the organ of taste; a soft fleshy viscus, moveable in all directions, composed of muscular fibres covered by a nervous membrane, upon which, especially at the tip and sides, are numerous nervous papillæ. The tongue is largely supplied by blood vessels, its arteries being branches of the ranine and labial, and its veins emptying into the great linguals which proceed to the external jugular; the nerves come from the fifth, and eighth, and ninth pairs. The tongue performs important functions, not only in tasting, but in articulating, and in eating or chewing or swallowing food, and in receiving drink.

TO'NIC. (From *Tone*.) In Music, the principal note of the key. It is the chief sound upon which all regular melodies depend, and in which they all terminate. Its octaves, both above and below, are equally called by the same name. It is, however, to be understood that the termination here alluded to has relation only to the chief melody, or to its bass, inasmuch as the inner or mean parts of the harmony conclude on the third or mediant, and the fifth or dominant.

TO'NICS. (Gr. τονοω, *I strengthen*.) Medicines which strengthen and increase muscular action. To this class belong vegetable bitters, stimulants, astringents, &c.

TO'NNAGE, implied originally the number of tons weight a vessel might safely carry. Prior to January, 1836, the rule established by act of parliament for the measurement of the tonnage of ships was founded on erroneous principles, and led to the most mischievous consequences.

By considering the breadth and depth nearly the same, the rule implied the square of the breadth; and hence increasing the breadth of a vessel increased her *nominal* tonnage for the payment of dues more than it increased her real capacity. Under this pernicious system vessels came to be built narrow and deep; and thus not only less efficient, but highly dangerous. In 1823 a committee, of which the celebrated Dr. T. Young was chairman, proposed to measure the internal capacity by taking the breadth and depth at each quarter of the length; but for some reason no step was taken. In 1832 another committee was appointed to consider the subject; and they concluded their labours in 1834 by recommending the method of Mr. Riddle, of the Royal Hospital, Greenwich. Mr. Riddle inferred that since a great number of direct measures for capacity would afford a result very near the truth, an approximation might be obtained by means of a smaller number of measures, provided additional weight was given in the calculation to those dimensions which extend through a greater part of the hull. He obtained the multipliers of these dimensions, the midship breadth and depth, by trial, from the vessels measured for the guidance of the committee; and the method is therefore founded on an arithmetical fact. The rule, briefly expressed, is as follows:—

Divide the upper deck, between the after part of the stem and the fore part of the sternpost, into six equal parts. At the foremost, middle, and aftermost points of division, measure, in feet and decimals, the depths from the under side of the upper deck to the ceiling at the limber strake. Divide each depth into five equal parts, and measure the inside breadths at 1-5th and 4-5ths (from the upper deck) at the two extreme depths, and at 2-5ths and 4-5ths of the midship depth. Measure the length, as above, at half the midship depth. To twice the midship depth add the extreme depths, for the sum of the depths. To the upper and lower breadths at the foremost division add three times the upper and lower breadths at the midship division, and the upper and twice the lower breadth at the aftermost division, for the sum of the breadths. Multiply the sum of the depths by the sum of the breadths, and the product by the length, and divide this product by 3500; the result is the tonnage for register.

In vessels with a poop or a break in the upper deck, measure the mean length, breadth, and height; multiply these together, and divide by 92·4, and add the result to the former quantity. In open vessels, the depth is measured from the upper edge of the upper strake. In steam vessels, the tonnage due to the content of the engine room (the depth being considered as the midship depth, and the breadth that at 2·5ths of this depth), divided by 92·4, is to be deducted.

The relative capacities of ships are determined very nearly by this method; that is, within little more than 4 or 5 per cent. generally, though, in extreme cases, the difference may amount to 10 or 12 per cent.: even this, however, is insignificant, as compared with the usual errors of the former method. The divisor by which cubic content is reduced to nominal tonnage was adopted, merely that while the reputed tonnage of most kinds of vessels would be corrected by the new rule, the total registered tonnage of the kingdom might remain unaltered. By the new method the dues paid on tonnage are proportioned to the capacities of the vessels; and as no advantage is gained in these respects by defective forms, a marked improvement in merchant vessels has followed the passing of the bill in 1835.

TONSILLI'TIS. Inflammation of the tonsils. *See* QUINSEY.

TONSILS. (Lat. tonsilla.) An oblong suboval gland on each side of the fauces, and opening into the cavity of the mouth by several large ducts.

TONTINE, a term derived from the name of the inventor Tonti, signifying a loan raised on life annuities with the benefit of survivorships. *See* ANNUITIES.

TOO'THING. In Architecture, bricks alternately projecting at the end of a wall, in order that they may be bonded into a continuation of it when the remainder is carried up.

TOP. In Naval Language, a small light platform near the lower mast-head.

TO'PARCHY (Gr. τοπος, *a place*, and αρχη, *government*), in Antiquity, signified a small state or lordship consisting only of a few cities or towns; or a petty country under the sway of a toparch. Thus Judæa was anciently divided into ten toparchies.

TO'PAZ. (Gr. τοπαζιον.) A crystallized mineral harder than quartz, of a yellow or wine colour, composed of 60 alumina, 35 silica, 5 fluoric acid. When heated, the Brazilian topaz becomes rose red, and is sometimes in this state passed off as a ruby; the Saxon topaz loses its colour by heat. When without flaws and of a good colour, it is much employed in jewellery. The Saxon is usually paler than the Brazilian, which often has a pinkish hue; the Siberian topaz is usually colourless, and the Scotch has a blue tinge.

TOPA'ZOLITE. (Gr. τοπαζιον, and λιθος, *a stone*.) A subvariety of garnet of a pale yellow colour, found in Piedmont. It is a silicate of alumina, lime, and iron, with traces of glucina and manganese.

TOPCHAINS. Chains used in action, by which the lower yard is hung in case of the slings being shot away.

TOPGALLANT. That which is above the topmast.

TO'PHET. A polluted unclean place near Jerusalem, into which the Jews used to throw the carcasses of beasts, or the bodies of men to whom they refused burial; and

where a fire was perpetually kept up to consume all that was brought. Hence Tophet is sometimes used metaphorically for hell. This place had also been defiled by human sacrifices which had been offered to Moloch. Hence Milton says of this hideous deity, that he

. . . . made his grove
The pleasant valley of Hinnom: Tophet thence
And black Gehenna called, the type of Hell.

The name is derived by some from Heb. toph, *a drum*, on account of the beating of drums and other instruments by which the cries of the children sacrificed to Moloch were stifled.

TO'PHUS. A soft tumour upon a bone. In Mineralogy, the term *tophus* has been applied to porous deposits of calcareous matter from water.

TO'PICS. (Gr. τοπος, *a place*.) In Rhetoric. By abstracting from a proposition which conveys a truth in the concrete (*i. e.* respecting certain circumstances expressed in the terms of the proposition) a portion of those circumstances denominated accidental, we arrive at the same truth in the abstract, or (in stricter language) more widely applicable, and accommodated to many different sets of accidental circumstances. Thus, for example, in jurisprudence, from an investigation of the truth in various insulated cases in which a too strict application of legal principles has been attended with evil effects, we deduce the general truth that such application is so attended; or, in the proverbial phrase, "summum jus summa injuria." Among the helps employed by the ancients in their favourite study of rhetoric was the collection and arrangement of a great variety of such general truths, according to the several sciences or subjects to which they belonged. These they termed *topoi*, or places; from which the modern term *topic* is derived. They considered it useful for the student in rhetoric to have at hand, by means of his memory, those compendious expressions of universal sentiment, and the general reasonings or declamations applicable to each of them, in order to employ them for particular use by performing the converse of that operation by which they were arrived at; viz. clothing them with the particular circumstances of the case. Thus the topos just cited might be useful to the forensic orator; it affords a subject for reasoning and declamation applicable to a great number of individual instances. Many of these topics answer to what in modern phrase we should term axioms; and, indeed, some of the axioms of pure mathematics are enumerated by Aristotle among the topics which are proper to every species of oratory.

TOPO'GRAPHY. (Gr. τοπος, *a place*, and γραφω, *I describe*.) Strictly the description of a place, or the science of describing places (distinguished from *chorography* or the description of a district, and from *geography*, the description of the earth.)

TOPPING LIFT. A rope for raising the end of any yard or boom.

TOP, SPINNING. A well-known toy. The steady motion which a well-spun top soon acquires suggested to Mr. Sisson, about eighty years ago, the employment of a mirror placed upon it at right angles to its axis, as an artificial horizon which might probably be used at sea; and on sending out the first of the late polar expeditions, the attention of Mr. Troughton was turned to the subject. But though useful observations might have been made on land with the instrument which he constructed, it was not found at sea to give results of any practical value; and we are not aware that any further attempts have been made to improve its construction, which is attended with considerable mechanical difficulties.

TOREU'MATO'LOGY (Gr. τορευμα, *sculpture*, and γραφω, *I describe*), signifies either the science or art of sculpture, or a description of ancient and modern sculpture and bas relief.

TOREU'TIC. (Gr. τορευτος, *polished*.) In Sculpture, a term applied to such objects as are executed with high finish, delicacy, and polish; but properly to all figures in hard wood, ivory, &c.

TO'RMENTIL ROOT. The root of the *Potentilla tormentilla*. It is occasionally used in medicine as an astringent.

TORNA'DO. (Spanish.) A violent hurricane or gust of wind, which, arising suddenly from the shore, veers round to all points of the compass, and indeed has been described as blowing from all points at once. Tornadoes are usually accompanied with thunder storms, and are generally of short duration. They are frequent in the Chinese seas and the West Indies. *See* STORMS.

TORNATE'LLA. A genus of oval marine Univales belonging to the *Plicaceæ*, found in the oolite and superjacent strata. Recent tornatellæ are found in shallow water, creeping upon and furrowing the sand.

TORPE'DO. (Lat. torpedo, *numbness*.) A genus of Cartilaginous fishes, separated from the *Raiæ* of Linnæus on account of the circular form of the body, and more especially from the presence of the electrical organs on which that form of the body mainly depends. Violent shocks are experienced on touching the living and active torpedo. It is probable that it exerts its electrifying or benumbing powers in order to secure its prey; and it is certain that the same power is employed in defending itself against assailants, to whose assaults it would be otherwise more exposed than are the ordinary rays; for the torpedo has a smooth skin, and is not defended by the spiny tubercles, or barbed and pointed bony weapons, with which the non-electric rays are provided.

TORQUES. In Antiquities, a chain or collar formed of a number of small ringlets interlaced with each other, framed of metal, and worn round the neck. No ornament perhaps was of more early or general use. It is mentioned in Genesis, xli. 42., as one of the ornaments conferred by Pharaoh on Joseph. It was in use among the Greeks and Romans, but peculiarly among the Celtic nations. The legends respecting the torques of the Gauls who invaded Rome are well known. It was from his victory over a Gaul that T. Mantius Torquatus derived his surname. (*Livy*, lib. vii. ch. 10.) And no relic is more commonly found in this country by antiquarian explorers. Boadicea wore a large golden torques. (*Dio. Cass.* lxii.) See the *Archæologia*, vol. xiv. p. 97. and *passim*, for descriptions of particular specimens.

TORREFA'CTION. (Lat.) The operation of roasting ores to deprive them of sulphur, arsenic, or other volatile ingredients. When drugs are highly dried, or partially toasted or roasted, they are also said to be torrefied.

TORRICE'LLIAN VACUUM. In Physics, the vacuum produced by inverting a tube of sufficient length, filled with mercury or any other fluid, in a vessel containing a portion of the same fluid, and allowing the fluid in the tube to descend until its weight is counterbalanced by that of the atmosphere. In this manner the first barometers were formed by Torricelli, and thence called *Torricellian tubes*. *See* BAROMETER.

TO'RRID ZONE. In Geography, the zone of the earth included between the tropics of Cancer and Capricorn. It extends from the equator, on both sides, to the parallel corresponding to the sun's greatest declination, about 23½ degrees. *See* ECLIPTIC, ZONE.

TO'RSION (Lat. torsio; from torqueo, *I twist*), in Mechanics, is the twisting or wrenching of a body by the exertion of a lateral force. If a slender rod of metal suspended vertically, and having its upper end fixed, be twisted through a certain angle by a force acting in a plane perpendicular to its axis, it will, on the removal of the force, untwist itself, or return in the opposite direction with a greater or less velocity, and, after a series of oscillations, will come to rest in its original position. The limits of torsion within which the body will return to its original state depend upon its elasticity. A fine wire of a few feet in length may be twisted through several revolutions without impairing its elasticity; and within those limits the force evolved is found to be perfectly regular, and directly proportional to the angular displacement from the position of rest. If the angular displacement exceeds a certain limit, the particles of the body will be wrenched asunder; or if the elasticity is not perfect (as in a wire of lead, for example) before disruption takes place, the particles will assume a new arrangement, or *take a set*, and will not return to their original position on the withdrawal of the disturbing force.

The resistance which cylinders or prisms formed of different substances oppose to torsion, furnishes one of the usual methods of determining the elasticity and strength of materials; and the property which a metallic wire or thread stretched by a small weight possesses of becoming twisted and untwisted in a series of isochronous and perfectly regular oscillations, has been ingeniously applied in the torsion balance to the measurement of very minute forces, and thereby to the establishment of the fundamental laws of electricity and magnetism, and to the determination of the mean density of the earth. *See* BALANCE OF TORSION.

The laws of torsion have been experimentally investigated by Coulomb in a variety of substances; as metallic wires, hairs, fibres of silk, &c. The method which he employed consisted in attaching a body of given form and dimensions to the extremity of the wire, and, after twisting it through a certain angle, to abandon it to the action of the force evolved, and observe the time of the oscillations. The following general laws were found to hold good:—

1. On loading a wire or thread with different weights, it will settle in different positions of stability; that is to say, an index attached to the weight will point in different directions if the weight be varied, and the angular deviation may amount even to a whole circumference.

2. The oscillations are isochronous.

3. The time of oscillation is proportional to the square root of the weight which stretches the wire.

4. The time of oscillation is as the square root of the length of the wire.

5. The time of oscillation is inversely as the square of the diameter of the wire.

From the second of these laws it follows that when the wire is twisted round from the position of rest, the force with which it tends to return to that position is proportional to the angle to be described in order to attain it. For it is a general result of mechanics, that all motions produced by forces acting according to this law have the property of tautochronism; that is to say, the oscillations are performed in equal times, whatever be the length of the arc. This fundamental property is usually enunciated by saying that the force of torsion is proportional to the angle of torsion.

Let F denote the force of torsion, measured by the weight which it would be necessary to apply by means of a pulley to a point p, situated at the unit of distance (one inch) from the axis of the wire, and invariably connected with it, to cause the point p to describe an arc of a circle equal in length to the unit of distance; then, by the property enunciated, the force which must be applied at p in order that the point may describe any arc ϕ is expressed by $F \cdot \phi$. If the arc of torsion is expressed in degrees instead of parts of the radius, we have $\phi = \pi \phi^{\circ} \div 180^{\circ}$ (π being the semicircumference to radius 1, or $= 3 \cdot 14159$); whence the expression of the force becomes $F \times \pi \phi^{\circ} \div 180^{\circ}$.

On this principle of the proportionality of the impelling force to the angle of deviation the problem of determining the time of an oscillation is solved. Suppose a body of any form attached to the extremity of a slender wire, whose weight in comparison of that of the body may be neglected, and let $d\,m$ be an element of the mass, r the distance of $d\,m$ from the axis of the wire, and T the time of an oscillation; the solution of the problem gives

$$T = \pi \sqrt{\left(\frac{\int r^2\,d\,m}{F}\right)}, \text{ or } T^2 = \pi^2 \frac{\int r^2\,d\,m}{F}.$$

The integral $\int r^2\,d\,m$ is the *moment of inertia* of the attached body. If the body be a cylinder whose axis coincides with that of the wire, and if a denote its radius and M its mass, then $\int r^2\,d\,m = \frac{1}{2} M a^2$; or, substituting the weight for the mass, and observing that if the weight be denoted by P, and the accelerating force of gravity by g ($= 32 \cdot 1908$ feet or $386 \cdot 2894$ inches in a second), we have $P = M g$, $\int r^2\,d\,m = P a^2 \div 2 g$. Hence the expression for the time becomes $T = \pi a \sqrt{\frac{P}{2 g F}}$.

If the attached body were a slender cylindrical needle suspended horizontally by its middle to the wire, we should, on denoting its length by l, have $\int r^2\,d\,m = \frac{1}{3} M l^2$; whence $T = \pi l \sqrt{\frac{P}{3 g F}}$.

The following results are deduced from the formula:— 1. The force of torsion is independent of the weight which stretches the wire, or F remains constant while P is varied. For suppose P to become P', and let T' be the corresponding time of oscillation, and F' the corresponding force; we have then

$$T^2 = \frac{\pi^2 a^2 P}{2 g F}, \quad T'^2 = \frac{\pi^2 a^2 P'}{2 g F'};$$

whence $T^2 : T'^2 :: P F' : P' F$. But, by the third experimental law, $T^2 : T'^2 :: P : P'$; therefore $F' = F$.

2. The force is inversely as the length of the wire. For, supposing P to remain constant, we have $T^2 : T'^2 :: F' : F$. But, by the fourth experimental law, $T^2 : T'^2 :: l : l'$; whence $F' : F :: l : l'$.

3. The force is proportional to the fourth power of the diameter of the wire. Let there be two wires of the same substance, but of different diameters, D and D', and stretched by the same weight P; and let T and T' be the corresponding times. By the fifth experimental law, we have $T : T' :: D'^2 : D^2$. But it has been shown that $T^2 : T'^2 :: F' : F$; therefore $F : F' :: D^4 : D'^4$.

To show the method of applying the formulæ, we shall compute one of the experiments of Coulomb. An iron wire was stretched by a vertical cylinder of ·8 of an inch radius, and weighing 2 lbs., and it was observed to make 20 oscillations in 242 seconds, or one in 12·1 seconds. It is proposed to determine the force F. From the formula for the time of an oscillation we have, by transposition, $F = \frac{\pi^2 a^2 P}{2 g T^2}$. Substituting numbers in this formula, we have $\pi^2 = 9 \cdot 8696$, $a^2 = \cdot 64$, $P = 2$, $g = 386 \cdot 2894$, $T^2 = (12 \cdot 1)^2 = 146 \cdot 41$; consequently $F = \frac{12 \cdot 633}{113113} = \cdot 0001117$ of a pound, or about ·78 of a grain. Hence the weight applied at the distance of one inch from the axis of the wire that would be required to twist the wire through a complete revolution, or 360°, is 6·283 times this quantity, or nearly five grains.

For the demonstration of the fundamental formula, namely, $T^2 F = \pi^2 \int r^2\,d\,m$, see Coulomb, *Théorie des Machines Simples*; or Biot, *Traité de Physique*, tom. i.

TORSO. (It.) In Sculpture, a statue of which nothing but the trunk of the human figure remains.

TORT. (Fr. wrong.) In Law, signifies injustice or injury.

TORTOISE. This name is usually applied to species of that division of the Linnæan genus *Testudo* including the terrestrial Chelonians, to which the generic name is now limited. *See* TESTUDO.

TORTOISE SHELL. The name given to the horny scutes or plates of the sea turtles; and in particular to those of the hawk's-bill turtle, *Chelone imbricata*.

TORTRI'CES. (Lat. torqueo, *I wreath.*) The name of a tribe of nocturnal Lepidopterous insects, comprising those the larvæ of which live concealed in leaves, which they roll around them for the purpose.

TO'RTURE. (Lat. torqueo, *I twist* or *torment.*) In a legal sense, the infliction of pain on an accused person in order to extort an avowal of guilt, or revelation of accomplices. Such a practice is sufficiently common among all half-civilized nations; but the Greeks and Romans were perhaps the first who introduced it as a part of their regular proceedings in criminal cases. Both at Athens and Rome torture was, however, considered as applicable only to extort evidence from slaves: towards them it was used profusely; and it was, in fact, a usual occurrence to order a whole family of slaves to the torture, in order to extract revelations where an atrocious crime had been committed, as, for instance, the murder of the master. Cicero, in several passages, condemns the use of torture; and Ulpian (Lex i. *De Quæstionibus*) says, "Res est fragilis et periculosa, et quæ veritatem fallit, nam plerique patientiâ sive duritiâ tormentorem ita et tormenta contemnunt, ut exprimi eis veritas nullo modo possit; alii tantâ sunt impatientiâ ut quid vis mentiri quam pati tormenta malint." (As to the torture at Rome, see *Gibbon*, vol. ii. p. 59. 4to ed.) Notwithstanding these recorded opinions of the highest luminaries of ancient jurisprudence, torture was adopted along with the rest of the process of the civil law in most European countries. (For its use in France, see QUESTION.) The general principle of the civilians was, that it could not be used unless *vehement suspicion* warranted its application. But no very definite meaning was attached in practice to these words; especially in Germany, where the abuse seems to have been carried to the greatest extent by the ignorant and cruel tribunals of her smaller states. When Howard visited the prisons of that country (about 1770), it was still in general use. (See his *Account of Prisons.*) The writings of various philosophical authors of the 18th century, especially Voltaire, Thomasius, and Beccaria (whose short treatise, *Dei Delitti e delle Pene*, obtained such singular notoriety), effected much towards bringing its employment into disrepute; but its general abolition can only be attributed to the superior regard for the rights of man introduced every where by the agitation of the French Revolution. In England, judicial torture was not recognized by the common law (for the peine forte et dure hardly falls within the same definition); and that it was also nearly unknown in practice, in the 14th century at least, may be inferred from the reluctance of Edward II. to submit the Templars to torture, which was overcome by the instances of Pope Clement V., and from a curious paper of questions addressed on that occasion by the archbishop of York to some divines, from which it appears that *no torturer could at that time be found in England.* (See Raynouard, *Mémoires sur les Templiers; Hallam's Constitutional History.*) The rack is said to have been introduced as an engine of state by the Duke of Exeter in the reign of Henry VI. However this may be, during the whole of the 16th century we find that the privy council assumed and exercised the right to direct torture-warrants to the lieutenant of the Tower and other officers, commanding them to submit to the torture persons accused not only of state offences, but of ordinary municipal crimes, when strong suspicion, but no sufficient evidence, existed. Torture-warrants were also issued, not by the council, but under the sign manual only. During this period the council seems, in fact, to have acted as a supplementary tribunal in aid of the regular courts, for the purpose of extorting discoveries of criminal offences. The instances of torture of seminary priests, &c., in Elizabeth's reign, have been often cited; but it is not so generally known that the practice was not confined to accusations of treason and sedition, but extended to other cases. (See *Jardine's Reading on the Use of Torture in England*, 1837.) Under James I. and Charles I. torture seems to have become less frequent, and to have been only employed in state offences; and this, perhaps, explains the well-known answer of the judges to Charles's question respecting Felton, the murderer of the Duke of Buckingham, that he ought not to be tortured, "for no such punishment is honour to our law." The last recorded case is that of William Archer, 1640; and as in that year the act for the abolition of the Star Chamber

granted a habeas corpus to all persons detained on warrants from the privy council, torture must then have been virtually abolished. In Scotland it was so in the 7th year of Anne.

TO'RUS. (Lat. *a rope.*) In Architecture, a large moulding used in the bases of columns, the profile whereof is semicircular. This term is also used in botany for the central part of the flower on which the carpels are placed.

TORY. A well-known party name in English history. (*See* WHIG.) The Irish malecontents, half robbers and half insurgents, who harassed the English in Ireland at the period of the massacre in 1640 and during the troubles which followed, were the first to whom this name was applied. It is said to have been transplanted into England about the time of the Popish Plot, when the public mind was agitated by chimerical fears respecting the apprehended employment of Irish Catholics to further that imaginary design; whence it was commonly applied by way of reproach to the court party, against which the popular hostility was then directed, as favouring and countenancing the supposed abettors of the plot. From the period of its introduction into England down to the present times the term Tory has been constantly employed to designate a large political party in this country. Down to the period when Hume wrote his *Essay on the Parties of Great Britain*, the conduct of the two great parties in the state (the Whigs and Tories) had been so vague and undetermined as to have led him to declare his utter inability to tell their nature, pretensions, and principles. Since that period, however, the conduct of the Tories has been more uniform; and it might now be easier to define the principles by which they have been guided during the last half century: but we shall not undertake the task. Within the last two or three years, the word Tory has been gradually displaced by *Conservative*, which seems likely to become the permanent designation of the Tory party. This term was originally assumed in contradistinction to *Destructives*, a name by which the more violent reformers came to be designated by their enemies; and it is now understood as referring to the whole Tory party, but more especially to what may be called the more liberal portion of that party.

TOTIPA'LMATES, *Totipalmati.* (Lat. totus, *entire*, and palma, *a palm.*) The name of a tribe of *Palmipedes*, or swimming birds, including those in which the hinder toe is enveloped in the same web with the three anterior toes.

TOUCH. In Medicine. The belief in the possibility of curing various maladies by the touch has produced a variety of singular superstitions. Plutarch attributes singular virtues to the touch of King Pyrrhus of Epirus. According to Suetonius, Adrian and Vespasian had the power of curing various diseases in the same manner. In what period the opinion respecting the virtue of the touch of the kings of France and England in curing epilepsy, scrophulas, &c. had its origin, it is difficult to ascertain. André Dulaurent, chief physician of Henry IV. of France, published a treatise on the subject. The ceremony of touching, by the kings of France, was practised at the four great feasts of the year; sometimes as many as 1500 were touched at a time. By an odd etiquette, the Spaniards had the first rank, then other foreigners, and the French last of all. The formula used at each imposition of the royal hand was, "Le roi te touche, et Dieu te guerit." Polydore Virgil attributes this virtue to Edward IV., and all our kings down to the end of the Stuart dynasty touched for the king's evil. Much efficacy has been attributed in different diseases, particularly tumours, &c., to the touch of the hand of a dead body; especially, according to Pliny and various modern authorities, of one who had died violently. We do not know whether the superstition is yet extinct under the influence of which scrophulous persons used to have themselves touched by the hands of criminals after execution. Boyle endeavours to explain away part of the miracle by attributing some virtue to the coldness of the application.

TOUCH. One of the five senses, resident in the nervous papillæ of the skin; it is also the sensibility diffused over the whole body. It is much more exquisite in some parts than others.

TOUCH. In Naval language, the sails are said to *touch* when the wind comes edgeways upon them.

TOUCH NEEDLES. Small bars, consisting of gold and silver alloyed with various definite proportions of copper, are thus termed by assayers, who use them to judge, by comparing their colour and streak upon a piece of hard black stone, such as basalt, with that of alloys of the precious metals, of the relative quantity of gold or silver in the latter. Hence also the term *touchstone*.

TOU'RMALINE. The more perfect forms of *schorl* go under this name. It is the *lyncurium* of the ancients. Its chief constituents are silica and alumina, with about 10 *per cent.* of soda, and a little oxide of manganese and of iron. The transparent coloured varieties are sometimes cut into ring-stones, and some of them are much valued for experiments on the polarization of light.

TOURN, in Law, was the turn or circuit anciently made thrice every year by the sheriff, for the purpose of holding in each hundred the great court leet of the county. The jurisdiction exercised by the sheriff on his tourn extended by the common law to the cognizance of all offences not capital; but sheriffs are prohibited by Magna Charta from holding any pleas of the crown in which they had a pecuniary interest in procuring a conviction; while a better tribunal was at the same time supplied by the establishment of annual circuits. The tourn, though never disallowed by law, has, with the curtailment of its jurisdiction, and the abandonment of the leet as a registry of pledges, long fallen into disuse; and the right of the jury or suitors at the tourn to present nuisances, or convict of minor offences, has, with other functions of courts leet, been transferred to the quarter sessions.

TOU'RNAMENT (in modern Latin torneamentum), or TOURNEY; originally derived from the Fr. tourner, modern Latin tornare, *to turn.* A well-known military sport of the middle ages, which without doubt arose from the exercises of military training. A joust or just is, properly speaking, the encounter of two knights in this species of exercise; the tournament, an assembly held for the purpose of exhibiting such justs, or the encounter of several knights on a side. The earlier tournaments were highly dangerous and sanguinary sports. They were performed with the ordinary weapons of warfare, the lance and the sword; and the combatants had only the strength of their armour to rely on for their defence. It was a recognized custom, according to Meyrick (*Hist. of Ancient Armour*), that whoever slew or disabled an adversary in the tournament was indemnified against all consequences. The account of the tournament given by the Count of Chablais in Savoy to Edward I. on his return from Palestine to England, as given by Thomas de Walsingham, represents a sort of violent mêlée, in which knights, squires, and archers were engaged on both sides, endeavouring to unhorse the riders and overthow the footmen by every possible means. But in the course of time this chivalric amusement became the subject of minute regulations, which in some degree diminished the danger and insured the fairness of the sport. The English *Statuta Armorum de Torneamentis* are assigned by Dr. Meyrick to the year 1295. (*See* SAINTE-PALAYE.) "Impartial taste," says Gibbon, "must prefer a Gothic tournament to the Olympic games of classic antiquity." (*Decl. and Fall*, ch. 50.)

In tournaments, when under the strict regulation of knightly usage, two sorts of arms were employed: those expressly made for the purpose, viz. lances with blunt heads of iron; and the ordinary arms of warfare, termed "armes a outrance," which were only employed by such champions as were desirous to signalize themselves in a more than ordinary degree, and frequently were not permitted by the judges of the tournament. Every knight attending was required to show his noble birth and rank, as a title to admission. These were at first proclaimed by the heralds with sound of trumpet; and hence the word blazonry, which signifies the correct deciphering of the heraldic symbols on a coat of arms, is derived by some from the German blasen, *to blow.* Afterwards, when armorial bearings became general, the shield of the knight gave token of his rank and family. The attendance of ladies at the tournaments, their distribution of prizes to those who had borne themselves best, arming and unarming the knights, &c., are various romantic circumstances well known to the reader of chivalric legends; but they must not be supposed to have been the necessary, or even usual accompaniments of these knightly sports, at least until a later age, when the taste for gallantry, combining with that for show and spectacle, turned these military exhibitions of skill into little more than gorgeous pageants. When we arrive at the reigns of Edward III. and Henry V., we find the justs usually held in honour of ladies, and every knight bound to possess in reality or in show a dame of his affections, for whose sake all his deeds of chivalry were performed. Dr. Meyrick quotes from a manuscript of the reign of Elizabeth the ordinances of justes, made by John Earl of Worcester, constable of England, in the sixth year of Edward IV.; from which it appears that the law of justs had become by that time the subject of very minute regulation. The prize belonged to him who broke most spears "as they ought to be broken;" *i. e.* on the head or body of the antagonist. From Stow we find that the lists erected in Smithfield in 1467, when the Bastard of Burgundy challenged Lord Scales, were 380 feet in length by 260 in breadth: these champions rode at each other two days with spears, and on the third encountered on foot with pole-axes. In the reign of Henry VIII., when the real spirit of chivalry was far advanced in its decline, the tournament was invested almost wholly with the character of a court pageant, but celebrated with a degree of splendour and costliness scarcely equalled in

former times. The famous volumes of woodcuts of the same period, styled the *Triumphs of Maximilian*, show that it was as favourite and almost as magnificent a spectacle at the court of Germany. The tragical death of Henry II. of France, in consequence of a blow received in a tournament, is well known, and was the cause of the final, although only gradual abolition, of this knightly amusement; which was revived at intervals in court solemnities in the seventeenth century, but rather as a memorial of past times than as a subsisting and popular custom.

The revival of the tournament was recently attempted in the west of Scotland by the Earl of Eglinton; but we scarcely suppose that the success of that attempt was either commensurate with its deserts, or was such as to induce any party to renew it. At the court of Wurtemburg tournaments are not unfrequently exhibited at this day.

See Sainte-Palaye, *Memoires sur la Chevalerie; Turner's History* (*Middle Ages*), vol. i. p. 472.; *Hist. de l'Ac. des Inscr.* vol. xix.; and Walter Scott's admirable delineation in *Ivanhoe*, which gives a more vivid idea of the tournament, with all its variety of martial exercises, than any serious work extant.

TOU'RNIQUET. (Fr.) A bandage which may be tightened to any extent by means of a screw, so as to exert pressure upon a cushion and compress the arterial trunks to which it is applied: it is chiefly used to prevent hæmorrhage in the operations of amputation.

TOW. To draw a vessel along by a rope. As the vessel towed affects the motions of the other, much attention is required on her part to second the intentions of the towing vessel.

TOWER. (Lat. turris.) In Architecture, a lofty building, square, polygonal, or circular on the plan, and often consisting of several stories. The tower of a church is that part which contains the bells, and from which the steeple rises.

TOWERS, ROUND. In Ireland, remarkable edifices of extreme antiquity, of which the origin has perplexed antiquaries to an unexampled degree. They are tall narrow edifices, varying in height from 80 to 120 feet. That at Kildare, we believe, is the highest; cylindrical in shape, with a door 8 or 10 feet from the ground, and narrow apertures at the top. There are sixty-two of these curious relics ascertained to exist in Ireland; and two in Scotland, at Abernethy and Brechin. They cannot have been watch-towers, their position being generally low; nor belfries, their shape and construction rendering such a supposition impossible, although some appear to have been used in that way in later times; and the notion that they were places of confinement for penitents or hermits seems extravagant. Common belief, however, attaches to them an ecclesiastical origin and use; and the well-known passage of Giraldus Cambrensis, a writer of the 12th century (who says that the fishermen of Lough Neagh reported that in clear weather remains of buildings, and among others round towers of the country fashion, were seen at the bottom), necessarily implies a greater antiquity. Irish antiquaries, however, as may be supposed, have luxuriated in hypotheses connecting them with ancient forms of pagan worship; such as the pyrolatry of the Persians, the Phallic rites, &c. (See *Moore's History of Ireland*, vol. i. ch. 2., for a variety of these opinions, and their authors.)

TOXICO'LOGY. (Gr. τοξικον, *poison*, and λογος, *a discourse*.) Poisons have been divided by Orfila and Christison into irritants, narcotics, and narcotico-acrids: the first class including those whose sole or predominating symptoms are those of irritation or inflammation; the second, those which produce stupor, delirium, and other affections of the brain and nervous system; and the third, those which are of a mixed character.

The chief effects of *irritants* are upon the alimentary canal, exciting inflammation, and sometimes ulceration of the tongue, fauces, and œsophagus, difficult deglutition, nausea, vomiting, and heat and pain of the stomach, with more or less tension of the abdomen, and pain on pressure. The sickness is generally accompanied by extreme anxiety and anguish, and the matters vomited consist, in the first instance, of any food that may have been in the stomach, with portions of the poison itself, and afterwards of viscid mucus, often streaked with blood and tinged with bile; the pain afterwards extends throughout the intestines, and mucous, bilious, and often bloody diarrhœa succeeds. The skin is cold and clammy, the pulse quick and feeble, the breathing often difficult, and the countenance expressive of extreme anxiety.

Narcotic poisons induce a train of symptoms of a very distinct character: headach, vertigo, confused vision, stupor, convulsions, paralysis, and coma, are their leading effects; but each particular poison is usually attended by certain peculiarities in the succession, violence, or generic character of the symptoms, which assist the experienced practitioner not only in determining the nature of the poison, but in discriminating between its effects and those of disease.

The symptoms of the *narcotico-acrid poisons* usually consist of those of the two former classes blended, and are often of a very complicated character; for the most part, however, their narcotic and irritant effects appear to be incompatible. In large doses, narcoticism predominates; in smaller, irritation: it is rarely that both are coexistent.

In the following tabular view of the principal poisons of the above classes, they are enumerated in the order in which they are described by Dr. Christison, to whose *Treatise on Poisons* the reader is referred for details which would be quite incompatible with the space which can be allotted to the subject in this work. Under the heads, however, of many of the individual substances mentioned in the following list, we have elsewhere given particulars respecting their composition and properties, and sometimes referred to their toxicological history.

I. Irritant Poisons.

Mineral acids.	Arsenic and its compounds.
Phosphorus.	Mercurial compounds.
Acetic acid.	Salts of copper.
Oxalic acid.	Antimonial poisons.
Fixed alkalies.	Salts of tin.
Nitre.	Salts of gold.
Alkaline and earthy chlorides.	Salts of silver.
Lime.	Salts of bismuth.
Ammonia and its salts.	Salts of chromium.
Alkaline sulphurets.	Salts of zinc.
Barytes.	Lead poisons.
Vegetable acrids.	Diseased and decayed animal matter.
Cantharides.	Mechanical irritants.
Venomous serpents.	

II. Narcotic Poisons.

Opium.	Hydrocyanic acid.
Hyoscyamus.	Carbazotic acid.
Lactuca.	Poisonous gases.
Solanum.	

III. Narcotico-acrid Poisons.

Nightshade.	Strychnia.
Thornapple.	Cocculus Indicus.
Tobacco.	Upas.
Hemlock.	Poisonous fungi.
Monkshood.	Poisonous grain.
Hellebore.	Alcohol.
Squill.	Ether.
Meadow saffron.	Empyreumatic oils.

The treatment of cases of poisoning must, of course, vary with the nature of the poison, the quantity taken, and the peculiarities of the individual. In almost all cases, copious vomiting should be excited as soon as possible by tickling the throat, and by emetics, such especially as sulphate of zinc, or ipecacuanha with emetic tartar; the former, however, in ten-grain doses dissolved in a little warm water, and repeated every ten or fifteen minutes till it freely operates, is generally most effectual. The use of the stomach-pump should also be resorted to. The vomiting should be kept up, and the stomach washed out with bland albuminous or mucilaginous fluids, such as milk, barley-water, flour and water, or thin paste, &c.; sometimes sugar and water.

The following is a short summary of the antidotes which may be resorted to, in reference to particular poisons. They should, of course, be administered as speedily as possible.

1. For *Mineral Acids*, or *Acetic and Oxalic Acid:* Chalk, or whiting and water; magnesia and water; soap and water; followed by albuminous diluents, such as milk, and white of egg mixed with water.

2. *Alkalies, Soda, Potash, Ammonia, &c.:* Vinegar, or any mild acid and water, or even very dilute mineral acids, such as water acidulated by them; olive oil, almond oil.

3. *Arsenic:* Emetics; and then milk, gruel, thick barley-water, and other similar diluents, in large quantities.

4. *Corrosive Sublimate:* White of egg and water; milk and cream; decoction of cinchona; infusion of galls.

5. *Sulphate of Copper* and other *Cupreous Poisons:* Sugar and water; white of egg and water.

6. *Antimonial Poisons:* Warm milk, gruel, or barley-water; infusion of galls; decoction of cinchona.

7. *Nitrate of Silver:* Copious draughts of warm salt and water.

8. *Sulphate of Zinc:* Solution of carbonate of soda in water, with milk, and mucilaginous or farinaceous liquids.

9. *Acetate of Lead:* Emetics; solution of sulphate of soda in water; milk; white of egg and water.

10. *Opium and its Preparations:* Emetics; strong

coffee; dashing cold water upon the face and breast; preventing torpor by forced exercise.

11. *Prussic Acid:* Ammoniacal stimulants cautiously applied to the nose; ammonia, or sal volatile, in repeated small doses; small doses of solution of chlorine in water; small doses of chloride of lime in water.

12. *Strychnia* and *Vegetable Alkaloids:* Infusion of gall nuts; decoction of cinchona; emetics.

TO'XODON. (Gr. *τοξον, a bow*, and *οδους, a tooth.*) An extinct genus of quadruped connecting the Pachydermal with the Rodent order, and distinguished by the curved form of all its teeth. The only known species, *Toxodon platensis*, Owen, was as large as the hippopotamus, and appears to have been restricted to the warmer parts of South America.

TO'XOTÆ. (Gr. *τοξον, a bow.*) In Greek Military History, bowmen. In the Plays of Aristophanes, the toxotæ mentioned, like the French "archers," are a kind of police, employed to keep order in the assemblies of the people and on other public occasions.

TRA'BEA. In Roman Antiquities, the robe used at first by the kings, but afterwards by consuls and augurs. The purple *trabea* was used only on the occasion of great sacrifices. The second sort, of purple and white, was commonly worn by consuls on state occasions. A third, of purple and scarlet, was the dress of the augurs.

TRABEA'TION. (Lat. trabes, *a beam.*) In Architecture, the same as *entablature;* which see.

TRA'CHEA. (Gr. *τραχεια*, from *τραχυς, rough.*) The windpipe. A cartilaginous and membranous tube through which the air passes into and out of the lungs. Its upper extremity is called the *larynx*, and consists of five cartilages. The uppermost forms a kind of valve at the mouth of the larynx or glottis, and is called the *epiglottis:* it closes the passage in the act of swallowing. The sides of the larynx are formed by the *aretenoid* cartilages, and the anterior part of the *thyroid* and *cricoid* or annular cartilages: these may be felt under the skin in the front of the neck. These cartilages are united by elastic ligaments, and are acted upon by appropriate muscles, so as to modify the dimensions and form of the aperture in the act of speaking: they are moistened by a mucous secretion. The canal from the larynx downwards is called *trachea*, till it divides into two *bronchiæ* opposite the fourth or fifth dorsal vertebra. They are kept open for the free passage of the air by their elastic cartilaginous texture, which consists of rings with intervening membrane and muscular fibres.

TRACHEÆ, in Botany, are what are now called spiral vessels, which received that name in consequence of their being considered the respiratory tubes of plants. *Trachenchyma* is a tissue composed of tracheæ.

TRA'CHEARIES, *Trachearia.* (Gr. *τραχεια, the windpipe.*) The name of an order of the class *Arachnida*, including those which breathe by means of tracheæ.

TRACHE'LIDANS, *Trachelidæ.* (Gr. *τραχηλος, a neck.*) The name of a family of Coleopterous insects, comprising those which have the head supported on a kind of pedicle or neck.

TRACHE'LIPODS, *Trachelipoda.* (Gr. *τραχηλος*, and *πους, a foot.*) The name given by Lamarck to an order of Mollusks, comprehending all those which have a free and flattened foot attached to the under side of the part of the body which he considers as analogous to a neck. The order corresponds nearly with the Pectinibranchiate Gasteropods of Cuvier.

TRA'CHEOCELE. (Gr. *τραχεια*, and *κηλη, a tumour.*) A tumour upon the trachea; an enlargement of the thyroid gland. *See* BRONCHOCELE.

TRACHEO'TOMY. (Gr. *τραχεια*, and *τεμνω, I cut.*) The operation of making an opening into the trachea in cases of threatened suffocation.

TRACHI'NUS. (Gr. *τραχυς, rough.*) A genus of spiny-finned fishes, characterized by their compressed body and approximated eyes: two dorsal fins; the first short, and with spinous rays; the second long, and with flexible rays. The anal fin is very long; the operculum is armed with a long spine directed backwards. By the wounds which the species of *Trachinus*, usually called "weevers," inflict with their opercular spine, they have become formidable to fishermen of all nations; and it is said that the French have a police regulation, by which the fishermen are directed to cut off the spines before they expose the fish for sale.

TRACH'ITIS. Inflammation of the trachea.

TRA'CHYTE. (Gr. *τραχυς, rough.*) A variety of lava which is often porphyritic, and when containing hornblende and augite passes into the varieties of trap called basalt, greenstone, dolerite, &c.

TRACT, TREATISE. In Literature, both originally from the same Latin word tractatus; the latter through the French. It would be difficult to assign any reason for the difference in signification between two words identical in origin and etymological meaning; but the first is now commonly used to describe short compositions, in which some particular subject is "treated," generally in the form of a pamphlet; the latter more extensive works.

TRA'CTION. (Lat. traho, *I draw.*) The act of drawing, or state of being drawn. In Mechanics, the *angle of traction* is the angle which the direction of the power makes with a given plane.

TRACTORS, METALLIC. Small bars of metal which were supposed to possess certain magnetic powers, and to cure painful affections and tumours by being drawn over the part. They bore the name of their inventor, Perkins, and were in considerable vogue about thirty years ago. A number of wonderful cures, however, having been attested, which were performed by means of spurious wooden tractors, the imaginary virtues of the magnetic or metallic fell into disrepute, and then into oblivion.

TRA'CTORY, or TRA'CTRIX (Lat. traho, *I draw*), in the geometry of curve lines, is the curve characterized by this property, that the tangent is always equal to a given line. It was called the tractory by Huygens, because it may be considered as described mechanically by a small weight attached to one extremity of a thread, while the other extremity is drawn along a given straight line. But in order that the curve may be described in this manner, it is necessary to suppose the friction of the plane of traction to be infinite, or at least to destroy at every instant the momentum which is generated by the motion of the small weight, otherwise the direction of the motion of the describing point would not be a tangent to the curve. The tractory has much analogy with the logarithmic whose *subtangent* is constant. The evolute of the curve is the common catenary. (D'Alembert, *Ency. Methodique; Peacock's Examples*, p. 174.)

TRADE. *See* COMMERCE.

TRADE WINDS, are winds which in the torrid zone, and often a little beyond it, blow generally from the same quarter, varying, according to circumstances, from N.E. to S.E.

The cause of this wind is to be ascribed principally to the high comparative temperature of the torrid zone, combined with the rotation of the earth from W. to E. The heated air at the surface ascending into the higher regions of the atmosphere, its place is supplied by the colder air rushing from the poles; which also becoming rarified, ascends in its turn, and is carried in the upper regions towards the poles to supply the stream of the under current: these under polar currents moving in progress towards the equator from the zones where the earth's motion is slower to others where it is more rapid, acquire an apparent relative motion in a westerly direction. The currents from the two hemispheres meeting near the equator, their meridional motions are there destroyed, and they therefore advance together with the remaining motion from the eastward round the globe. The regularity of the trade winds is disturbed in some places by local causes, and chiefly by the superior rarefaction of the air over land heated by the sun's rays. They extend farther to the northward or southward according as the sun's declination is north or south; and in some places they become periodical, blowing one half of the year in one direction, and the other half in the opposite one. (*See* MONSOON.) In the great Pacific ocean, however, the trade wind blows with a uniform and gentle breeze all the year round. The name of *trade winds* was given them from their important influence in navigation. *See* WINDS.

TRADI'TION. (Lat. trado, *I deliver.*) A truth of doctrine or fact, delivered or handed down to one from another, and received on the faith that the first to whom it was so delivered received it from an authentic source. In common language, the word is used to signify records of facts preserved in the memory of successive persons or generations only, and not committed to writing. In Theology, tradition means, generally, that body of doctrine and discipline supposed to have been put forth by our Saviour or his inspired Apostles, and not committed to writing; and thus the word is used in a contrary sense from "Scripture." And such traditions are of two sorts: tradition of doctrine (such as that of the Trinity), which is commonly said to be directly affirmed by tradition and proved by Scripture; and tradition of rites and ceremonies, called by Hooker "traditions ecclesiastical," or "ordinances made in the prime of Christian religion, established with that authority which Christ has left to his church in matters indifferent, and, on that consideration, requisite to be observed till like authority give just cause to alter them." (*Eccl. Pol.* v. 65.)

It is, of course, impossible to deny that Revelation may have been communicated to man in this manner, as well as in the form of Scripture. Therefore, when a Protestant asserts that Scripture is the *only* rule of faith, he must mean this only, that the evidence on which Scripture rests is solid, while no particular tradition has sufficient evidence to support it; for if any tradition had evidence to support it, there can be no *à priori* reason assigned why it should not be as binding as any Scripture. "I

make no scruple to grant," says the high church writer Hammond, "that apostolical traditions, such as are truly so, as well as apostolical writings, are equally the matter of that Christian's belief, who is equally secured by the fidelity of the conveyance that as the one is apostolical writing, so the other is apostolical tradition:" one of those unmeaning phrases which are of such common occurrence in this widely spread controversy; for the only real questions are, whether we *can* be "equally secured by the fidelity of the conveyance," in the case of tradition and of Scripture? and, secondly, who is to be the judge for us what is authentic tradition and what is not?

In the latter question lies the real difference, on this subject, between Romanist and Protestant. The former holds tradition of equal authority with Scripture; but then he also holds that the church, that is, the pope, with or without a council, is the authoritative declarer of tradition.

It is curious to observe that at the Council of Trent this fundamental difficulty, namely, who is to say what is tradition and what is not, struck the minds of the divines who were contending to fix the doctrine of the Catholic church. They were probably hardly agreed as to the form, rather than the substance, of its solution. "All agreed," says Paolo Sarpi, "that Christian faith is contained partly in Scripture and partly in tradition. Yea, some said more: that tradition was the only foundation of the Catholic doctrine; for the Scripture itself is not believed but by tradition." But Vicenzo Lanello, a Franciscan friar, thought "that they ought first to treat of the church, which is a more principal foundation;" since "Scripture itself is founded upon it," according to Saint Augustin's saying, and "that no use can be made of traditions, except by grounding them upon the same authority." But his opinion had no followers. "Some objected that the synagogues of the heretics would also arrogate the authority of a church." Others thought that the authority of the church was sufficiently declared already. (Book 2.) Perhaps some confusion would have been avoided if the father's suggestion had prevailed: but there is no doubt that the Romanist, by tradition, means tradition declared to be such by the church.

Protestants, on the other hand, without laying it down as a doctrine that tradition is equal to Scripture, have, in general, assented to the proposition that an authentic tradition of doctrine is binding; but on the question, what is the authority competent to pronounce a tradition authentic, they have wandered strangely indeed, from a reluctance to admit to its full extent that very right of private judgment on which they founded their dissent from Rome. And this is peculiarly the case with those reformed divines who dislike parting with the title "Catholic."

When the early Reformers, especially those of the Lutheran and Anglican schools, attacked a doctrine or practice of Rome, their first endeavour was generally to show that it was not scriptural; their second, that it was not *ancient*, *i. e.* did not rest on tradition. For this purpose, they opposed to the authority of the church, as it existed in their day, the authority of early fathers and councils, as expounding the belief of an earlier age. Thus they *recognised* the right of private judgment to try the authority of the existing church by comparing it with authorities of earlier times; they permitted each individual to apply for himself the historical test. But at the same time they denied, more or less directly, the right of private judgment to go further, and criticise the ancient authority itself; to examine, for instance, whether a doctrine acquiesced in, in the fourth century, might not have been altogether unknown to the first; whether corruption in the church may not have commenced at so very early a period as to invalidate greatly the testimony even of the oldest father; and, lastly, whether traditions, resting on high historical authority, are or are not consistent with Scripture. And even to the present day, the high church school of Anglican divinity does practically consider all these as points without the reach of private judgment.

Now this we cannot but think an untenable position. Either the church has and always had authority to declare to us what is tradition, or it has not. If it had, then the Reformation was an unlawful thing *ab initio;* and no church commencing in schism can be said to have a pure and real existence. If it had not, then each man, in the last resort, must judge for himself of the authenticity of what is propounded to him as tradition. He will be bound to judge with humility, respect, and submission; but the decision belongs ultimately to the *forum* of his proper conscience.

He will, therefore, feel it necessary to examine the value of the evidence for the doctrines or rules of discipline presented to him as traditional, by the same principles of criticism which he would apply to other testimony; not receiving all in the mass, on the faith of any alleged adoption of it by the church. For example, he finds that, scarcely two centuries after the lifetimes of the Apostles, several hundred bishops, convened from all parts of Christendom, at the Council of Nice, declared that the doctrine of the Trinity, as embodied in the creed of that council, had been "handed down" in their respective churches from the beginning. He accepts this as evidence of the highest authority to show that there was an oral teaching of that doctrine by the Apostles and their successors, corresponding with the indications afforded, but not expanded into the same explicit form, in Scripture. But when he is required to receive the doctrines, for instance, of the Apostolical succession as commonly understood, or of the sanctity of celibacy, or the use of language widely deviating from that of Scripture respecting the Sacraments, on the ground that these are "traditions," he holds himself at liberty to inquire, first, whether the language of fathers and councils respecting them is distinct and consistent, when freed from rhetorical exaggeration; next, whether it is not least strong in the age nearest the Apostles, and increases in force as we proceed lower; and, lastly, whether on all these subjects their testimony was not likely to be warped by the ordinary causes of error which throw discredit on witnesses, and from which we have no right whatever to imagine the Christian writers of the fourth, third, or second centuries exempt; such as the ambition of the clergy, the tendency to admit gnostic and heathen influences, and the deficiency in solid judgment and reasoning power which characterized the educated men of those ages. Again; he will not be influenced by the common Romish argument already alluded to, and frequently in use among high Anglican writers also, that "Scripture itself is found to be such by tradition." Because we receive the testimony of early Christian writers that such and such books were *canonical*, *i. e.* received in the church in their time, it by no means follows that we must receive their deductions from Scripture as having the form of tradition; not even when they style these the deductions of the church. Such reasoning would not pass for eminent in any but theological controversy. We receive the testimony of Xenophon and Plato as to the actions and sayings of Socrates; we do not, therefore, admit as authoritative their exposition of his philosophy, not even as an authoritative representation of what was regarded as his philosophy at Athens; and yet they were his cotemporaries. Irenæus, the earliest father on whom we depend for any thing like extensive testimony to tradition, lived a hundred years after the Apostles, and a hundred years of much corruption and dissention.

Lastly, he will know that if an overweening contempt of the authority of early uninspired writers, and of old ecclesiastical traditions, is most unbecoming a Christian inquirer, an exaggerated and superstitious veneration for them, if a more amiable error, is scarcely a less serious one. There could be no traditions more venerable, more sanctioned by the apparent "authority of the church," than those of the Jews at the time of our Saviour; yet our Saviour does not on that account in any degree mitigate his condemnation of them, or speak of them as entitled even to respect, when he denounces those who teach for doctrines the commandments of men.

(It would be impossible to refer to particular works on this subject of controversy. The extreme Protestant view of tradition is no where so fully argued as by Chillingworth, *passim.* For a concise and fair view, on high church principles, of the estimate of tradition by the English Reformers, see *Palmer's Church of Christ,* vol. i. p. 493. 504.)

TRA'GACANTH. A variety of gum: it is the produce of the *Astragalus Tragacantha*, a native of Africa, and imported in small twisted or flattened pieces, white or yellowish, and translucent or nearly opaque. When put into water they swell up, and gradually form a gelatinous or pasty mass; not dissolving into a clear solution, as is the case with gum arabic. An analogous kind of gum is found in other plants, and the generic name of *tragacanthin* is sometimes applied to it.

TRA'GEDY. (Gr. *τράγος, a goat,* and *ᾠδή, a song.*) A species of drama, in which the diction is elevated and the catastrophe melancholy. The name is usually derived from the ancient Greek custom of leading about a goat in procession at the festivals of Bacchus, in whose honour those choral odes were sung which were the groundwork of the Attic tragedy. Some recent writers, however, have given a new explanation of the word *τράγος*, considering it an ancient Greek adjective, and translating it "melancholy," or "lamentable." *See* DRAMA.

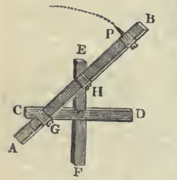
TRAGI-CO'MEDY. In Literature, a compound name, invented to express a class of the drama which should partake both of tragedy and comedy. If the mixture of serious with humorous portions in the piece alone entitles it to this name, then all the Plays of Shakespeare (with the single exception of the *Merry Wives of Windsor*, to which some add the *Twelfth Night*), as being pure comedies, belong to this class; as do, indeed, almost all the works of the old English dramatists. But *Troilus and Cressida* alone, of the Plays of Shakespeare, bears this title in old

editions: on what account we do not know. French critics define the distinction to be, that the *event* of the tragi-comedy is not unhappy or bloody. Dacier condemns them as illegitimate. Guarini, the Italian poet, wrote an essay on the subject.

TRA'GUS, in Anatomy, is the term applied to the small cartilaginous eminence at the entrance of the external ear: in the adult it is beset with small hairs.

TRAJE'CTORY. (Lat. trajectus.) The curve which a body describes in space; as a planet or a comet in its orbit, or a stone thrown obliquely upwards in the air. The form of the trajectory depends on the initial velocity with which the body is projected, the law and direction of the forces which act upon it, and the resistance of the medium in which it moves. The planetary orbits would be strictly elliptical, were it not for the disturbing forces which they exert on each other; and but for the resistance of the air, a body projected obliquely from the earth would describe a portion of a parabolic curve.

TRA'MMEL. (Old French, tramel.) An instrument for drawing ovals, much in use among joiners and other artificers. It consists of a cross, C D E F, in which are cut two grooves at right angles to each other; and a beam, A B, carrying two pins, G, H (which are clamped to A B, and slide in their grooves), as well as a pencil, P: these parts are called the cross and the beam. By turning A B round, the pins G, H slide along the grooves, and the pencil P describes an elliptic curve. A demonstration of the properties of this instrument may be seen at p. 700. vol. xiv. of *Hutton's Abridgment of the Philosophical Transactions*.



TRAMONTANE. See ULTRA-MONTANE.

TRANSCENDE'NTAL. In Algebra, a term applied to any quantity which cannot be represented by an algebraic equation of a finite number of terms with determinate indices. Such quantities include all exponential and logarithmic expressions and trigonometrical lines in terms of the arc. Thus a^x, x^x, log. x, tan. x, &c. are transcendental expressions; and any equation into which such expressions enter is called a *transcendental equation*, and any curve defined by such an equation is called a *transcendental curve*.

But by *transcendental equations* are sometimes meant such differential equations as can only be integrated by means of curves, logarithms, or series.

TRANSCENDENTAL. A word used by German philosophers to express that which *transcends* or *goes beyond* the limits of actual experience. This general meaning is somewhat restricted by Kant, who draws a distinction between the *transcendental* and the *transcendent*. The transcendental he defines to be that which, though it could never be derived from experience, yet is necessarily connected with experience, and which may be shortly expressed as the intellectual *form*, the *matter* of which is supplied by sense. "I call," says he, "all knowledge transcendental, which has regard in general not so much to *objects* as to our mode of knowing or apprehending objects (that is to say, to formal knowledge), so far as this is conceived to be possible *à priori*. A system of such conceptions would be named transcendental philosophy, as the system of all the principles of pure reason." The *transcendent*, on the contrary, is that which regards those principles as objectively real to which Kant assigns only a subjective or formal reality, and consequently is by him regarded as beyond the limits of the human reason altogether.

TRA'NSEPT. (Lat. trans and septum.) In Architecture, the cross part of a cathedral which extends on the north and south sides of the area between the nave and the choir, and forming, as it were, the short arms of the cross upon which the plan is laid out.

TRANSFIGURA'TION. The supernatural change which is described to have taken place in the appearance of Christ, when, as is recorded in Matth. xvii., Mark ix., Luk. ix., he took Peter, James, and John up into a high mountain with him, and was transfigured before them, his face shining as the sun, and his raiment showing white as light. There appeared in conversation with him Moses and Elias; and the apostles erected three tabernacles or tents to them. An ancient tradition assigns Mount Tabor as the scene of this event, upon which three contiguous grottoes have been fashioned to represent the three tabernacles.

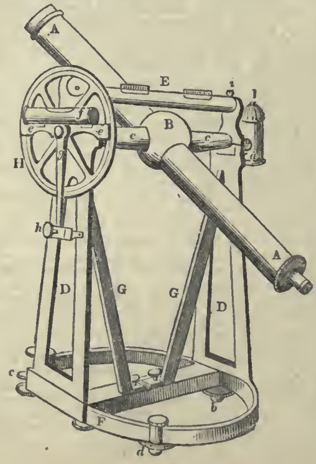
TRANSFU'SION. The injection of blood from one living animal into another. It was at one time supposed that this operation might be resorted to, to sustain life in cases of great loss of blood from accidental hæmorrhages and other causes; and that in certain cases of mental and bodily disease a cure might be effected by abstracting a large quantity of blood, and supplying its place by transfusion from another animal, such as a calf or sheep. Some of these experiments appeared at first to be attended with success, but bad consequences followed; and in two or three cases in which it was tried upon the human subject it proved fatal.

TRA'NSIT (Lat. transitus, *passage*), in Astronomy, is the culmination or passage of a celestial object across the meridian of any place. The determination of the exact times of such transits is one of the most important operations of practical astronomy, as it is by this means that the differences of right ascensions, and consequently the relative situations of the fixed stars, and the motions of the planets and comets in respect of the celestial meridians, become known; and it is most easily and accurately effected by the aid of the *transit instrument*, the nature and method of using which will be explained under that term.

Transit is also used to signify the passage of an inferior planet across the sun's disk. See MERCURY and VENUS.

TRANSIT INSTRUMENT. This important instrument, called by the French *instrument des passages*, *lunette méridienne*, consists essentially of a telescope firmly attached to a transverse horizontal axis, the ends of which are directed to the east and west points of the horizon. The extremities of the axis are formed into cylindrical pivots of exactly equal diameters, which rest in notches (technically called Y's, from their resemblance to that letter), formed in metallic supports, susceptible of nice adjustment both horizontally and vertically, so that the axis can be placed perfectly horizontal, and at right angles to the plane of the meridian in which the telescope moves. In the focus of the eye-piece is placed a system of three, five, or sometimes seven vertical and equidistant wires or spider lines, generally crossed by two horizontal ones, between which it is convenient that the passage of objects over the vertical wires should be observed. By means of adjusting screws the diaphragm, or plate to which the wires are attached, is brought into such a position that the middle vertical wire intersects the optical axis of the telescope, in which position it is permanently fixed.

When the system of wires is brought into this position, the middle one will be a visible representation of that part of the meridian to which the telescope is directed; and when a star is seen to pass this wire, it is in the act of culminating, or *transiting* the celestial meridian. The instant of the transit is noted on a clock or chronometer, which is an indispensable accompaniment of the instrument; and in order to render the observation more certain, the instant at which the star passes each of the vertical wires is noted, when practicable, and the mean taken as the true instant of passing the vertical wire. The times at which the sun and certain principal stars pass the meridian of Greenwich (and consequently the meridian of any other place whose longitude from Greenwich is known) being given in the *Nautical Almanac*, the comparison of the time indicated by the clock and the time in the almanac gives the *clock error;* and by observing the same stars from day to day the *clock rate* is determined. In this manner we are enabled to assign the exact interval of sidereal time between the transits of the different stars, and consequently the difference of their right ascensions. For determining the absolute place of a celestial body it is necessary to know also its polar distance, which is given by the mural circle; so that the



transit instrument and mural circle are the two essential instruments of an astronomical observatory.

The annexed diagram represents the *portable* transit instrument, as at present constructed by Troughton and Simms, when the telescope does not exceed twenty inches or two feet in focal length. The telescope tube A A is in two parts, connected together by a sphere B, which also receives the larger ends of the two cones C C placed at right angles to the telescope, and forming the horizontal axis. The axis terminates in two cylindrical pivots, which rest in Y's fixed at the top of the vertical standards D D. One of the Y's has a small motion in azimuth, by means of which the telescope can be adjusted exactly to the plane of the meridian. A spirit level E, which is made to stride across the telescope and rest on the two pivots, serves to show when the axis is horizontal. The standards D D are fixed by screws upon a brass circle F, which rests on three screws, *b*, *c*, *d*, forming the feet of the instrument, and by which the levelling is performed. G G are two oblique braces for the purpose of steadying the supports. On the extremity of one of the pivots, which extends beyond its Y, is fixed a divided circle H, which turns with the axis; while a double vernier remains stationary in a horizontal position, and shows the altitude to which the telescope is elevated. The verniers are set horizontal by means of a spirit level *f*, and are fixed in their position by a brass arm *g h*, clamped to the supports. The whole of this apparatus is moveable with the telescope, and when the axis is reversed can be attached in the same manner to the opposite standard. For the purpose of illuminating the wires when observations are made at night, one of the pivots is pierced, and admits the light of a lamp I, which is thrown upon the wires by a reflector placed diagonally in the sphere B. (*Simms's Treatise on Mathematical Instruments.*)

Adjustments. — In practice, the transit instrument is subject to three principal errors. 1st, The axis may not be perfectly horizontal, which is called the error of inclination. 2d, The optical axis of the telescope may not be quite perpendicular to the axis of the instrument, which is called the error of collimation. And 3d, The axis may not be exactly east and west, or the optical axis may not be exactly in the meridian, which is called the error of azimuth. To place the axis exactly horizontal, the level E is suspended in the proper manner from the pivots, and the air bubble brought to the middle by means of the foot screws. The level is then reversed, that is, the end which was turned to the west is now turned to the east; and if the air bubble still stands at the middle, the axis is horizontal; if not, the foot screws are adjusted until it stands at the middle in both positions of the level. The error of collimation is detected by pointing the telescope to a distant well-defined terrestrial object, and bisecting it by the middle vertical wire; the telescope is then lifted out of its supports and reversed (that is, the end of the axis which was turned to the west is now turned to the east), and brought again to bear on the same object. If the middle wire is found to be still bisected, the adjustment is perfect; if not, the diaphragm is moved a little to the right or left by means of the adjusting screws, until the middle wire bisects the object in both positions of the axis. To place the instrument exactly in the meridian some knowledge of practical astronomy is required. It is easy to place it *nearly* in the meridian by the transit of the sun at apparent noon, or of any star whose right ascension is known; and when in this approximate position to the meridian, the deviation may be discovered and corrected in various ways. One of the simplest is to observe two successive transits of Polaris (or any circumpolar star) above and below the pole. If the interval between the two transits is exactly twelve sidereal hours, the telescope is exactly in the meridian; and the difference of the interval from twelve hours shows both the amount and the direction of the azimuthal error. Another method consists in observing the transits of two stars differing considerably from each other (not less than 50°) in declination, and whose right ascensions (which should be nearly the same) are accurately known. The deviation from the meridian, in *seconds of time*, will then be given by this formula $(\Delta\ T - \Delta\ (A\ R.)$ $\times \dfrac{\cos.\ N \cos.\ S}{\sin.\ (N + S) \cos.\ L}$; where Δ T is the difference of the observed times of the two transits in sidereal seconds; Δ (A R) the observed difference of right ascensions, also in seconds of time; N the declination of one of the stars, supposed north; S the declination of the other, supposed south; and L the latitude of the place. If Δ T is greater than Δ (A R), the deviation will be to the east; and if less, to the west. A few repetitions of this process will suffice to place the instrument exactly in the meridian. In the case of fixed instruments, a meridian mark is usually made on some distant object, and permanently established for the convenience of ready reference.

The transit instrument appears to have been invented by the Danish astronomer Roemer, by whom it was first described in 1700, in the *Miscellanea Berolinensia*, tome iii. Dr. Halley placed a transit instrument in the Greenwich observatory in 1721, the telescope of which was about five feet in length; but it was little used until 1742, when Bradley commenced a regular series of meridional observations. The transit instrument at present in use in the Royal Observatory is the workmanship of Troughton, and was set up in 1816. The object-glass of the telescope is 5 inches in clear aperture, and the focal length 10 feet. Its horizontal axis, including the pivots, is 3 feet 10 inches. There are seven fixed vertical wires in the focus, and two horizontal axes; and the distance of the former from each other is such that an interval of about 18·3 seconds elapses while a star in the equator passes between each adjoining two.

For full details respecting the construction and adjustments of this important instrument, see *Pearson's Practical Astronomy; Memoirs R. Astr. Society*, vol. i.; and the article in the *Penny Cyclopedia.*

TRANSI'TION ROCKS. A Geological term, formerly applied to the older secondary series, under the idea that they were formed during the transition of the globe from the uninhabited to the inhabited state. *See* GEOLOGY.

TRA'NSITORY ACTIONS. In English Law, actions in which the *venue*, *i. e.* place alleged in the declaration, is immaterial, and consequently the trial may be had in any county; opposed to local actions, in which the trial can only be had in the county where the alleged injury was committed. To the former class belong actions of contract and quasi contract (assumpsit, debt, &c.). *See* ACTION, VENUE.

TRANSLA'TION. In Literature, the rendering of a literary work from the original language into another. The peculiar merits and peculiar difficulties of successful translation have often been pointed out by critics, but their judicious directions have been seldom realized by authors. In truth, those difficulties require a talent of so high an order to surmount them, that few writers are fit to undertake the office of translators (we mean of works of any high literary merit), except those whose genius has more congenial occupation in original composition; for notwithstanding Dryden's sarcastic remark, that "imitation of an author is the most advantageous way for a translator to show himself, but it is the greatest wrong which can be done to the memory and reputation of the dead," we are inclined to doubt whether, in reality, imitation be not the more advantageous method of the two. "Every author," says an able critic (*Edin. Review*, vol. xxxvi.), "is a mannerist. This manner constitutes, as it were, the identity of each author; it is what the translator ought to catch, and is nevertheless the very thing which is apt to evaporate in translation." Or, to borrow again the language of Dryden, the office of the translator is especially to render the "particular turn of thoughts and expression which are the characters that distinguish, and, as it were, individuate him from all writers." But nothing is so arduous as the attempt to catch this spirit, or manner, when the writer is also bound by the duty of rendering faithfully the sense. The imitator, freed from the necessity of exactly copying the sense, is far more at liberty to devote himself to seizing the evanescent qualities of the manner. This truth might, as it appears to us, be exemplified by many instances. Terence and Horace seem to have aimed at familiarizing Roman ears with the best poetry of Greece, not by translation, but by imitation. Indeed, much as the Romans borrowed from the Greeks, actual translation seems to have been uncommon; the only two examples which we at this moment recollect are Cicero's version of Aratus, and that by Catullus of a poem of Callimachus. Among modern authors, which of the English translators of Horace has approached half so near him as Pope in his *Satires?* Where, among all the translations of the Greek drama, shall we find any thing so thoroughly imbued with the spirit of that noble order of poetry as the *Sampson Agonistes* of Milton, and the *Bride of Messina* of Schiller? What translator of Lucan is nearly so Lucanic as Corneille? We do not mean to disparage the utility of translations, or the merits of some few among those which have passed into popularity; but as, with scarcely an exception, they are in relation to the originals, to use the well-known phrase of Cervantes, only the "wrong side of the tapestry turned outwards," so, in themselves, considered as literary works, they generally leave an impression of that peculiar stiffness which belongs to all copies.

These observations apply with greater force to poetical than prose translations; and, among the latter, more to works of taste and fancy than to scientific or historical treatises. In the latter, an easy style, clearness, and fidelity appear of greater importance in translation, than the more difficult feat of catching the manner and spirit of the author. In literary, and especially poetical translation, much controversy has been carried on between the advocates of literal and loose adherence to the sense of the author. Each has its advantages and merits; but

the last, approaching most nearly to the character of *imitation*, appears to us, on the whole, the better extreme of the two. *Three* distinct styles of translation are not ill characterized by a lively writer in the *Quarterly Review* (on "Mitchell's Aristophanes"), vol. xxiii. p. 482.

"It is the office of the translator to represent the forms of language according to the intention with which they are employed: he will therefore, in his translation, make use of the phrases in his own language to which use and custom have assigned a similar conventional import; taking care, however, to avoid those which from their form, or any other circumstances, are connnected with associations exclusively belonging to modern manners. He will likewise, if he is capable of executing his work upon a philosophic principle, endeavour to render the personal and local allusions into the *genera* of which the local or personal variety employed by the original author is merely the accidental type, and to reproduce them in one of those permanent forms which are connected with the universal and immutable habits of mankind. The *faithful translator* will not venture to take liberties of this sort; he renders into English all the conversational phrases according to their grammatical and logical form, without any reference to the current usage which has affixed to them an arbitrary sense, and appropriated them to a particular and definite purpose. The *spirited translator*, on the contrary, employs the corresponding modern phrases; but he is apt to imagine that a peculiar liveliness and vivacity may be imparted to his performance by the employment of such phrases as are particularly connected with modern manners; and if at any time he feels more than usually anxious to avoid the appearance of pedantry, he thinks he cannot escape from it in any way more effectually than by adopting the slang and jargon of the day. The peculiarities of ancient times he endeavours to represent by substituting in their place the peculiarities of his own time and nation."

He proceeds to exemplify these distinctions by an instance from Aristophanes: —

λοιδορεισθαι δ'οὐ πρεπει
ἀνδρας ποιητας ὡσπερ ἀρτοπωλιδας.

This, says he, the faithful translator will render literally, "scold each other like bakers' wives." The spirited translator will adopt the modern popular phrase most nearly analogous, — "like oyster wenches." The translator *par excellence* will choose a phrase rendering the particular and obsolete expression of the ancient by a general equivalent which must be equally appropriate in the idiom of all times and countries, — "like market-women," or "hucksters." Without cavilling at this ingenious piece of criticism, we must be permitted to doubt whether a translation of a highly idiomatic author conducted on this last principle would not preserve his general meaning with the serious sacrifice of his spirit.

In most modern languages there are some few translations which have attained celebrity. In English, Fairfax's *Tasso*, one of the earliest, has great beauty, but is rather enervate. The versions of Dryden are distinguished by their poetical power; though we agree with Mr. Hallam (*Introduction to the Literature of Europe*, iv. 536.), that he did not give the example as well as precept of rendering the "particular turn of thought and expression" of his authors. The utter want of individuality in his respective translations is plainly perceptible; for instance, in that from the fourth book of Lucretius. (It may be observed, in passing, that the remarks of Dryden on the art of translation, of which so much has been said, are chiefly to be found in his prefaces to *Ovid's Epistles*, and to his *Second Miscellany*.) Pope's *Homer* is a bad and careless version (critically speaking) of the Latin translation of the Greek poet: but it has one essential characteristic of the original, namely, his sustained energy; which renders it, even now, more popular than the cold, though not unfrequently dignified and elegant work of Cowper. Some portions of Cumberland's versions from *Aristophanes* deserve mention, although on the whole he is prosaic, and has not dared to follow the bold flight or imitate the metrical variety of his original. Mitchell's *Aristophanes* has been much admired; but it is wearisome from the continual striving after effect. Some of Elton's translations are very pleasing, especially of parts of *Hesiod*. Shelley has left two of the most beautiful essays in this line of composition which are to be found in our language: the *Hymn to Mercury* of Homer, and the *Walpurgis Night Scene* from Goethe's *Faust*. In the latter, indeed, he laboured under the disadvantage of an inadequate knowledge of the language; but none of Goëthe's more critical translators (not even Dr. Anster) has so powerfully seized his "turn of thought and expression." The same cannot be said of Byron's performance, — the first book of the *Morgante Maggiore*; which is, however, a remarkable feat of dexterity, from its extreme literalness: a feat in the same kind as Lord Brougham's recent version of the *De Coronâ* of Demosthenes. Mickle's *Lusiad*, though now little read, is one of the most poetical of English translations. Coleridge's *Wallenstein* is a truly wonderful work. So carelessly written that the poet has omitted whatever he found difficult, or thought unornamental, it is so exact and so spirited, that the reader is constantly impressed with the idea of Schiller himself rewriting his own drama in English, with here and there a variation as perfectly Schiller-like as the German original. Among prose translations, Philemon Holland's numerous ones, particularly that of *Pliny*, are still occasionally referred to by literary antiquaries, for their quaintness rather than their merit. Melmoth's *Epistles of Cicero and Pliny*, once much admired, are polished but cold. Gordon's *Tacitus* is a creditable attempt at rendering an extremely difficult author. Among our numerous translators from the German in the present times, none bears so high a reputation as Mrs. Austin. Mr. C. Lewis's translation of Boeckh's *Public Economy of Athens* is a work of great merit. French is a language affording so many advantages to the prose translator, from its condensation, its exactness, its rhetorical force, that it is, perhaps, rather to be wondered at that higher distinction has not been attained by individual French writers in that line. But few French translators are much remembered, except Amyot; and he chiefly for his vernacular language, possessed of great sweetness as well as quaintness, which formed a mode of style in the 16th century. The Chevalier Townley's translation of *Hudibras* is worth mentioning as a phenomenon, from its singular fidelity and spirit. Italian, on the other hand, seems to be an unfit language for the purposes of translation, from extreme diffuseness; yet it boasts of one translator of *Tacitus* (Davanzati), who made a point of rendering that affectedly concise historian in fewer words than the Latin. But of all modern languages, at least of those generally known in the literary world, German has by far the greatest capabilities for this purpose. This must be conceded, *à priori*, by those who are familiar with its peculiar powers and flexibility; and not less by those who are acquainted with this portion of its literature. Among the most highly esteemed poetical works of this description in Germany are Voss's *Homer* and *Virgil*; Streckfuss's *Dante*; Schlegel and Gries's *Calderon*; Schlegel's *Shakspeare*. In prose, the complicated syntax of the Germans, perhaps we may add the as yet unformed character of their prose style, detract from the natural powers of the language; still they have some excellent specimens of prose translation, among which Strombeck's *Tacitus* holds a high rank. (See also *Ed. Rev.* vol. xxxvi.)

TRANSLU'CENCY. (Lat. transluceo, *I shine through*.) Semitransparency. The term is chiefly used in descriptive mineralogy as applied to minerals which admit of a passage of the rays of light, but through which objects cannot be definitely distinguished.

TRANSMIGRATION OF SOULS. *See* METEMPSYCHOSIS, PYTHAGOREAN PHILOSOPHY.

TRANSMUTA'TION. In Alchemy, the operation of changing the imperfect metals (as they were termed) into the two precious, — gold and silver. This was the great object of that pretended science. *See* ALCHEMY.

TRANSMUTA'TION, in Geometry, the change of one figure or body into another of equal area or solidity; as a triangle into an equivalent square, a sphere into a cube, &c.

TRA'NSOM. (Lat. transenna, *a stretched cord*.) In Architecture, the horizontal piece framed across a double-light window: when a window has no transom it is called a *clere-story* window.

TRANSPA'RENCY, is that quality in certain bodies by which they give passage to the rays of light, and is generally supposed to be a consequence of the homogeneity of the matter of which they are composed.

TRANSPLA'NTING. The art of removing a plant or tree from one situation to another in such a manner as not to interrupt its growth. This operation is commonly performed in the winter season, or in autumn and spring, when vegetables are generally in a dormant state; and the great object of the transplanter is to lift as many of the roots as possible without injuring them, and to replace them in a new situation to which the tree is transplanted in such a manner as to facilitate their growth. With herbaceous plants and young trees this is comparatively a simple operation; but with large trees it is an operation of skill, care, and labour. The tree to be transplanted should be considerably under the normal age of the species; and to prepare it for the change which it is to undergo other trees, or objects of its own height, with which it is immediately surrounded, should be taken away a year or two previous to removal, in order to accustom the tree to the direct action of the light and air on every part of it which is above ground. The next part of the operation is to dig a trench round the tree, equidistant from the trunk, at the distance of three, six, nine, or twelve feet, according to its height, and to such a depth as to cut through all the horizontal roots. The tree may then be removed to its new situation, with or without the earth attached to that part of the roots which remain; or, which is a more certain mode, the trench may be left open during a year, in order that the sections

of the amputated roots may heal over, and be prepared to emit new fibrous roots after the tree is transplanted; or, and which is the more general mode, the trench may be filled up with finely pulverized soil, in order to encourage the production of fibrous roots; and at the end of a year, or of two years if the tree is very large, it may be removed to its final situation. Hitherto we have said nothing of the trunk and branches of the tree to be removed. In a moist climate, such as that of Ireland or the west of Scotland, all the branches may be retained; but in dry climates, such as that of England, the branches require to be thinned out in proportion to the roots cut off; and in dry and warm climates, such as that of central France, the greater number of the branches require to be removed. The proper season for transplanting all ligneous plants, whether small or large, is in autumn, after the leaves of deciduous trees have dropt, and when the sap of evergreen trees, in consequence of the decline of temperature, is comparatively in a dormant state.

TRA'NSPORT. A vessel hired by government to convey stores, troops, &c.

TRANSPORTA'TION. In Law, a species of punishment. It is not known to the common law of England, and was originally a commutation of punishment, pardon being granted to various descriptions of offenders on condition of undergoing transportation: generally for seven or fourteen years, or for life. It is now a statutable punishment for a great variety of offences. It is said to have been first inflicted as a punishment by 39 Eliz. c. 4., enacting that such rogues as were dangerous to the inferior people should be banished. At that time the English plantations in North America were the receptacles of transported convicts. Virginia, the Jerseys, Delaware, Maryland, &c. are the districts which received the greatest accession to their population from this cause. At the very commencement of the practice, the same arguments were employed against it by Lord Bacon which are urged at this day by many law reformers. "It is," he says, "a shameful and unblessed thing to take the scum of people, and wicked condemned men, to be those with whom you plant." It was not, however, brought into general use as a punishment until 1718, by 4 Geo. 1., which act gave the courts a discretionary power to banish felons entitled to clergy to the American plantations. After the loss of the greater part of our American colonies, several years elapsed before the government fixed on any place by way of substitute. At length, in 1787, Botany Bay, on the coast of New South Wales, was fixed upon: 760 convicts were despatched that year. But when the expedition arrived, it was discovered that Botany Bay (discovered by Cook in 1770) afforded no practicable site for the colony; which was consequently landed at Port Jackson, where the town of Sydney was founded. From that period to the present great numbers of convicts have been transported to Port Jackson, and to the later founded colony of Van Diemen's Land — our only two penal settlements. Much has been done of late years towards regulating the condition of the convicts in the colony, and subjecting the worse part of them to severe privations; in particular, by transporting some of them to particular depôts, where they are liable to close inspection and hard labour. Among the writers who have lately contended against the policy of continuing the punishment of transportation, we may particularly mention Archbishop Whately. (See his *Tracts on Secondary Punishments and Transportation.*)

Returning from transportation before the legal expiration of sentence was an offence formerly punishable with death; but by 4 & 5 W. 4. c. 67. those who commit the offence, or aid others in its commission, are punishable with transportation for life. A great mass of evidence on the effect of transportation as a punishment for crime in Great Britain, and its effect on the moral condition of the Australian colonies, will be found in the volumes published by the two committees of 1838 and 1839. It requires, however, to be read with much caution, on account of the evident bias of the committees themselves; for every one knows how effectually the inclinations of a committee give a colour to the evidence taken before it, from the mode in which the operation is performed. The views of that committee, resembling those of Archbishop Whately, of the inutility of the punishment here, and its mischievous effects in the colonies, have had some effect on the proceedings of government; so far, at least, as to produce the abolition of the practice of the immediate assignment of convicts as labourers on their arrival, and the detention of considerable numbers in the hulks in lieu of the full execution of their sentence.

Many of the vices ascribed to the system are undeniable; but it must never be forgotten that the truly philosophical or sensible mode of looking at it is by comparison with other secondary punishments. Take *any* mode of punishment in the abstract, and the eyes of the inquirer will soon detect so much of mischief caused to the sufferers, and so little visible good produced on the community, as to tempt him to regard it as detestable. In the first place, transportation must be considered without the bad practice of immediate and indiscriminate assignment, which was a mere abuse. Thus corrected, let it be compared with the best regulated system of imprisonment — 1. In respect of its effects on the convict himself; and it may be doubted whether in the Penitentiary, whether on the silent or separate system, the mind of the majority of sufferers goes through a more wholesome process than in the penal settlements, notwithstanding all we have heard even of the frightful condition of Norfolk Island, which is not an ordinary sample. 2. In respect of its effects on the ill-disposed population at home; and here, defective as transportation is commonly supposed to be, the experience of any one conversant with courts of justice will decide which sentence appears to produce the greatest impression when announced, — imprisonment, or banishment. And it must not be forgotten that it is not the real severity, but the action on the imagination, which deters from crime: the worst inflictions of the gaol are thought little of by any one except the sufferer, while the evils of expatriation are greater in idea than in reality. 3. In respect of the ultimate reform of the offender; and here transportation possesses an incalculable advantage over every other secondary punishment. The convict who has undergone it begins life afresh: he remains, indeed, under some disabilities, sufficient to mark the sense entertained by society of the difference between him and the man unstained by crime; but there is nothing to prevent his rising by regular and honest conduct, if he chooses, into a station of comfort, and even of respectability. The man who leaves a gaol is utterly ruined: society has devised, perhaps can devise, no means of extending to him a *jus postliminii*, and bringing him back within the pale of citizenship. His character is gone for ever; and if it could be really ascertained how many among relapsed offenders are actually driven into the recommission of crime by the hopelessness and infamy of their condition, if not by the actual want which results from it, we suspect that many who are now ready to give their suffrage for the abolition of transportation would be induced at least to pause until they can see their way through this difficulty.

TRANSPOSI'TION, in Algebra, is the transposing of a term from one side of an equation to the other, and is in effect the adding of equal quantities to or subtracting equal quantities from each side of the equation, the *sign* of the quantity being changed from + to —, or from — to +. For example, if $a + x = c - d$, by transposing a we have $x = c - d - a$; or if $a + b = c - x$, by transposing x and $a + b$ we get $x = c - a - b$. The object of transposition generally is to bring all the unknown terms to one side of the equation for more conveniently finding their value with respect to the known terms.

TRANSPOSITION. In Music, the change which takes place by performing the same melody in a higher or lower pitch, which may always be effected by altering the signature as the pitch of the new key note may require.

TRANSUBSTANTIATION. The doctrine held by the church of Rome, that in the Eucharist the bread and wine are annihilated and replaced by the body and blood of Christ. In one of its liturgical offices it says, "This *is not bread*, but God and Man, my Saviour." It is maintained by Protestants that this dogma, which was made the principal test of a true faith by the Papists at the Reformation, is not found in Scripture, which in the most literal acceptation only asserts of the elements that *they are Christ's body and blood;* i. e. that the substances coexist in some mysterious manner. Nor can they discover it in the writings of the fathers, or in the canons of the early church. They affirm that the first theologian who asserted even the consubstantiation, or union of substances, was Paschasius, in the ninth century, and that he was accused of making too gross an explanation of the mystery. It was in the course of these disputes, and in consequence of the formal and definite statement of their opinions to which controversialists were forced, that this idea of transubstantiation came into fashion among theologians; nor was it ever propounded as an article of faith by the authority of a council till the beginning of the 13th century in the papacy of Innocent III.

TRANSUDA'TION. (Lat. trans and sudo, *I transpire.*) The oozing of fluids through membranes, or through porous bodies.

TRANSVERSAL. In Geometry, the name applied to a line (whether straight or curved) which *traverses* or intersects any system of other lines; as when a straight line intersects the three sides of a triangle. The properties of straight and circular transversals are discussed by Carnot, in his *Géometrie de Position*, and *Essai sur la Théorie des Transversales.*

TRANSVERSE AXIS, in Conic Sections, is the diameter which passes through both foci. It is the longest diameter in the ellipse, the shortest in the hyperbola; and in the parabola it is infinite, as in that curve all diameters are. *See* CONIC SECTIONS.

TRAPE'ZIUM (Gr. τραπεζα, *table*), in Geometry, is the general name for a plane figure bounded by four straight lines. When two opposite sides are parallel, it is

called a trapezoid; when both pairs of opposite are parallel, it is called a parallelogram.

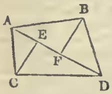
The following are a few of the most remarkable elementary properties of this figure.

1. The sum of any three sides is greater than the fourth side.

2. The sum of the squares of the diagonals is equal to the sum of the squares of the sides, and four times the square of the line joining the middle points of the diagonals.

3. The lines joining the middle points of the sides form a parallelogram.

4. If the figure can be inscribed in a circle, the sum of each pair of opposite angles is two right angles, and the sum of the rectangles of each pair of opposite sides, are equal to the rectangle of the diagonals.



To find the area of a trapezium, let A D be a diagonal, and C E, F B perpendiculars upon it; then A D × ½ (C E + B F) = the area.

TRAPEZIUS. In Anatomy, a muscle situated immediately below the integuments of the posterior part of the neck and back. Its principal action is upon the scapula; and it also acts upon the neck and head, drawing the latter backwards, and turning it on its axis.

TRAPEZO'ID. A trapezium which has one pair of opposite sides parallel. The area of a trapezoid is equal to half the sum of the parallel sides multiplied by the perpendicular distance between them.

In Anatomy, the *trapezoides* is the second bone of the second row of the carpus.

TRA'PPISTS. The name of a religious order which still exists in Normandy. It was founded in 1140 by a Count de Perche, in a deep valley called La Trappe, whence the name of the order, and has survived all the changes and revolutions of France. The rules of this order are of the strictest kind. It was, however, far less celebrated under its original foundation, than from the reform it underwent under the celebrated Abbé de Rancé, in the reign of Louis XIV. The history of this celebrated man is well known: he was a gallant and daring profligate, whose conversion was owing to the sudden death of a mistress. His character and reform were a favourite subject of discussion in the court of that king in its last and devout period; and he was himself the fashion, and much consulted and thought of by the fashionable devotees of the time. Perhaps the best appreciation of him will be found in the notices scattered through the *Memoirs* of Saint Simon, who reverenced him, but was too clear-sighted to idolize any one. His rule was of the austerest description; comprising, among other severities, absolute silence on the part of those admitted for a considerable period. At the Revolution the community of La Trappe was dispersed: many members escaped to England, and were received by Mr. Weld, the proprietor of Lulworth in Dorsetshire. There are now several congregations of Trappists. The famous Baron Geramb, so long the lion of the fashionable circles in London, ended his career by entering one of them. (See the *Encyl. Methodique*, "Théologie.") There is an account of the present state of the original convent in the *Revue de Paris*, vol. xxix. It is a melancholy picture. Many of the stories told of the austerities of La Trappe — *e.g.* that each of the monks is employed in digging every day a portion of his grave, &c. — are fables. But the main features of the discipline, the enforced silence, the complete seclusion from the world (insomuch that the superior alone receives news of the decease of a relation of any monk, and it is only announced to the community by a direction to pray for the soul of the kinsman of *one* of the brethren, without naming him), are as commonly reported.

TRAP ROCKS. (From the Swedish trappa, *a flight of steps*, because these rocks frequently occur in large tabular masses rising one above another like the successive steps of a staircase.) They are apparently of igneous or volcanic origin, and composed of felspar, augite, and hornblende, the predominance of one or other of these minerals giving rise to many varieties. See GEOLOGY.

TRAUMA'TIC. (Gr. τραυμα, *a wound.*) Relating to wounds; hence the traumatic balsams and ointments of old pharmacy.

TRAVELLER. In Naval affairs, a ring or hoop which slides along a rope or spar.

TRA'VERSE. In Law, a name given to a plea containing a denial of some matter of fact alleged on the other side, and offering to refer the matter to the decision of a jury.

In cases of misdemeanour, where the defendant postpones the trial of the indictment until the next sessions or assizes, he is said to traverse the indictment. The delays which this form formerly occasioned have been materially abridged by the act 60 G. 3. and 1 G. 4. c. 4.; under which persons in custody or held to bail twenty days before the sessions are bound to plead, unless a certiorari has been delivered before jury sworn.

TRAVERSE SAILING, in Navigation, is sailing on different courses in succession; and the method of reducing such compound courses and distances into an equivalent single course and distance is called *resolving a traverse.* The reduction may be effected either by geometrical projection or trigonometrical computation; but it is generally performed by inspection, with the aid of a *traverse table.*

TRAVERSE TABLE, in Navigation, is the tabulated form in which the northing, southing, easting, and westing are made on each individual course and distance in a traverse, for the purpose of finding readily the difference of latitude and departure made upon the whole; the difference between the sums of the northings and southings being the *diff. lat.*, and between the sums of the eastings and westings the *departure.*

The northing, southing, easting, and westing are generally taken by inspection from a table which contains the parts of a right-angled plane triangle corresponding to a given acute angle, and a hypothenusal line of every unit in length from 1 to 300, and sometimes to 500; an extent sufficient for the wants of the practical navigator. This table itself is also called a *traverse table*, from the facility which it affords in resolving a traverse; but it may be applied advantageously to many other purposes.

In the annexed figure A B C is a plane triangle right-angled at B; and if A B represent a portion of the meridian passing through A, and A C the distance from A to C, then the angle A is called the course, A B the difference of latitude, and B C the departure; and to a given angle A the corresponding values of A B and B C, being computed and entered in a table, form for the assumed value of A a portion of a traverse table.

The table is thus constructed to A C and angle A as *arguments*, the angle being taken to every degree and every quarter point of the compass, and the hypothenuse to every integer from unity to as high a number as may be thought requisite. But the table being formed, any two elements which geometrically determine the triangle may be assumed as the given one, and the other found by inspection from the table. But the use of the table is not limited to the solution of right-angled triangles only; for every case of oblique triangles may be solved by means of it.

TRA'VERTIN. (Ital. travertino.) A limestone, deposited from water holding carbonate of lime in solution. The word is a corruption of *tiburtinus*, this kind of stone being abundantly formed by the river Anio at Tibur near Rome. The species about Alba is usually called *peperino.* They are both of good quality, and were much used by the ancient Romans. Its Latin name was *lapis tiburtinus.*

TRAVE'STIE. (Fr. travestir, *to disguise.*) In Literature, a word used in the same signification as parody. *See* PARODY.

TREACLE. The viscid brown syrup which drains from the sugar in the refining moulds. Its specific gravity is generally 1·4, and it contains on the average 75 per cent. of solid matter. (*Ure's Dictionary.*)

TREAD. (Sax. tredan, *to set the feet on.*) In Architecture, the horizontal part of a step on which the foot is placed.

TREAD MILL. A recent invention for giving useful employment to persons imprisoned for crime.

Its usual form is that of a cylindrical wheel of about 5 feet diameter, and 16 feet long; and several of such wheels are sometimes coupled together. The circumference is furnished with twenty-four equidistant steps, on which the prisoners are made to work on the mill. Each individual treads in a separate compartment, boarded off so that no intercourse can take place between the parties at work at the same time.

All mounting the first step together, their weight sets the wheel in motion, bringing down the step trod upon; when they step up to the next one, which descends in the same manner, and so on, producing a continuous rotatory motion in the wheel, which may be applied as the moving force to a mill for grinding corn, or in turning any other machinery.

The prisoners at work on the wheel are assisted and supported by a hand-rail before them. The wheel makes about two rounds per minute, which is equivalent to a vertical ascent of about 32 feet per minute, and this is about the maximum of labour usually permitted on the wheel. These machines, which have now been introduced into all the great prisons in England and Wales, have been most efficacious in counteracting that feeling which disposes the worthless to balance the pleasures of idleness against the discomforts of confinement. The application of it to prisoners *before trial* was much denounced as an abuse. (See *Ed. Rev.* vol. xxxix. for a paper by the Rev. Sydney Smith on this subject.) The Court of King's Bench, however, refused a mandamus to compel the justices of Yorkshire to allow food, except bread and water, to prisoners committed for trial who refused to work.

TREASON, or HIGH TREASON. By the statute 35 E. 3. c. 2. the limits of this great offence were first accurately defined; and although subsequent enactments at different periods widely enlarged the range of actions which might be drawn within its penal character, yet most of these have been regarded as encroachments upon the principles of our jurisprudence. To compass the death of the king, queen, or king's eldest son and heir; to violate the king's wife or daughter, or the wife of the heir apparent; to levy war against the king in the realm; to assist the king's enemies in the realm or elsewhere; to counterfeit the king's privy seal; to clip or counterfeit the king's money; to slay the chancellor or other high judicial magistrates; — these are the seven species of treason constituted by this act. The many fresh species devised during the troubled periods which followed that reign, and by the arbitrary genius of Henry VIII., were repealed in the first year of the reign of Queen Mary. Of new treasons since created by analogy to those which were previously so considered, the principal are defined by 36 G. 3. c. 7.: such as conspiring to excite foreigners to invade the realm; levying war in order to compel the king to change his measures or counsels, or to overawe either house of parliament; and the expressions or declarations of such opinions by printing, writing, or any other overt act. Counterfeiting the king's money, or filing and clipping the king's coin, are still treasons; as well as having coining tools in possession, and importing false coin from abroad. Most other offences relating to the coin are of a lower description. In high treason all parties concerned are principals, no accessaries being recognised in this offence. (See the *Sixth Report of the Commissioners of Criminal Law.*)

TREA'SURER, LORD HIGH. Formerly the third great officer of the crown in England. The office is now executed by five persons, styled the lords commissioners of the treasury; one of whom holds also the office of chancellor of the exchequer. *See* TREASURY.

TREASURE TROVE. During the middle ages, *treasure trove*, or money dug from the ground, formed an important branch of the revenue of this and of most other European states. The security of property which we have enjoyed since the Revolution has, however, put, long ago, a complete stop to the practice of burying treasure in Great Britain. But down to a late period the practice was common in Ireland, and is, perhaps, not yet altogether abandoned in that country; and it is also common in some of the Continental states. Neckar mentions that in France, under the *ancien régime*, the vassals of many of the nobles, afraid of subjecting themselves to the violence of their masters, buried all the money they could scrape together; and during the anarchy and brigandage of the Revolution, vast sums were thrown into the earth. The well-informed Russian economist, M. Storch, mentions that the practice of burying treasure is still extremely prevalent in Germany, Italy, and Russia; and it must necessarily be more or less prevalent in every country exposed to the ravages of war, and where the rights of property are imperfectly protected. But it is chiefly in the despotical states of Asia, and in Turkey in Europe, that the burying of money is carried to the greatest extent. *There* every rich individual estimates his wealth, not by the stock or capital he has lent to others, or has employed in the great work of production, but principally by the amount of the treasure he has been able to conceal; and every poor man deposits in the earth whatever he can contrive to withdraw from the grasp of his avaricious masters. "The rajahs," says Mr. Luke Scrafton, in his valuable tract on Hindostan, "never let their subjects rise above mediocrity; and the Mohammedan governors look on the growing riches of a subject as a boy does on a bird's nest: he eyes their progress with impatience, then comes with a spoiler's hand and ravishes the fruit of their labour. To counteract this, the Hindoos bury their money under ground, often with such secrecy as not to trust even their own children with the knowledge of it; and it is amazing what they will suffer rather than betray it. When their tyrants have tried all manner of corporeal punishments on them, they threaten to defile them: but even that often fails; for resentment prevailing over the love of life, they frequently rip up their bowels, or poison themselves, and carry the secret to the grave." Mr. Scrafton considers that the universality of this practice, and the quantity of the precious metals which must in consequence have been lost, has been a principal cause of the long-continued drain of specie to the East. From the discovery of the American mines down to a very late period, the greatest portion of their produce has been directly or indirectly exported to Turkey, Hindostan, and other eastern countries; and yet it is said that the precious metals do not seem to have become more abundant in those countries, or the prices of commodities to be materially increased. But, without attempting to investigate the precise degree of credit that ought to be attached to this statement, it is abundantly certain that the want of security which has caused this locking up of so large a quantity of capital must be one of the main causes of the poverty and wretchedness in which the people of India, Persia, Turkey, &c. are involved.

TREA'SURY, BOARD OF. In England, the board to which is entrusted the management of all matters relating to the sovereign's civil list or other revenues. This office was formerly committed to the lord high treasurer, the third great officer of the crown; but in modern times a lord high treasurer has not been appointed, the duties of his office being executed by a board of five lords commissioners. The chief of these, or first lord of the treasury, is generally the prime minister for the time being; and, when a commoner, also chancellor of exchequer; though Sir Robert Peel has recently deviated from this practice. The salary of the first lord of the treasury is 5000*l.* per annum; that of the others 1200*l.* each. The other officers of the board are, two joint secretaries, a number of clerks (chief, senior, junior, minute, copying, &c.), a receiver of fees, a keeper of the papers, a solicitor, a chamber keeper, messengers, housekeepers, extra clerks and extra messengers.

TREA'TY. In Law, an agreement between two or more independent states. Grotius (*De Jure Belli et Pacis*, l. ii. ch. 15. s. 5.) divides treaties into two classes: those which turn on things to which the contracting parties are already bound by the law of nature, such as mutual amity, commerce, &c.; and those which contain stipulations for something more, such as treaties regulating boundaries, conceding particular powers, &c. The municipal constitution, in every state, determines in whom resides the authority to make and to ratify treaties. In most monarchies it is vested in the sovereign; in republics, in the chief magistrate, senate, or executive council; in federal states, sometimes exclusively in the federal authority, as in the United States; while in the Germanic federation the particular states retain the right of making treaties of alliance and commerce not inconsistent with the fundamental laws of the confederation. In order to enable a public minister or other diplomatic agent to conclude and sign a treaty, he must be furnished with a full power; and when so concluded the treaty is binding on the state, in the same manner as an agent is bound by the act of his principal. But the question how far, and in what cases, ratification is necessary, has been the subject of much debate among writers on international law. It is usual to reserve a power to ratify in the treaty itself. It is necessary also, in most constitutional governments, for the sanction of the legislative body to be subsequently given to treaties of commerce, or imposing taxes on the people, entered into by the executive. Thus the government of Great Britain, when making treaties, granting subsidies, &c. usually stipulates that the king will recommend to parliament to make the grant necessary for the purpose; but under the constitution of the United States, it has been thought that congress is bound to sanction treaties in general made by the president with the advice and consent of the senate. Treaties have been divided into real and personal: the former of which are said to bind the contracting parties, independently of any change of sovereignty or in the rulers of the state; the latter are made with express reference to the person of the actual ruler. But treaties properly so called, as of friendship and alliances, commerce and navigation, even if perpetual in terms, are said to expire — 1. In case either of the contracting parties cease to be an independent state; 2. When the internal constitution of government is so changed as to render the treaty no longer applicable. In this they differ from what are called transitory conventions, which pass from one government to another; such as treaties of cession, boundary, &c. (See *Wicquefort*, book ii.; *Vattel*, book ii.; Schoell, *Hist. des Traités de Paix*, 4 vols. Brussels, 1817.)

TREBLE. (Said to be the same as "threefold," sed quære?) In Music, the highest part in a concerted piece. Thus we say a treble violin, a treble hautboy, &c. In vocal music, this part is committed to boys or females. The treble is divided into first or highest treble, and second or low treble. Half treble, or, as it is sometimes called, *mezzo soprano*, is a high counter-tenor.

TRECKSCHUYT. (Dutch, *track ship or boat.*) The covered boats drawn by horses or cattle, and used for the conveyance of goods and passengers on the Dutch and Flemish canals, are so called. For an admirable description of the accommodations and management of the "treckschuyt," now so rapidly falling into disuse from the introduction of railways, see *Murray's Handbook for Northern Germany*.

TREENAILS. In Naval Language, wooden bolts by which the planks of a ship's bottom are secured to the timbers.

TREFOIL. (Lat. tres, *three*, and folia, *leaves*.) In Architecture, an ornament of three cusps in a circle; resembling three-leaved clover.

TREFOIL. A name given in English to different kinds

of three-leaved plants. White trefoil is *Trifolium repens;* yellow trefoil is *Trifolium minus;* black trefoil is *Medicago lupulina;* bird's-foot trefoil, *Lotus corniculatus.* All such plants are used for the food of cattle. The French word *trefle* has a similar application.

TREMA'NDO, *Tremolo.* (It. *trembling.*) In Music, a direction for one of the graces of harmony, which consists in a reiteration of one note of the chord: this, however, applies more directly to the word *tremolo,* whilst the *tremando* is a general shake of the whole chord.

TRE'MATODES, *Trematoda.* (Gr. τρημα, *a hole.*) The name of an order of Sterelminthans, or Parenchymatous Entozoa, comprising those which have organs of imbibition and adhesion in the form of suckers.

TREME'LLA. (Lat. tremo, *I tremble.*) A jelly-like plant of the lowest organization, found in damp walks and similar situations. It is composed of a thallus containing microscopical spores, and is closely allied to the plants called lavers.

TRE'MOLITE. A mineral, often of a fibrous texture, generally containing silica, magnesia, and carbonate of lime, originally found in the valley of Tremola on St. Gothard.

TRE'NCHES (Fr. tranché), in Fortification, are places cut out by besiegers to approach the place attacked in greater security. They are generally from 8 to 10 feet wide, and in depth something more than the height of a man, being commonly about 7 feet.

TRENT, COUNCIL OF, in Ecclesiastical History, was assembled by Paul III. in 1545; and continued, in twenty-five sessions, until 1563, under Julius III. and Pius IV. This celebrated council was convoked at a period when the Christian world was agitated by the early efforts of the reformers; and its most important decrees have therefore reference to the points on which the controversies of the Reformation chiefly turned: *e.g.* transubstantiation, image-worship, the authority of the pope. There is a certain degree of ambiguity in the expression of some of its decrees, owing to the uncertainty which the doctrines of the reformers caused in the minds of supporters of the Romish faith. But, on the whole, it cannot be denied that they express the general belief of Western Christians at the period when they were drawn up; and that they condemn, although with little decision and firmness, many of the more gross abuses of the church. The authority of these decrees (except so far as the more strictly doctrinal part of them is embodied in the creed of Pope Pius IV.) has been much debated among Romish ecclesiastics. In Germany, Poland, and Italy, they appear to have been adopted from the beginning without restriction; in Spain only with a reservation of the rights of the monarch; in France they have never been solemnly received. But as regards the more important portions of them which contain the rule of faith, they probably accurately express the belief of the Roman Catholic church at the present day. The famous history of Father Paul (*Paolo Sarpi*) is in many respects a noble model, but does not always contain a fair estimate of the subject. That of Cardinal Pallavicino represents the more Romanist view. (See *Mosheim,* vol. iii.; *Robertson's Charles V.; Hallam's Intr. to the Literature of Europe,* vol. ii.)

TREPA'N. (Gr. τρυπαω, *I perforate.*) A circular saw for perforating the skull. The term *trephine* is also applied to a similar but improved form of the instrument. (See the article "Trephine," in *Cooper's Surgical Dictionary.*)

TRE'SPASS, in Law, strictly is any transgression of the law less than felony, or misprision of felony; but is generally used to signify any wrong or damage which is done by one private person to another. *Trespass vi et armis* is where an act is done which is in itself an immediate injury to another's person or property; such as assault and battery, or breaking and entering a house or close. *Special trespass,* or *trespass on the case,* where an act is not immediately injurious, but only by consequence and collaterally. Trespass is a personal action of tort, and lies for injuries of a very miscellaneous character. Trespass on the case, as a form of action, arose originally out of a power given to the Court of Chancery to frame new writs for injuries which could not be redressed under the common forms of trespass or covenant. *Trover* and *assumpsit* are, in their origin, different forms of trespass on the case.

TRE'SSURE. In Heraldry, a border running parallel with the sides of the escutcheon, which should contain about one quarter of the bordure. It is generally either double or triple; and has usually fleur-de-lis, arranged in opposite directions alternately, perpendicular to the length of the tressure: it is then called *flory counter-flory.* The tressure forms part of the royal arms of Scotland, and of those of many noble Scottish houses.

TRESTLE TREE. *See* MAST.

TRET. In Commerce, an allowance of 4 lbs. for every 104 lbs. for the waste which certain kinds of goods are liable to from dust, &c.

TRIAD. (Gr. τρεις, *three.*) As to the mysterious triad of deities or dæmons, who are supposed by some to have been the basis of the dæmon-worship of the Greeks, according to a passage in Proceus on the *Timæus* of Plato (see *Bryant's Ancient Mythology,* vol. iii. p. 107.), "they could," he says, in accordance with his singular theory, "be no other than the three sons of Noah, who were the Baalim of the Scriptures, and the Δαιμονες and Αθανατοι of Greece." Others have imagined that the Triad of Plato and his followers was connected with the Christian Trinity. What are called by Cymric antiquaries the *Triads of the Welsh Bards* are poetical histories, in which the facts recorded are thrown into a kind of triplets. Thus, to take the commencement of the first Triad as an example,—"Three names have been given to the Isles of Britain since the beginning: Clas Merddin, Til Inys, and Inys Pridain." The Triads are supposed to be of no greater antiquity than the reign of Edward I., although they probably contain fragments of old history. (See *Turner's Anglo-Saxons,* vol. i.: "Britannia after the Romans.")

TRIAD. In Music, a compound of three sounds, which, from the extraordinary property it has of being naturally divisible into two thirds, one major and the other minor, constituting a fifth in the whole, has received the name of the *harmonic triad.* Its name is founded on its being formed of a third and a fifth, which, with the bass or fundamental sound, make three different terms.

TRIAL, in Common Law, is the examination and disposal of an issue of fact, either in criminal or civil proceedings. Trials are by *certificate.* by *inspection,* by the *record,* and *per pais,* or by a jury. The three first are of a peculiar character. Trial by certificate is where the evidence of the person certifying is the only proper test of the issue; as, the customs of the city of London are to be tried by the *certificate* of the mayor and aldermen, &c. Trial by inspection is said to be where the judges personally examine and decide the question in dispute; a practice long obsolete. Trial by the record is where the point at issue being whether or not a certain record exists, or certain averments in it, it is decided by the production of the record itself. But the ordinary trial of all facts, with these very rare exceptions, is by a jury, summoned to try the issue raised by the pleadings. Trials at bar of civil actions are those which take place before all the judges of the court of which the record is; the original, and, as it were, direct mode of trial, from which all others are variations, although it is now very rare in practice. In ordinary cases, it has been long superseded by trial at Nisi Prius (since 13 Ed. 1.). (*See* NISI PRIUS.) A trial at bar is now only granted on special grounds. Trials before the sheriff are when the demands do not exceed 20*l.*, by virtue of the stat. 3 & 4 W. 4. c. 42. s. 17. These are the only modes of disposing of issues raised on records in the superior courts; and trials of actions in courts of limited jurisdiction are governed by the same general rules. Criminal trials are had in like manner when an issue of fact, generally guilty or not guilty, is raised by the pleadings. *New trials,* in civil cases, are granted where the court of which the record is, sees reason to be dissatisfied with a verdict, either on the ground that evidence was improperly received or rejected; or that the judge misdirected the jury as to the law applicable to the facts; or that the verdict was against the weight of evidence; or that a party was unfairly surprised; or, lastly, that fresh evidence has since been discovered.

TRIA'NGLE. (Lat. triangulum.) A three-sided figure, which consequently has also three angles.

Triangles are rectilineal, spherical, or curvilineal. Rectilineal or plane triangles are bounded by straight lines; spherical triangles are formed on the surface of a sphere by the intersection of the planes of three great circles; curvilineal triangles are those which are bounded by three curves of any kind whatever.

Triangles receive other distinctive denominations from the relation of their sides and angles. Plane triangles are denominated *equilateral* when their three sides are all equal; *isosceles* when two only are equal; and *scalene* when all three are unequal. They are called *right-angled* when one of the angles is a right angle; *oblique-angled* when one of the angles is more than a right angle; and *acute-angled* when each of the angles is less than a right angle; and triangles are said to be *similar* when their angles are respectively equal each to each.

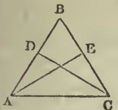
The following are some of the principal properties of plane triangles.

1. The greater side is opposite the greater angle, and *vice versâ.*

2. The sum of any two sides is greater, and the difference of any two less than the third side.

3. The sum of the three angles is equal to two right angles; and if one of the sides be produced, the exterior angle is equal to both the interior and opposite ones.

4. If A E and C D be perpendiculars from the angles A and C on the opposite sides A B and B C, then, generally, $AC^2 = AB \cdot AD + CB \cdot CE$; and, consequently, if the angle B is a right angle, $AC^2 = AB^2 + BC^2$.



5. Lines which bisect the angles of a plane triangle will pass through the centre of the inscribed circle; perpendiculars from the middle of the sides pass through the centre of the circumscribing circle; and lines drawn from the angles to the middle of the opposite sides pass through the centre of gravity.

6. Triangles are to each other in the compound ratio of their bases and altitudes.

The area of a plane triangle is found by multiplying the length of one of the sides into that of the perpendicular let fall upon it from the opposite angle; but there are various other expressions for the area, for which see TRIGONOMETRY.

TRIANGLE. In Astronomy, one of the forty-eight constellations of Hipparchus, situated in the northern hemisphere. The same name is also given to one of the twelve southern constellations formed by Bayer. There is also the *Little Triangle*, added by Hevelius, near the first named. *See* CONSTELLATION.

TRIANGLE. In Music, a small steel triangular musical instrument of percussion, open at one of its angles. It is set in vibration by being struck with a short bar of the same metal as that whereof the instrument is composed.

TRIANGLE, ARITHMETICAL. The name given by Pascal to a table of certain numbers disposed in the form of a triangle. The first vertical column of the table contains units only; the second contains the series of natural numbers; the third the series of triangular numbers; the fourth the series of pyramidal numbers; and so on. (*See* FIGURATE NUMBERS.) Thus —

1						
1	1					
1	2	1				
1	3	3	1			
1	4	6	4	1		
1	5	10	10	5	1	
1	6	15	20	15	6	1
&c.	&c.	&c.	&c.	&c.	&c.	&c.

Any number in the table is obtained by adding the number next above it, in the same column, to the number in the same line in the next preceding column; and it will be observed that the oblique diagonal rows, beginning at the left and descending towards the right, are the same as the vertical columns. One of the properties of the table is, that numbers taken on the horizontal lines are the coefficients of the different powers of a binomial. For the description and uses of the table, see the Introduction to *Hutton's Mathematical Tables*.

TRIANGULAR COMPASSES. Compasses having three legs; two opening in the usual manner, and the third turning round an extension of the central pin of the other two, besides having a motion on the central joint of its own. The instrument is useful in the construction of maps and charts, as three points may be taken off at once.

TRIANGULAR NUMBERS. The series of numbers formed by the successive sums of the terms of an arithmetical progression, of which the common difference is 1. Thus,

Arithmetical progression,	1, 2, 3, 4, 5, 6, &c.
Triangular numbers,	1, 3, 6, 10, 15, 21, &c.

The general term of the series is $\frac{1}{2}n(n+1)$. *See* FIGURATE NUMBERS.

TRIA'RII. The third, last, or veteran rank of infantry in the Roman legion. (*See* LEGION.) There is an essay on this particular rank, *Mem. de l'Ac. des Inscr.* vol. xxix.

TRIBE. (Lat. tribus.) A principal subdivision of the Roman people. The word signifies a division into three, which was the number of the patrician tribes; which were distinguished by the names Ramnes, Titienses, and Luceres. The first of these consisted of the original body of patricians; the next two were added at different times under the kings from the free citizens, who grew up round the first. The plebeian tribes, which finally included the whole people, were quite distinct from the above. They were instituted by Servius Tullius, who divided the city into four regions, and the rest of the Roman territory into twenty-six; most probably making in all thirty tribes, to correspond to the number of patrician *curiæ*. Ten of these are supposed to have been swept away by the cession of the territory on the Etruscan bank of the Tiber to Porsenna, as we hear of only twenty-one immediately after that event; the one having been most probably added. In later times, the number of tribes was increased to thirty-five, and they then included all the free citizens. In the mean time the patrician tribes became quite extinct; when all the difference of privileges enjoyed by their respective curiæ were abolished. (See *Niebuhr's Hist. of Rome*, 2d edit. p. 417.)

TRIBO'METER. (Gr. τριβω, *I rub*, and μετρον, *measure*.) In Mechanics, the name given by Musschenbroek and Coulomb to a sort of sledge, or apparatus for measuring the force of friction. *See* FRICTION.

TRIBU'NAL. A judgment seat in the forum of Rome, built by Romulus in the form of a half moon; hence any judgment seat: also a raised place in a camp, whence the general addressed his soldiers and issued orders.

TRI'BUNE. Properly, as the name denotes, the chief magistrate of a *tribe*. There were several kinds of officers in the Roman state that bore the title. 1. The plebeian tribunes, who were first created after the secession of the commonalty to the Mons Sacer (260 A. U.), as one of the conditions of its return to the city. They were especially the magistrates and protectors of the commonalty, and no patrician could be elected to the office. At their first appointment the power of the tribunes was very small, being confined to the assembling the plebeians, and the protection of any individual from patrician aggression; but their persons were sacred and inviolable, and this privilege consolidated their other powers, which, in the later ages of the republic, grew to an enormous height, and were finally incorporated with the functions of the other chief magistracies in the person of the emperor. The number of the tribunes varied from two to ten, and each of these might annul the proceedings of the rest by putting in his veto. (See *Niebuhr's Hist. of Rome*, 2d edit. i. 624.; Lableterie, *Mém. de l'Ac. des Inscr.* vol. xxxvii.) 2. Military tribunes were first elected in the year 310 A. U. in the place of the consuls, in consequence of the demands of the commonalty to be admitted to a share of the supreme power. This measure was not, however, a complete concession of their demands, but, in fact, evaded them in a great degree; for the tribunate was not vested with the full powers or honours of the consulate, not being a *curule* magistracy, and though it was open to all the people, patricians were almost invariably chosen. The number of the military tribunes was sometimes six, and sometimes three. For above seventy years sometimes consuls were elected and sometimes military tribunes; at last the old order was permanently restored, but the plebeians were admitted to a share of it. (See *Mem. de l'Ac. des Inscr.* vol. xxxvii.) 3. Legionary tribunes, or tribunes of the soldiers, were the chief officers of a legion, six in number, who commanded under the consul, each in his turn, usually about a month: in battle each led a cohort.

TRIBUNE. In Ancient Architecture, a raised seat or stand whence speeches were delivered to the people; the term is still used in this sense in the French chambers.

TRI'BUTE. (Lat. tribuo, *I give*.) A sum of money paid by inferior sovereign or state to a superior potentate, to secure the friendship or protection of the latter. The *black mail* formerly levied by the Scottish borderers on their less powerful neighbours, for protecting their property from the depredations of caterans, was a species of tribute.

TRI'CA. In Botany, one of the names of the shield or reproductive organ of a lichen.

TRICHE'CHUS. (Gr. θριξ, *hair*, and ιχθυς, *fish*.) A name invented by Artedi to designate the manatee, as being the only species of fish, or whale-fish, that was hairy: "quia solus inter pisces fere hirsutus sit." Linnæus, in his *System of Nature*, adopted the term *trichechus* as the generic appellation for the manatee (*Trichechus manatus*); but he added the walrus as a second species of the genus. Subsequent zoologists, in separating these very different animals, and placing them in distinct genera, have in this, as unfortunately in too many other cases, invented a new generic name for the animal so well designated by its original epithet, and have restricted the application of the term *trichechus* to the walrus, for which it was not originally designed.

TRICHI'ASIS. (Gr. θριξ, *a hair*.) A disease of the eyelids, in which the eyelashes grow inwards and irritate the bulb of the eye.

TRICHI'DIUM. (Gr. θριξ.) A netted filamentous organ, resembling a netted purse, in which the spores of some kinds of fungi are included.

TRICHI'NA. (Gr. diminutive of θριξ.) The name of a genus of microscopic encysted Entozoa, which infest the muscular tissue of the human subject.

TRICHIU'RUS. (Gr. θριξ, and ουρα, *a tail*.) The name of a genus of spiny-finned fishes, literally rendered in their popular English name of "hair-tails," significative of their most striking generic character, which is taken from the single elongated hair-like filament that terminates the rayless tail. The *Trichiuri* have no anal fin, and have neither ventral fins nor supplemental scales. But one species, viz. the silvery hair-tail (*Trichiurus lepturus*, Linn.), has been admitted into the catalogue of British fishes.

TRICHOCE'PHALUS. (Gr. θριξ, and κεφαλη, *a head.*) The name of a genus of Hematoid Entozoons, one species of which (*Trichocephalus dispar*, Rudolphi) infests the human intestinum cœcum.

TRICHOP'TERANS, *Trichoptera*. (Gr. θριξ, and πτερον, *a wing.*) The name of an order of insects founded by Kirby for the case-worm flies, which are characterized by four hairy membranous wings, resembling in their nervures those of the Lepidopterans; the under ones folding longitudinally.

TRICLI'NIUM. (Gr. τρεις, *three*, and κλινη, *a couch.*) In Ancient Architecture, a room furnished on three sides with couches, the fourth side being left open for facilitating the attendance of the servants, in which company was received and the repasts served. The winter triclinia were placed to the west, and those for summer to the east.

TRI'COLOR. The national French banner of three colours, blue, white, and red, adopted on the occasion of the first revolution. The immediate occasion for adopting them is said to have been that they were the colours worn by the servants of the Duke of Orleans; and they were first assumed by the people when the minister Neckar was dismissed in 1789. But these colours, in combination, appear to have formed a national emblem in France from a very early period. It is also said to have been formed by uniting the three colours successively used in the French standards at different periods; viz. the blue of the banner of St. Martin, the red of the oriflamme (*see* ORIFLAMME), and the white of the white cross, supposed to have been assumed under Philip of Valois. The three colours were given by Henry IV. to the Dutch on their desiring him to confer on them the national colours of his country; and they have since been borne successively by the Dutch republic and the kingdom of the Netherlands. The domestic livery of Louis XIV. was tricoloured, as were also the liveries of the Bourbon kings in Spain. At the Revolution, when the three colours were assumed on the national flag, they were borne in the same order as the Dutch, but in a different position, viz. the division of colours parallel to the flag staff; whereas in the Dutch flag it is at right angles with it. Tricoloured flags have been adopted in some of the German states, and in Belgium, &c.; and they are often employed as emblematical of liberty.

TRICU'SPID VALVE. The valve of the right ventricle of the heart.

TRI'DENT. (Lat. tres, *three*, and dens, *a tooth.*) The sceptre which the poets and painters of antiquity placed in the hand of Neptune is so called by way of eminence. It is in the form of a spear or fork with three prongs or teeth; hence the name. *See* NEPTUNE.

TRI'ENS. A small Roman copper coin, worth one third of the *as* (which see), as the derivation of the word implies. This was the piece of money usually placed in the hands of the deceased poor to pay Charon for their passage over the Styx.

TRIERA'RCHIA. (Gr. τριηραρχια.) An Athenian institution which imposed on a certain body of citizens the duty of fitting out triremes for the use of the state. About 1200 citizens were usually chosen for this purpose from the richest individuals, and these were subdivided into clubs of 12 or 16 to each ship. Demosthenes introduced a new regulation, by which the burden to be borne by each individual was made to bear a given proportion to his property. (See Boeckh, *Public Economy of Athens*, ii. 319. 360.)

TRIE'TERIS. (Gr. τρεις, *three*, and ετος, *a year.*) In Grecian Chronology, a cycle invented by Thales to connect his year, which consisted of 12 months of 30 days each, amounting to 360 days; this falling short of the true solar year, he inserted a month of 30 days at the end of every three years, by which means he made it exceed the true year by 13 days.

TRIFO'RIUM. (Lat.) In Gothic Architecture, an arched story between the lower arches and the clerestory in the aisles, choir, and transepts of a church. An example may be seen in Westminster Abbey, where the triforium affords a communicating gallery entirely round the church.

TRI'GAMOUS (Gr. τρεις, *three*, and γαμος, *marriage*), is a name applied by some botanists to plants containing three sorts of flowers in the same flower-head; that is to say, males, females, and hermaphrodites.

TRIGE'MINI. (Lat. tres, *three*, and geminus, *double.*) The fifth pair of nerves: they arise from the crura of the cerebellum, and are divided within the cranium into three branches; namely, the orbital, and the superior and inferior maxillary. The orbital branch is divided into the frontal, lachrymal, and nasal nerves; the superior maxillary into the spheno-palatine, posterior alveolar, and infra-orbital nerves; and the inferior maxillary into two branches, the internal lingual, and one more appropriately termed the infra-maxillary.

TRI'GLYPH. (Gr. τρεις, *three*, and γλυφω, *I carve.*) In Architecture, an ornament in the Doric frieze, consisting of two whole and two half channels, separated by flat spaces called *femora*.

TRI'GONALS, *Trigona*. (Gr. τρεις, *three*; γωνια, *an angle.*) The name of a family of Decapodous Crustaceans, the carapace of which is nearly triangular. *Trigonia* is also the name of a genus of Bivalves of a triangular form, and of which most of the species are fossil.

TRIGO'NIA. (Gr. τριγωνος, *having three corners.*) A name applied by Lamarck to a genus of Ostracean Bivalves, most of the species of which are found fossil; but which has a beautiful recent representative in the seas of the southern hemisphere, remarkable for the iridescent lining of the valves, *La Trigo nacrée* of Lamarck. It is also the name of a genus of South American plants.

TRIGONOCE'PHALUS. (Gr. τριγωνος, and κεφαλη, *a head.*) A genus of poisonous serpents, characterized by having the tail terminated by a horny conical process or spur. No species is known to inhabit Europe or Africa, in which continents the *Trigonocephali* are replaced by the vipers. The poisonous serpent of the island of Martinique, called by the French settlers "fer de lance," is a species of the present genus (*Trigonocephalus lanceolatus*).

TRIGONO'METRY. (Gr. τριγωνος, *triangle*, μετρον, *measure.*) This term, as its derivation implies, originally signified the measurement of triangles, or the branch of mathematics which treats of the relations between the sides and angles of triangles; but in its modern acceptance it includes all formulæ relative to angles or circular arcs, and the lines connected with them, these lines being expressed by numbers or ratios. In relation to its practical utility, it may be regarded as the most important of all the applications of mathematics.

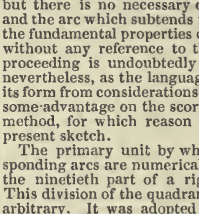
The magnitude of an angle is usually measured by the circular arc which has its centre at the angular point, and is intercepted by the straight lines forming the angle; but there is no necessary connection between an angle and the arc which subtends it, and in some modern works the fundamental properties of trigonometry are explained without any reference to the circle. This method of proceeding is undoubtedly more direct than the other; nevertheless, as the language of trigonometry has taken its form from considerations respecting the circle, there is some advantage on the score of perspicuity in the ancient method, for which reason we shall adhere to it in the present sketch.

The primary unit by which angles and their corresponding arcs are numerically expressed is the *degree*, or the ninetieth part of a right angle or of a quadrant. This division of the quadrant into ninety parts is entirely arbitrary. It was adopted by the ancient Greeks, and has been all but universally followed down to the present time; for although the French mathematicians attempted to introduce the decimal system, by dividing the quadrant into a hundred parts, their example has not been imitated, as the first effect of the alteration would be to derange and render useless the whole of the existing trigonometrical tables.

The degree is divided into 60 minutes, and the minute into 60 seconds. Anciently the seconds were subdivided into thirds; but the practice of writing down the parts of seconds as decimals is now universally followed. The expression $20^{\circ}\ 16'\ 43{\cdot}57''$ is read 20 degrees, 16 minutes, 43 seconds, 5 tenths and 7 hundredths of a second.

Let B A C (fig. 1.) be an angle contained by the two straight lines A B, A C; with A as a centre, and radius A B, describe a circle; let B A be produced to meet the circumference in E, and draw the diameter D F perpendicular to B E. From C draw C H and C K respectively perpendicular to B E and D F; and let B L and D M be also perpendicular to B E and D F, meeting A C produced in L and M. Now, since the angles at the centre of a circle are proportional to the arcs on which they stand, the arc B C may be taken as the geometrical measure of the angle B A C, and both will be expressed without distinction by the same number of degrees, minutes, &c. The following definitions are used.

(1.)



The arc D C, which is the defect of B C from the quadrant, is called the *complement* of B C; and C E, which is its defect from the semicircle, is called its *supplement*. C H is the *sine* of the arc B C, and C K or A H is the sine of its complement, or the *cosine* of B C; B L is the *tangent* of the arc B C, and D M is the tangent of its complement, or the *cotangent* of B C; A L is the *secant* of B C, and A M the secant of its complement, or its *cosecant*; B H is the *versed sine* of B C, and D K its

co-versed sine. These appellations are abridged as follows: — The arc being denoted by the single letter A, its sine is expressed by *sin* A; its cosine by *cos* A; its tangent by *tan* A; its cotangent by *cot* A; its secant by *sec* A; its cosecant by *cosec* A; its versed sine by *ver sin* A; and its co-versed sine by *co-ver sin* A.

Since the arc B C is assumed as the measure of the angle B A C, the above lines may be regarded respectively as the sine, cosine, tangent, &c. of the angle; and since all quantities used in trigonometry are to be expressed by numbers, we may take, instead of those lines, any numbers which are proportional to them; and thence we may assume the ratio of the arc B C to the radius A B, that is, B C÷A B, as the measure of the angle BAC. In like manner the sine of the angle B A C may be represented by C H ÷ A B, its cosine by A H ÷ A B, its tangent by B L ÷ A B, its secant by A L ÷ A B, its cotangent by D M ÷ A D, and its cosecant by A M ÷ A D. Adopting these definitions, the values of the trigonometrical functions of the angle B A C will evidently remain the same when the angle remains constant, whatever be the magnitude of the circle to which they are referred. It is usual to regard the radius A B as a unit, in which case the sines, cosines, tangents, &c. will be expressed in terms of that unit by the decimal notation. This is the way in which they are expressed in the trigonometrical tables.

From the right-angled triangles in the above diagram, we have $AH^2 + HC^2 = AC^2$, $AB^2 + BL^2 = AL^2$, $AD^2 + DM^2 = AM^2$; and because the three triangles A H C, A B L, A D M are similar, we have also

$$AH : HC :: AB : BL :: DM : DA;$$
$$HC : CA :: BL : LA :: DA : AM;$$
$$CA : AH :: LA : AB :: AM : DM.$$

Making the radius A B = A C = A D = 1, and denoting the angle B A C by A, these proportions give

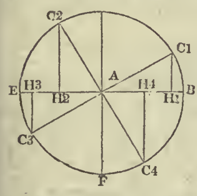
$$\cos A : \sin A :: 1 : \tan A :: \cot A : 1;$$
$$\sin A : 1 :: \tan A : \sec A :: 1 : \operatorname{cosec} A;$$
$$1 : \cos A :: \sec A : 1 :: \operatorname{cosec} A : \cot A;$$

from which, and the above equations, we obtain the following table of formulæ, exhibiting the relations among the trigonometrical lines: —

$$\cos^2 A + \sin^2 A = 1.$$
$$\sec^2 A - \tan^2 A = 1.$$
$$\operatorname{cosec}^2 A - \cot^2 A = 1.$$
$$\cos A \sec A = 1.$$
$$\sin A \operatorname{cosec} A = 1.$$
$$\tan A \cot A = 1.$$
$$\tan A \cos A = \sin A.$$
$$\cot A \sin A = \cos A.$$
$$\sin A \sec A = \tan A.$$
$$\cos A \operatorname{cosec} A = \cot A.$$
$$\tan A \operatorname{cosec} A = \sec A.$$
$$\cot A \sec A = \operatorname{cosec} A.$$

Of the Signs of the Trigonometrical Lines. — In the above definitions and formulæ the angle A was assumed to be less than a right angle, or less than 90°, and the sine, cosine, tangent, &c. were all regarded as positive. We have now to inquire what the expressions severally become as the arc increases through all its values from 0 to 360°. As before, let B E and D F (fig. 2.) be two diameters of the circle at right angles to each other; suppose the arc to begin at B; let BC_1 be less than a quadrant, and let the arc BC_1 or angle BAC_1 be denoted by A. Draw AC_2 at right angles to A C ; then, since C_1C_2 is 90°, the arc $BC_2 = 90 + A$. Let C_1A be produced to meet the circumference in C_3; then (reckoning always in the same direction) $BC_3 = 180° + A$. Lastly, let C_2A be produced to meet the circumference in C_4, and we have BC_4 (or $BDEC_4$) $= 270° + A$. Draw C_1H_1, C_2H_2, &c. perpendicular to E B. Now, according to the usual conventions of analytical geometry, if the point A be regarded as the origin of the co-ordinates, and distances measured in the direction A B be considered as positive, those measured in the direction A E will be negative; and of the lines perpendicular to E B, if those above E B be positive, those below it will be negative. Hence the sines and cosines of arcs in the different quadrants will be as follows: —

(2.)



In the first quadrant the arc BC_1 (= A) is less than 90°, and C_1H_1 and AH_1 are both positive; that is, sin A and cos A are positive. In the second quadrant we have $BC_2 = 90° + A$; its sine is C_2H_2 which is positive, and its cosine is AH_2, which is negative. But from similar triangles we have $C_2H_2 = AH_1$, and $AH_2 = C_1H_1$; therefore, $\sin(90° + A) = \cos A$, and $\cos(90 + A) = -\sin A$. In the third quadrant, we have $AC_3 = 180 + A$; the sine is C_3H_3 negative, and the cosine is AH_3 positive; but $C_3H_3 = C_1H_1$, and $AH_3 = AH_1$; therefore $\sin(180° + A) = -\sin A$, and $\cos(180 + A) = -\cos A$. In the fourth quadrant we have $AC_4 = 270° + A$; the sine is C_4H_4 negative, and the cosine is AH_4 positive. But $C_4H_4 = AH_1$, and $AH_4 = C_1H_1$; therefore $\sin(270° + A) = -\cos A$, and $\cos(270° + A) = \sin A$.

Having found the directions and values of the sine and cosine of an arc in each of the different quadrants, those of the tangent, cotangent, secant, and cosecant are also determined; for the above formulæ give

$$\tan A = \frac{\sin A}{\cos A},\ \cot A = \frac{\cos A}{\sin A},\ \sec A = \frac{1}{\cos A},$$
$$\operatorname{cosec} A = \frac{1}{\sin A}.$$

Whence it appears that the tangent and cotangent will be positive when the sine and cosine have both the same sign, that is, in the first and third quadrants; and negative when the sine and cosine have opposite signs, that is, in the second and fourth quadrants. It follows also that the secant has always the same sign as the cosine, and the cosecant the same as the sine.

On these principles the following table is constructed, which will very frequently be found useful in calculation, as it shows not only the sign to be prefixed to the several trigonometrical lines when the arcs to which they belong exceed 90°, but also how to find those lines in tables which contain them only for the first quadrant.

1st Quadrant.	2d Quadrant.
+ sin A	sin (90° + A) = + cos A
+ cosec A	cosec (90° + A) = + sec A
+ cos A	cos (90° + A) = — sin A
+ sec A	sec (90° + A) = — cosec A
+ tan A	tan (90° + A) = — cot A
+ cot A	cot (90° + A) = — tan A
3d Quadrant.	**4th Quadrant.**
sin (180° + A) = — sin A	sin (270° + A) = — cos A
cosec(180°+A)=—cosec A	cosec (270°+A) = — sec A
cos (180° + A) = — cos A	cos (270° + A) = + sin A
sec 180° + A) = — sec A	sec (270°+A) = + cosec A
tan (180° + A) = + tan A	tan (270° + A) = — cot A
cot (180° + A) = + cot A	cot (270° + A) = — tan A

Of the Trigonometrical Tables. — We now proceed to show how the different trigonometrical lines may be computed. The ordinary tables contain the logarithms of the sines, cosines, tangents, and cotangents for every ten seconds, and some of the better tables, as Taylor's, Baguay's, &c., for every second of the quadrant; but it is evident from the formulæ given above that if the values of any one of the four be computed for the different angles between 0 and 90°, the values of all the others will be obtained at the same time. Thus, since $\cos A = \sin(90° - A)$, a table of the values of the sine is also a table of the values of the cosine; and since $\tan A = \sin A \div \cos A$, the logarithm of the tangent of any angle is obtained by subtracting the logarithm of the cosine from the logarithm of the sine, and the logarithm of the cotangent by subtracting the logarithm of the sine from that of the cosine. The whole difficulty, therefore (or nearly the whole, for some peculiar artifices must be employed when the angles differ very little from 0, or from 90°), is reduced to the computation of the sine; and as this is expressed indefinitely in terms of the arc, it is necessary, first of all, to determine the length of the whole circumference in terms of the radius, from which the arc corresponding to any given number of degrees, minutes, and seconds, is found by proportion.

It is usual to designate the semicircumference of a circle whose radius is 1 by π. A great number of formulæ have been given for computing the value of π by means of infinite series. The following, which was discovered by Mechin, is the most rapidly convergent, and therefore the best adapted for computation: —

$$\pi = 16\left(\frac{1}{5} - \frac{1}{3 \cdot 5^3} + \frac{1}{5 \cdot 5^5} - \frac{1}{7 \cdot 5^7} + \frac{1}{9 \cdot 5^9} - \text{\&c.}\right)$$
$$-4\left(\frac{1}{239} - \frac{1}{3 \cdot 239^3} + \frac{1}{5 \cdot 239^5} - \frac{1}{7 \cdot 239^7} + \text{\&c.}\right).$$

By computing a few of the terms of this series, the value of π is readily obtained. The following is its value correct to 20 decimals: —

$$\pi = 3{\cdot}14159265358979323846, \text{ \&c.}$$

The series which give the trigonometrical lines in terms of the arc are as follows: — Let x be any arc less than 90°, then

$$\sin x = x - \frac{x^3}{1 \cdot 2 \cdot 3} + \frac{x^5}{1 \cdot 2 \cdot 3 \cdot 4 \cdot 5} - \frac{x^7}{1 \cdot 2 \cdot 3 \cdot 4 \cdot 5 \cdot 6 \cdot 7} + \text{\&c.}$$
$$\cos x = 1 - \frac{x^2}{1 \cdot 2} + \frac{x^4}{1 \cdot 2 \cdot 3 \cdot 4} - \frac{x^6}{1 \cdot 2 \cdot 3 \cdot 4 \cdot 5 \cdot 6} + \text{\&c.}$$

$$\tan x = x + \frac{x^3}{3} + \frac{2x^5}{3\cdot 5} + \frac{17x^7}{3^2\cdot 5\cdot 7} + \frac{62x^9}{3^2\cdot 5\cdot 7\cdot 9} + \text{\&c.}$$

$$\cot x = \frac{1}{x} - \frac{x}{3} - \frac{x^3}{3^2\cdot 5} - \frac{2x^5}{3^3\cdot 5\cdot 7} - \frac{x^7}{3^3\cdot 5^2\cdot 7} - \text{\&c.}$$

$$\sec x = 1 + \frac{x^2}{1\cdot 2} + \frac{5x^4}{1\cdot 2\cdot 3\cdot 4} + \frac{61a^6}{1\cdot 2\cdot 3\cdot 4\cdot 5\cdot 6} + \text{\&c.}$$

$$\operatorname{cosec} x = \frac{1}{x} + \frac{x}{1\cdot 2\cdot 3} + \frac{7x^3}{3\cdot 4\cdot 5\cdot 6} + \frac{31x^5}{3\cdot 4\cdot 5\cdot 6^2\cdot 7} + \text{\&c.}$$

For other and more expeditious methods of computing the trigonometrical lines, or deriving them from one another, the reader is referred to the Preface to the *Tables Trigonometriques Decimales*, by Delambre; or to *Callet's* or *Hutton's Tables*.

The following expressions for the sine and cosine of an angle, found by John Bernoulli, are of frequent use in analytical trigonometry:—Let $e = 2{\cdot}7182818$ (the base of the Napierean logarithms), then

$$\sin x = \frac{e^{x\sqrt{-1}} - e^{-x\sqrt{-1}}}{2\sqrt{-1}};$$

$$\cos x = \frac{e^{x\sqrt{-1}} + e^{-x\sqrt{-1}}}{2}.$$

To these we may add the following formula for a multiple angle, discovered by Demoivre, which is readily deduced from them (m is any number whatever):—

$$\left(\cos x + \sin x\sqrt{-1}\right)^m = \cos mx + \sin mx\sqrt{-1}.$$

Formulæ relative to Two Arcs.— In trigonometrical calculations, it is very frequently necessary to express the sines, cosines, &c. of the sum or difference of two angles in terms of the sines, cosines, &c. of the single angles. The following table contains a synopsis of the most useful formulæ; the first four are easily demonstrated by means of a simple geometrical construction, and all the others are deduced from these four by the ordinary algebraic transformations:—

$$\cos(A + B) = \cos A \cos B - \sin A \sin B.$$
$$\cos(A - B) = \cos A \cos B + \sin A \sin B.$$
$$\sin(A + B) = \sin A \cos B + \cos A \sin B.$$
$$\sin(A - B) = \sin A \cos B - \cos A \sin B.$$
$$\cos B + \cos A = 2\cos\tfrac{1}{2}(A + B)\cos\tfrac{1}{2}(A - B).$$
$$\cos B - \cos A = 2\sin\tfrac{1}{2}(A + B)\sin\tfrac{1}{2}(A - B).$$
$$\sin A + \sin B = 2\sin\tfrac{1}{2}(A + B)\cos\tfrac{1}{2}(A - B).$$
$$\sin A - \sin B = 2\cos\tfrac{1}{2}(A + B)\sin\tfrac{1}{2}(A - B).$$

$$\tan(A + B) = \frac{\tan A + \tan B}{1 - \tan A\tan B}.$$

$$\tan(A - B) = \frac{\tan A - \tan B}{1 + \tan A\tan B}.$$

$$\cot(A + B) = \frac{1 - \tan A\tan B}{\tan A + \tan B}.$$

$$\cot(A - B) = \frac{1 + \tan A\tan B}{\tan A - \tan B}.$$

$$\tan A + \tan B = \frac{\sin(A + B)}{\cos A\cos B}.$$

$$\tan A - \tan B = \frac{\sin(A - B)}{\cos A\cos B}.$$

$$\cot A + \cot B = \frac{\sin(A + B)}{\sin A\sin B}.$$

$$\cot B - \cot A = \frac{\sin(A - B)}{\sin A\sin B}.$$

$$\tan A + \cot B = \frac{\cos(A - B)}{\cos A\sin B}.$$

$$\cot A - \tan B = \frac{\cos(A + B)}{\sin A\cos B}.$$

$$\cos 2A = 1 - 2\sin^2 A,\quad \sin 2A = 2\sin A\cos A.$$

$$\tan 2A = \frac{2}{\cot A - \tan A},\quad \cot 2A = \tfrac{1}{2}(\cot A - \tan A).$$

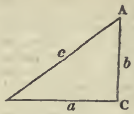
$$\cos\tfrac{1}{2}A = \sqrt{[\tfrac{1}{2}(1 + \cos A)]},\quad \sin\tfrac{1}{2}A = \sqrt{[\tfrac{1}{2}(1 - \cos A)]}.$$

$$\tan\tfrac{1}{2}A = \frac{\sin A}{1 + \cos A},\quad \cot\tfrac{1}{2}A = \frac{\sin A}{1 - \cos A}.$$

Solution of Plane Triangles.— Having explained the nature of the trigonometrical quantities, and exhibited some of their most useful relations, we come next to apply them to the solution of triangles, which forms the proper object of trigonometry. Of the six parts of which a triangle consists, namely, the three sides and the three angles, it is known from geometry that when any three (excepting the three angles) are given, all the rest are determined; accordingly, we have to find expressions for each part in terms of three others, and so arranged that they can be immediately calculated from a table which contains the logarithms of the sines, cosines, tangents, and cotangents to every minute or smaller division of the quadrant. The solution of triangles may therefore be regarded as the art of applying such a table to each particular case. It is convenient to consider the cases of the right-angled triangles separately.

Right-angled Plane Triangles.— In all the solutions which follow, the sides of the triangle will be denoted by a, b, c; and the angles respectively opposite by A, B, C. In the right-angled triangle A B C (fig. 3.), let C be the right angle, and consequently c the hypothenuse. There are four distinct cases, and in each case the solution follows immediately from the definition of the sine, cosine, tangent, and cotangent.

(3.)



Case 1. Given the two sides a and b to find the angles A and B, and the hypothenuse c. Here we have from the definition

$$\tan A = \frac{a}{b};\ \tan B = \frac{b}{a};\ \cos A = \frac{b}{c};\ \text{whence } c = \frac{b}{\cos A},$$

or in like manner $c = a \div \cos B$.

Case 2. Given the hypothenuse c and a side a, to find the angles A and B and the side b. Here

$$\sin A = \cos B = \frac{a}{c};\ \sin B = \frac{b}{c};\ b = c\sin B = c\cos A.$$

The side b may be found independently of the angles; for since $b^2 = c^2 - a^2$, we have $b = \sqrt{[(c + a)(c - a)]}$.

Case 3. Given a side a and one of the acute angles A, to find the other side b, the hypothenuse c, and the angle B.

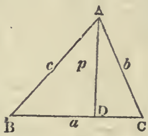
$$\text{Here } \cot A = \frac{b}{a};\ \sin A = \frac{a}{c};\ b = a\cot A;\ c = \frac{a}{\sin A}.$$

For the angle we have $B = 90^\circ - A$.

Case 4. Given the hypothenuse c and an angle A, to find the sides a and b and the other angle B. Here $a = c\sin A$; $b = c\cos A$; $B = 90 - A$.

Oblique-angled Plane Triangles.— The solutions of the different cases are all derived from the three following propositions: First, the sum of the three interior angles of any triangle is equal to two right angles; that is, $A + B + C = 180^\circ$ . . . . (1.) Secondly, in any triangle, the sides are to each other as the sines of the opposite angles. For, draw A D (fig. 4.) perpendicular to B C, and let A D $= p$; we then have $\sin B = \frac{p}{c}$, $\sin C = \frac{p}{b}$;

(4.)



whence $\frac{\sin B}{\sin C} = \frac{b}{c}$. The same property must evidently hold true of sides a and c, and a and b; whence

$$\frac{\sin A}{\sin B} = \frac{a}{b};\ \frac{\sin B}{\sin C} = \frac{b}{c};\ \frac{\sin C}{\sin A} = \frac{c}{a}\ \ldots\ (2.)$$

The third general property may be derived from the second, but is more readily found as follows:—In the last figure let B D $= m$, D C $= n$; we have then $m = a - n$, whence $m^2 = a^2 + n^2 - 2an$. Adding p^2 to both sides, and observing that $m^2 + p^2 = c^2$, $n^2 + p^2 = b^2$, and $n = b\cos C$, we have $c^2 = a^2 + b^2 - 2ab\cos C$, and consequently

$$\cos C = \frac{a^2 + b^2 - c^2}{2ab}\ \ldots\ (3.)$$

We now proceed to give the solutions of the different cases, of which there are four.

Case 1. Given the three sides, a, b, c, to find the three angles A, B, C.

$$\text{Put } s = \tfrac{1}{2}(a + b + c),\ M = \sqrt{\left\{\frac{(s-a)(s-b)(s-c)}{s}\right\}};$$

$$\text{then } \tan\tfrac{1}{2}A = \frac{M}{s - a},\ \tan\tfrac{1}{2}B = \frac{M}{s - b},\ \tan\tfrac{1}{2}C = \frac{M}{s - c}.$$

Case 2. Given two sides, a, b, and the included angle C, to find the other side c, and the other angles A, B.

Find first the sum and difference of A and B from these two formulæ, $A + B = 180^\circ - C$, $\tan\tfrac{1}{2}(A - B) = \frac{a - b}{a + b}\tan\tfrac{1}{2}(A + B)$; then

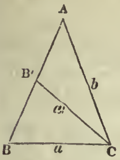
$$A = \tfrac{1}{2}(A + B) + \tfrac{1}{2}(A - B).$$
$$B = \tfrac{1}{2}(A + B) - \tfrac{1}{2}(A - B).$$
$$c = a\frac{\sin C}{\sin A} = b\frac{\sin C}{\sin B}.$$

Case 3. Given two sides a, b, and the angle opposite one of them, A, to find the third side c, and the other angles B, C.

Here we have $\sin B = \frac{b}{a}\sin A$; $C = 180^\circ - (A + B)$;

$c = a \dfrac{\sin C}{\sin A} = b \dfrac{\sin C}{\sin B}$. In this scae, however, it is necessary to remark, that if the side which is adjacent to the given angle be greater than the side opposite to it (that is, if b be greater than a), then there are two triangles which furnish the same data, and consequently the solution is ambiguous. For with C (fig. 5.) as a centre, and radius equal to C B, describe an arc of a circle intersecting A B in B′, and join C B′; it is obvious that the data a, b, A belong to both triangles A C B and A C B′, and the solution gives alike $c =$ A B, and $c =$ A B′. The solution is therefore said to be ambiguous.

(5.)



Case 4. Given two angles, A, B, and the side between them c.

In this case the third angle is likewise given by reason of $C = 180^\circ - (A + B)$, and consequently the sides are found from the formulæ

$$a = c \frac{\sin A}{\sin C},\ b = c \frac{\sin B}{\sin C}.$$

Area of a Plane Triangle.—Euclid has shown that the area of any plane triangle is equal to the rectangle contained under half the base and the perpendicular let fall on it from the opposite angle; that is, area $= \frac{1}{2} a p$ (fig. 4.) But for p we may substitute $b \sin C$ (or $c \sin B$), and we have area $= \frac{1}{2} a b \sin C$. If from this expression we eliminate b by the first of the equations (2.), we shall have the area in terms of a side and the three angles; or, if we eliminate sin C by means of the formula (3.) and the equation $\cos^2 C = 1 - \sin^2 C$, we shall have an expression for the area in terms of the three sides. Assume $s = \frac{1}{2}(a + b + c)$; then the area is expressed by any of the following formulæ:—

$$\text{area} = \frac{a b \sin C}{2} = \frac{a^2 \sin B \sin C}{2 \sin A} = \sqrt{[s(s-a)(s-b)(s-c)]}.$$

Spherical Trigonometry.—This branch of trigonometry considers the relations between the sides and angles of triangles formed on a sphere. Before giving the formulæ for the solutions of the different cases, it will be useful to state a few elementary properties of spherical triangles, depending on principles purely geometrical.

The following definitions must be premised:—1. The common section of the spherical surface and any plane passing through the centre of the sphere is called a *great circle* of the sphere. 2. The *pole* of a great circle is a point on the surface of the sphere from which all straight lines drawn to that great circle are equal. 3. A *spherical angle* is the angle on the surface of the sphere made by two great circles at their intersection. It is identical with the angle made by the planes of the circles, and is measured by an arc of the great circle whose pole is at the angular point. 4. A *spherical triangle* is a figure on the surface of the sphere bounded by three arcs of great circles, each of which is less than a semicircle. 5. Any arc of a great circle is the measure of the plane angle formed at the centre of the sphere by the two radii passing through the extremities of the arc.

From these definitions the following properties are easily derived:—

1. The distance of a great circle from its pole is a quadrant.

2. If two great circles cut one another at right angles, each passes through the pole of the other; and, consequently, if two great circles cut a third at right angles, they will meet in its pole.

3. A spherical triangle which has two equal sides has the angles opposite to those sides equal, and the greater side has the greater angle opposite to it.

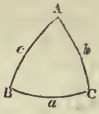
4. The sum of any two sides is greater than the third, the difference of any two less than the third; and the sum of all the three sides is less than the circumference of a great circle.

5. If about the angular points of a spherical triangle as poles there be described three great circles on the sphere, these, by their intersections, will form a triangle which is said to be *supplemental* to the former; and the two triangles are such that the sides of the one are the supplements of the arcs which measure the angles of the other.

6. The sum of the three angles of any spherical triangle is greater than two right angles, but less than six right angles.

Solution of Spherical Triangles.—The solutions of all the different cases of spherical triangles are comprehended in the four following sets of formulæ; and it will be remarked that the different formulæ in each set express all the same property, and are formed by merely interchanging the letters. Those of the first set are readily demonstrated from the properties of the triangular pyramid, or *tetraedron*, and the others may be all deduced analytically from the first; so that, in fact, the whole of spherical trigonometry is comprehended in the first of the underwritten equations. The radius of the sphere is supposed to be unity; the three sides or arcs are respectively denoted by a, b, c (fig. 6.), and the measures of the angles respectively opposite by A, B, C. It is to be observed that the sides a, b, c (as well as the angles A, B, C), are expressed in degrees, minutes, &c.; and not, as in plane trigonometry, in absolute measures, as feet, yards, &c.

(6.)



I.

$$\cos a = \cos b \cos c + \sin b \sin c \cos A.$$
$$\cos b = \cos a \cos c + \sin a \sin c \cos B.$$
$$\cos c = \cos a \cos b + \sin a \sin b \cos C.$$

II.

$$\frac{\sin b}{\sin a} = \frac{\sin B}{\sin A},\ \frac{\sin c}{\sin a} = \frac{\sin C}{\sin A},\ \frac{\sin b}{\sin c} = \frac{\sin B}{\sin C}.$$

III.

$$\cot a \sin b = \cot A \sin C + \cos b \cos C.$$
$$\cot a \sin c = \cot A \sin B + \cos c \cos B.$$
$$\cot b \sin a = \cot B \sin C + \cos a \cos C.$$
$$\cot b \sin c = \cot B \sin A + \cos c \cos A.$$
$$\cot c \sin a = \cot C \sin B + \cos a \cos B.$$
$$\cot c \sin b = \cot C \sin A + \cos b \cos A.$$

IV.

$$\cos A = -\cos B \cos C + \sin B \sin C \cos a.$$
$$\cos B = -\cos A \cos C + \sin A \sin C \cos b.$$
$$\cos C = -\cos A \cos B + \sin A \sin B \cos c.$$

The above general formulæ apply to every case of spherical triangles; but when one of the angles is a right angle, they become considerably more simple; and, in the case of oblique-angled triangles, they admit of transformations, by which they are rendered more convenient for logarithmic calculation.

Right-angled Spherical Triangles.—As before, let C be the right angle and c the hypothenuse.

(7.)

Case 1. Given the two sides a, b, to find the hypothenuse c, and the two oblique angles A, B. Here

$$\cos c = \cos a \cos b;\ \tan A = \frac{\tan a}{\sin b};\ \tan B = \frac{\tan b}{\sin a}.$$

Case 2. Given the hypothenuse c and a side b, to find the other side a and the two oblique angles.

$$\cos a = \frac{\cos c}{\cos b};\ \cos A = \frac{\tan b}{\tan c};\ \sin B = \frac{\sin b}{\sin c}.$$

Case 3. Given a side a and the opposite angle A, to find the other side b, the hypothenuse c, and the angle B.

$$\sin b = \frac{\tan a}{\tan A};\ \sin c = \frac{\sin a}{\sin A};\ \sin B = \frac{\cos A}{\cos a}.$$

In this case it is necessary to observe, that as a sine belongs to the supplement of the angle as well as to the angle itself, each of the things to be found has two values; and consequently the solution is ambiguous, as two distinct triangles may be formed of the same data.

Case 4. Given a side a, and the adjacent angle B; to find b, c, and A.

$$\tan b = \sin a \tan B;\ \cot c = \cot a \cos B;\ \cos A = \cos a \sin B.$$

Case 5. Given the hypothenuse c, and an angle A, to find the sides a, b, and the angle B.

$$\sin a = \sin c \sin A;\ \tan b = \tan c \cos A;\ \cot B = \cos c \tan A.$$

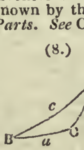
Case 6. Given the two oblique angles A, B, to find the two sides a, b, and the hypothenuse c.

$$\cos a = \frac{\cos A}{\sin B};\ \cos b = \frac{\cos B}{\sin A};\ \cos c = \cot A \cot B.$$

All the six cases of right-angled spherical triangles, it is proper to remark, were reduced by Lord Napier, the inventor of the logarithms, to two rules, which are known by the name of *Napier's Rules of the Circular Parts*. *See* CIRCULAR PARTS.

Oblique-angled Spherical Triangles.

(8.)



Case 1. Given the three sides a, b, c, to find the three angles A, B, C.

Find $s = \frac{1}{2}(a + b + c)$, and put M =

$$\sqrt{\left\{\frac{\sin(s-a)\sin(s-b)\sin(s-c)}{\sin s}\right\}};$$

then $\tan \frac{1}{2} A = \dfrac{M}{\sin (s-a)}$, $\tan \frac{1}{2} B = \dfrac{M}{\sin (s-b)}$,

$$\tan \tfrac{1}{2} C = \frac{M}{\sin (s-c)}.$$

Case 2. Given two sides a, b, and the included angle C, to find c, A, and B.

$$\tan \tfrac{1}{2}(A+B) = \frac{\cos \frac{1}{2}(a-b)}{\cos \frac{1}{2}(a+b)} \cot \tfrac{1}{2} C;$$

$$\tan \tfrac{1}{2}(A-B) = \frac{\sin \frac{1}{2}(a-b)}{\sin \frac{1}{2}(a+b)} \cot \tfrac{1}{2} C;$$

$$A = \tfrac{1}{2}(A+B) + \tfrac{1}{2}(A-B);\ B = \tfrac{1}{2}(A+B) - \tfrac{1}{2}(A-B);$$

$$\sin c = \sin a \frac{\sin C}{\sin A} = \sin b \frac{\sin C}{\sin B}.$$

The side c may be otherwise found without finding the angles A and B. Thus, find an auxiliary angle ϕ, such that $\cot \phi = \tan a \cos C$; then

$$\cos c = \frac{\cos a \sin (b+\phi)}{\sin \phi}.$$

Case 3. Given two sides a, b, and the angle opposite one of them A, to find the third side c, and the angles B, C.

Find two subsidiary angles ϕ and ψ, such that $\cot \phi = \tan b \cos A$, $\tan \psi = \cos b \tan A$; then

$$\sin (c+\phi) = \frac{\cos a \sin \phi}{\cos b},\ \sin B = \sin A \frac{\sin b}{\sin a},$$

$$\sin (C+\psi) = \cot a \tan b \sin \psi.$$

This case is ambiguous for the same reason as the corresponding case of plane triangles.

Case 4. Given two angles A, B, and the side between them c, to find the other sides a, b, and the remaining angle C.

Find two angles ϕ and ψ, such that $\tan \phi = \cos c \tan A$, $\tan \psi = \cos c \tan B$; then

$$\tan a = \frac{\tan c \sin \phi}{\sin (B+\phi)},\ \tan b = \frac{\tan c \sin \psi}{\sin (A+\psi)},$$

$$\cos C = \frac{\cos A \cos (B+\phi)}{\cos \phi} = \frac{\cos B \cos (A+\psi)}{\cos \psi}.$$

Case 5. Given two angles A, B, and the side opposite one of them a, to find the other sides b, c, and the remaining angle C.

Find two angles ϕ and ψ, such that $\tan \phi = \tan a \cos B$, $\cot \psi = \cos a \tan B$; then

$$\sin b = \sin a \frac{\sin B}{\sin A},\ \sin (c-\phi) = \cot A \tan B \sin \phi,$$

$$\sin (C-\psi) = \frac{\cos A \sin \psi}{\cos B}.$$

This case is also ambiguous.

Case 6. Given the three angles A, B, C, to find the sides a, b, c.

Find $S = \frac{1}{2}(A+B+C)$, and assume

$$N = \sqrt{\left(\frac{-\cos S}{\cos (S-A) \cos (S-B) \cos (S-C)}\right)};\ \text{then}$$

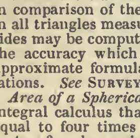
$$\tan \tfrac{1}{2} a = N \cos (S-A);$$
$$\tan \tfrac{1}{2} b = N \cos (S-B);$$
$$\tan \tfrac{1}{2} c = N \cos (S-C).$$

When the sides of a spherical triangle are very small in comparison of the radius of the sphere, as is the case in all triangles measured on the surface of the earth, the sides may be computed from the observed angles with all the accuracy which the observations will admit of by approximate formulæ, which greatly abridge the calculations. *See* SURVEYING.

Area of a Spherical Triangle.—It is known from the integral calculus that the area or surface of a sphere is equal to four times that of one of its great circles, or $= 4 \pi r^2$; where r is the radius of the sphere, and $\pi = 3{\cdot}14159$. Hence, surface of hemisphere $= 2 \pi r^2$.

Now it is manifest that the portion of the spherical surface included between two great semicircles, and which is called a *lune*, will have the same ratio to the surface of the hemisphere as the angle of the lune has to 180°; therefore if the angle of the lune be A°, its surface will be $2 \pi r^2 (A \div 180)$.

(9.)



Let A B C (fig. 9.) be a triangle upon the hemisphere A B H E, and let the sides B C and A C be produced till they meet again in F on the opposite hemisphere; then, since C D F and C E F are semicircles, they are equal to A C D and B C E; whence A C = D F and B C = F E, and the two triangles A B C and D E F are every way equal.

Let S = surface of the triangle A B C; then S = surface of hemisphere − B H D C − A G E C − D C E = $2 \pi r^2$ − (lune A H D − S) − (lune B G E − S) − (lune C D F E − S) $= 2 \pi r^2 \left(1 - \dfrac{A}{180} - \dfrac{B}{180} - \dfrac{C}{180}\right) + 3$ S; therefore $S = \dfrac{A+B+C-180}{180} \pi r^2 = \dfrac{E}{180} \pi r^2$, where $E = A + B + C - 180°$.

From this it follows that the area of a spherical triangle is proportional to the excess of the sum of its three angles above 180°; and hence this quantity, which is called the *spherical excess*, is sometimes taken as the measure of the area of the triangle. The spherical excess and the area are immediately deducible from each other. *See* SPHERICAL EXCESS.

In the above formula the area is given in terms of the three angles. The following elegant formula, which gives the spherical excess in terms of the three sides, is due to L'Huillier:—Let $s = \frac{1}{2}(a+b+c)$; then

$$\tan \tfrac{1}{4} E = \sqrt{[\tan \tfrac{1}{2} s \tan \tfrac{1}{2}(s-a) \tan \tfrac{1}{2}(s-b) \tan \tfrac{1}{2}(s-c)]}.$$

Trigonometry owes its origin to the Greek astronomers of Alexandria. The solutions of the most useful cases of spherical triangles have been known from the time of Hipparchus, and the fundamental formulæ appear in the *Analemma* of Ptolemy. The Greeks, however, instead of the *sines*, employed the *chords* of the double arcs. The sines were introduced by the Arabians, to whom the science is indebted for some other improvements. Regiomontanus introduced the *tangents*, which have greatly simplified the calculations. But the present elegant and compact form in which the solutions now appear is the result of improvements in modern analysis. The treatises on trigonometry are extremely numerous. For the history the reader may be referred to Montucla, *Histoire des Mathématiques;* Delambre, *Histoire de l'Astronomie;* and the Introduction to *Dr. Hutton's Mathematical Tables*.

TRILA'TERAL. (Lat. tres, *three*, and latus, *side*.) Three-sided; a term applied to all triangular figures.

TRI'LLION. In Arithmetic, a million of billions, or a million of million of millions. The term is said by Dr. Johnson to have been invented by Locke.

TRI'LLO. (It.) In Music, a term by which it is intimated that the performer is to beat quickly on two notes in conjoint degrees alternately one after another, beginning with the highest and ending with the lowest. It is marked with a single T as well in a vocal as in an instrumental part.

TRI'LOBITES. (Lat. tres, *three*, and lobus, *a lobe*.) The name given by Cuvier to an order of Crustaceans, comprehending those remarkable fossil species in which the body is divided into three lobes by two fissures which run parallel to its axis.

TRI'LOGY. (Gr. τρεις, *three*, and λογος, *a discourse*.) The word applied to a series of three dramas, which, although each of them is in one sense complete, yet bear a mutual relation, and form but parts of one historical and poetical picture. All the plays of Æschylus, and the *Henry VI.* of Shakspeare, are examples of a *trilogy*.

TRIM. The position of the keel of a ship with respect to a horizontal line. Also the disposition of the weights or stowage, as favourable or otherwise for sailing, which are expressed by *in trim*, and *out of trim*.

TRI'MERANS, *Trimera*. (Gr. τρεις, *three*, and μερος, *a part*.) The name of a section of Coleopterous insects, including those which have each tarsus composed of three articulations.

TRI'MMER. In Architecture, a piece of timber framed at right angles to the joists opposite chimneys or the well holes of stairs, which receives the ends of the joists intercepted by the opening.

TRIMMING JOIST. In Architecture, a joist into which a trimmer is framed.

TRI'MYARIES, *Trimyaria*. (Gr. τρεις, *three*, and μυων, *a muscle*.) The name by which those Bivalves are distinguished which present three muscular impressions on each valve.

TRINE. (Lat. trinus, *threefold*.) Of threefold dimensions,—length, breadth, and thickness. In Astrology, the trine is one of the five aspects of the influential bodies, the angle subtended by the two planets as seen from the earth being 120°, or the third of the zodiac. The trine was supposed to be a benign aspect. *See* ASTROLOGY.

TRI'NGA. (Lat. *a wading bird*.) A genus of wading birds (*Grallæ*), characterized by a compressed bill of moderate length, enlarged at the point; and a hind toe, too short to reach the ground. It is by the latter character that the lapwings (*Tringæ*) are distinguished from the plovers (*Charadeii*), in which the hind toe is wanting.

TRINITA'RIANS. A religious order, founded in 1198 under the pontificate of Innocent III. Its members devoted themselves especially to the duty of ransoming captives taken by the Moors and other infidels. Another body of Trinitarians was formed in consequence of a reformation of the order in 1578. There was also a female

order of the same name, and dedicated to the same objects.

TRI'NITY. The three persons comprised in the Godhead, and distinguished as the Father, the Son, and the Holy Ghost. The term is not found in the Scriptures, and its introduction is referred at the earliest to the 2d century. All denominations of Christians that believe in the Trinity, or Triune Deity, are comprised under the general name of Trinitarians. Several theories have been framed as to the existence of supposed doctrines of a Trinity in Pagan systems. (See, as to the Orphic, Platonic, Egyptian, Greek and Latin, Magian, and Indian Trinities, *Dale's Chronology*, vol. iv.)

TRINITY SUNDAY. The Sunday next after Whit Sunday; so called on account of a feast which was anciently and still continues to be held on that day, in the Romish church, in honour of the Holy Trinity. This feast does not appear to have been fully established in the Western Church until the year 1334, under Pope John XXIII.

TRINO'MIAL. (Lat. tres, *three*, and nomen, *name*.) In Algebra, a quantity consisting of three terms connected by the signs + or —; as $a + b\,c^2 - d^3$.

TRI'O. (It.) In Music, a composition consisting of three parts. Besides those general rules of counterpoint which forbid that two octaves or fifths follow one another either to the bass or any other part in trios, the third must be heard in every time of the bar, either with the bass or between the other two upper parts; or in other words, one of the parts must make a third with the bass, and the other a fifth or octave.

TRIOLET. A stanza of eight lines, in which the first line is thrice repeated.

TRIO'NES. In Astronomy, the seven principal stars in the constellation Ursa Major, popularly called Charles's Wain; four of the stars being fancied to represent a wain or waggon, and the three others the horses by which it is drawn.

TRIPHA'NE. A synonym of the mineral called also *spodumene*.

TRI'PHTHONG. (Gr. τρεις, *three*, and φθογγη, *sound*.) In Grammar, a composite sound of three vowels, as a diphthong is of two; such as the German "aeu." There is no such sound in English, nor, strictly speaking, in French, unless the combinations "ieu" in that language be so considered.

TRI'PLE. (Gr. τριπλους, *threefold*.) In Music, one of the kinds or measures of time, of which there are many different subdivisions. There are, however, only four principal ones, whereof the others are varieties. See art. MUSIC.

TRIPLE SALTS. A term by which, in Chemistry, certain salts are sometimes designated, in which two bases are combined with one acid. Thus, emetic tartar, which is composed of oxide of antimony and of potassa with tartaric acid, and Rochelle salts in which soda and potassa are combined with the same acid, are *triple tartrates*. These salts, however, are more properly regarded as *double salts*; that is, as consisting of tartrate of antimony and of tartrate of potassa, or of single equivalents of tartrate of potassa and tartrate of soda.

TRI'PLETS. In Poetry, three verses rhyming together. Thus, in the famous lines of Pope.

> "Waller was smooth, but Dryden taught to join
> The varying verse, the full resounding line,
> The long majestic march and energy divine."

In Music, notes grouped together by threes; thus,

. In common time, where three of the quavers are intended to be equal in duration to a crotchet, a 3 is sometimes placed over them; but they are generally known by being grouped together, and thus form one of the single parts of the whole measure.

TRIPLICATE RATIO. In Arithmetic and Geometry, the ratio of the cubes is the cube of the simple ratio. Thus the triplicate ratio of 2 to 3 is the same as that of 8 to 27. Similar solids are to each other as the triplicate ratio of their like dimensions.

TRI'POD. (Gr. τρεις, *three*, and πους, *a foot*.) In Architecture, a vessel, table, seat, or instrument having three feet. It was from such a seat that the Pythian goddess rendered oracular answers at Delphi.

TRI'POLI. A mineral used for polishing, originally from Tripoli in Barbary. It occurs in friable earthy masses of a dull clay colour. Its essential components are silica, alumina, and oxide of iron; but the varieties of tripoli appear to vary extremely in composition. Ehrenberg has found the different tripolis to be aggregates of silicified animalcules.

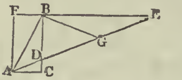
TRI'REME. (Lat. tres, and remus, *oar*; Gr. τριήρης, *a galley with three rows of oars*.) The usual war vessel of the Greeks at the time of the Persian and Peloponnesian wars, and nearly down to the period of the first Punic, when we find quinqueremes pretty generally substituted. With respect to the construction, and the difficulties attending its explanation, see GALLEY. Some light has been thrown on Athenian naval matters by the recent discovery of some inscriptions at the Piræus, which have been commented on by Boeckh. (See *Foreign Quart. Rev.* Jan. 1841. See also his *Public Economy of Athens*, transl. i. 372 &c.).

TRISA'GION. (Gr. τρις, *thrice*, and ἅγιον, *holy*.) In the Greek Church, the threefold invocation of the Deity as "Holy." (Lat. tersanctus.) This invocation takes its origin from Isaiah, vi. 3.; Revelations, iv. 8. The ordinary form is that in Isaiah, "Holy, Holy, Holy Lord God of Hosts, all the earth is full of thy glory." A different form of the trisagion is repeated daily in the service of the Greek church, and is attributed to Saint Proclus. Concerning the war which was raised A.D. 508-518, by the addition of the words "who was crucified for us," see *Gibbon*, chap. xlvii.

TRISE'CTION. (Lat. trisectio.) The dividing of any thing into three equal parts.

TRISECTION OF AN ANGLE. In Geometry, a problem of great celebrity among the ancient Greek mathematicians. The indefinite trisection of an angle cannot be effected by plane geometry, that is to say, by means of the straight line and circle, inasmuch as the analytical equation on which it depends rises to the third degree; but it may be accomplished by means of the conic sections and some other curves, as the quadratrix. The geometrical conditions on which the solution of the problem depends may be explained as follows:—

Let B A C be the angle, and suppose D A C to be its third part. Through any point B in A B draw B C perpendicular to A C, and B E parallel to A C; produce A D to meet B E in E, and complete the rectangle A F B C. Now since D A C is the third of B A C, therefore B A D is equal to twice D A C, or twice B E A. Draw B G, making the angle E B G equal to B E G; then B G A, being equal to G B E and G E B together, is equal to twice B E A, and consequently equal to B A G. Hence the two triangles E G B and G B A are isosceles, or G E = G B = B A. Again, the angle G B D is the difference between a right angle and E B G, and G D B or its equal A D C is the difference between a right angle and D A C, which is equal to E B G; therefore G B D is equal to G D B, whence G D is equal to G B or A B. It thus appears that D G and G E are each equal to A B, or that D E is equal to twice A B, which is a given line. If, therefore, in a rectangle A F B C, a straight line A D could be drawn from the angular point A, so that on producing it to meet the opposite side F B the produced part should be equal to a given straight line, the problem would be solved. This is the condition to which the trisection of the angle is reduced by Pappus of Alexandria, in the 4th book of his *Mathematical Collections*, where he shows how it may be constructed by means of an hyperbola. When, however, the rectangle A F B C becomes a square, that is, when the given angle B A C is half a right angle, the construction is easily effected by elementary geometry. (See *Leslie's Geometrical Analysis*.)



TRI'SMUS. (Gr. τριζω, *I gnash*.) Lockjaw; tetanus affecting the jaw. There are two species of this malady: the one caused by wounds, or, under certain circumstances, by exposure to cold; the other attacking infants during the two first weeks from their birth.

TRI'SPAST, or TRISPASTON. (Gr. τρεις, *three*, and σπαω, *I draw*.) A machine with three pulleys acting in connection with each other for raising heavy weights.

TRI'THEISM. (Gr. τρεις, *three*, and Θεος, *God*.) In Controversial Theology, an error into which some divines appear to have unconsciously fallen in their zeal to support the honour due to each of the three persons of the Trinity. Sherlock in his controversy with South, whose views seemed to tend to confound the separate natures of the Father, Son, and Spirit, and were generally characterized as Sabellian, is accused of having been betrayed into the opposite dogma of Tritheism.

TRI'TICUM. *See* WHEAT.

TRI'TON. In Mythology, a marine deity, son of Neptune. Tritons are sometimes mentioned in the plural number. They were represented as half fish in form. In Zoology, the name *Tritonia* has been given to a genus of marine, naked, gastropodous Mollusks, or sea-slugs.

TRI'TONE, or TRITONUS. (Gr. τρεις, *three*, and τονος, *tone*.) In Music, an interval, now generally called a sharp fourth, consisting of four degrees, and containing three tones between the extremes, on which account the ancients gave it its name. It is moreover divisible into six semitones, three diatonic and three chromatic. In dividing the octave, we find on one side the tritone and on the other the false fifth.

TRITO'XIDE. In Chemistry, such oxides as contain one atom of base united to three atoms of oxygen.

TRI'UMPH. (Lat. triumphus.) The highest military

honour that could be obtained by a Roman general. It was a solemn procession, with which the victorious leader and his army advanced through the city to the capitol, accompanied by the captives taken in war, and vehicles bearing the spoils, and all the furniture that could add magnificence to the spectacle. On arriving at the capitol the general offered up a prayer of thanksgiving to Jupiter and the other gods, and sacrificed white bulls. A triumph was decreed by the senate, and sometimes by the people against the will of the senate, to the general who in a just war with foreigners, and in one battle, had slain above 5000 enemies of the state, and enlarged the limits of the empire. *See* OVATION.

TRIUMPHAL ARCH. In Architecture, an arch erected to perpetuate the memory of a conqueror, or of some remarkable victory or important event. At first it consisted of a single arch, decorated merely with a statue and spoils of the victorious commander; but arches were afterwards erected with two, and then with three passages. Those on the Via Triumphalis in Rome were the most magnificent; and in cases where they served as gates, they were usually constructed with two openings, so that one was appropriated for carriages passing into, and the other for carriages passing out of the city. The following is a list of some of the principal triumphal arches of antiquity: — The arch at Rimini, erected in honour of Augustus on the completion of the repairs of the Flaminian Way from Rome to that city. It was one of the noblest as well as most ancient of the arches of the ancients, having a single passage about thirty-three feet wide, and was, contrary to the usual practice, crowned with a pediment. The lesser arch of Septimus Severus at Rome, commonly called the *Arch of the Goldsmiths*, is a curious example, being of a single opening, and crowned with a flat lintel. An extremely elegant arch at Susa, on the Italian side of Mont Cenis, in honour of Augustus. The arches of Aurelian and Janus, which possess more singularity than beauty. The arch of Pola, in Istria, which is curious from the use of coupled columns which it exhibits, and was erected by Salvia Posthuma, in honour of Sergius Lepidus and his two brothers. The arch of Trajan at Ancona, which, though it has been stripped of its bronze ornaments, retains the beauty of its effect and proportions, and is still in tolerable preservation. It stands at the entrance of the mole of the port, and has four Corinthian columns on pedestals. The arch of Titus at Rome, in which the order used is Composite, and was probably erected after the emperor's death. An arch at Benevento, in honour of Trajan, somewhat resembling that of Titus at Rome, also of the Composite order. An arch of Gavius at Verona, called *del Castel Verchio*, but no longer in existence. The arch of Septimus Severus at Rome, at the foot of the capitol, and that of Constantine in the same city. All these are each with three openings. For the latter the arch of Trajan was despoiled of its ornaments, as the greater part of the bassi-relievi upon it represent the victories of that emperor. It is in better preservation than any of the other arches that we have mentioned, and was indebted for its state to the care of Pope Clement XII.

TRIU'MVIRATE. In Ancient History, this term was applied to two great coalitions of the three most powerful individuals in the Roman empire for the time being. The first of these was effected in the year 60 B.C. between Julius Cæsar, Pompey, and Crassus, who pledged themselves to support each other with all their influence. This coalition was broken by the fall of Crassus at Carrhæ in Mesopotamia; soon after which the civil war broke out, which ended in the death of Pompey, and establishment of Julius Cæsar as perpetual dictator. After his murder, 44 B.C., the civil war again broke out between Antony, who wished to avenge the death and succeed to the fortunes of Cæsar, and the republic, on whose side were ranged Octavius and Brutus. Lepidus with a large army remained in suspense which side to take. But after the battle of Mutina, in which both consuls fell, 43 B.C., Antony, Octavius, and Lepidus coalesced; thus forming the second triumvirate, each party confirming the bond of union by the sacrifice of some of his own friends to the hatred of the others, — in which case was Cicero, who was delivered up by Octavius to the vengeance of Antony. Against this confederation Brutus still held out, with the rest of the conspirators against Cæsar, till their destruction at the battle of Philippi. The triumvirates divided the provinces of the empire, Octavius taking the west, Lepidus Italy, and Antony the east; but the iniquitous union was soon broken by the passion of Antony for Cleopatra, which induced him to repudiate Octavia, the sister of Octavius. War ensued, which was terminated by the defeat and death of Antony at Actium, in 32 B.C.; after which every thing fell into the hands of Octavius, Lepidus offering no obstacle.

TRI'VIUM. (Lat. *three ways.*) The name given in the schools of the middle ages to the three first liberal arts (grammar, rhetoric, and logic), which were studied together. The other four (arithmetic, music, geometry, and astronomy) formed what was termed the quadrivium; and the two following mnemonic lines comprehend the whole: —

Gram. loquitur; Dia. verba docet; Rhe. verba ministrat;
Mus. canit; Ar. numerat; Ge. ponderat; As. colit astra.

TRO'CAR. An instrument used in tapping for the dropsy. The name is said to be corrupted from the French *trois-quarts*, from the three sides of its point.

TROCHA'NTER. (Gr. τρεχω, *I run;* because the muscles inserted into it are those chiefly concerned in the act of running.) A name given to two processes (greater and less trochanter) at the upper end of the thigh-bone.

TRO'CHE. (Lat. trochus, or trochescus, dim. of *wheel.*) A small round lozenge or cake, generally composed of sugar and mucilage, united with small portions of more active remedies, intended to be allowed gradually to dissolve in the mouth.

TRO'CHEE. (Gr. τροχαιος.) A rhythmical measure consisting of two syllables, a long and a short; thus, — ◡.

TRO'CHILUS. (Gr. τροχιλος, *a small bird.*) This term was applied by Linnæus to the genus of small and brilliantly coloured birds which, from the energy and rapidity of the vibrations of their wings during flight, are called humming-birds. This genus includes the smallest of the feathered tribe, and, if we except a few fishes, the most diminutive of vertebrated animals: some humming-birds scarcely exceed a humble-bee in size; they are unable to escape from the strong webs of the large spiders of the American tropics, and thus sometimes become their prey.

The humming-birds are characterized by a long and slender bill, inclosing an extensile bifid tongue, by which they extract the nectar and the small insects which may lurk in the recesses of flowers. They have very small feet, long and narrow wings, a broad and entire sternum with an unusually deep keel and a short and strong humerus; all combining to form a mechanism for rapid and powerful flight, like that of the swift. Humming-birds live in pairs: they have the character of being very quarrelsome, the males fighting desperately with each other: both sexes combine to defend their nests with courage.

TRO'CHLEA. (Gr. τροχαλια, Lat. trochlea.) In Mechanics, the same as pulley or tackle. *See* PULLEY.

In Anatomy, the term *trochlea* is applied to the cartilage through which the tendon of the *trochlearis muscle* passes. It is the superior oblique muscle of the eyeball, and is accompanied by the *trochlearis nerve*.

TRO'CHOID. (Gr. τροχος, *a wheel*, and ειδος, *form.*) The curve described by any point in a wheel rolling straight forward on a level. It is the same as the cycloid; and for an account of its principal properties, see CYCLOID. The same name is also given to another curve, sometimes called the companion of the cycloid, or *curve of arcs*.

TRO'CHUS. (Gr. τροχος.) The name given by Linnæus to a genus of the *Vermes Testacea*, characterized by a subconical spiral shell, with the margin entire, without a fissure or canal for the siphon of the mantle, the animal not possessing any respiratory tube. The mouth of the shell is closed by an operculum, or some analogous part. The species to which the characters of the Linnæan genus are applicable constitute a family of Pectinibranchiate Gastropods in the system of Cuvier, called *Trochoida*, which includes the following genera: — *Tectaria*, Montfort; *Calcar*, Montf.; *Rotella*, Lam.; *Cantharis*, Montf.; *Infundibilum*, Montf.; *Telescopium*, Montf.; *Solarium*, Montf.; *Euomphalus*, Sowerby. The Gastropod called *Turbo pica* by Linnæus, having been ascertained to have an operculum, is now referred to the genus *Trochus*.

TRO'GLODYTES. (Gr. τρωγλη, *cave*, and δυνω, *I enter.*) Tribes of men who have their dwellings in subterraneous caverns. Several such tribes are mentioned by ancient authors, and the remains of their dwellings still attest their existence; especially along the banks of the Nile, in Upper Egypt and Nubia, and in parts of Syria and Arabia. (See *Bryant's Mythology*, iv. 381.)

The chimpanzee has been called by Blumenbach *Simia troglodytes*.

TROMBO'NE. (It.) A brass musical wind instrument serving as the bass to the trumpet, to which in general form it is similar, but of much larger dimensions.

TRO'NA. A native sesquicarbonate of soda found on the banks of the soda lakes of Sukena in Africa.

TRON WEIGHT. The most ancient of the weights used in Scotland; and though its use is now prohibited by law, it is still occasionally employed in some of the rural districts in weighing wool, cheese, butter, &c. The tron pound was not a well-defined weight, but varied from 21 to 28 ounces avoirdupois.

TROOP. A body of mounted soldiers, equivalent to *company* in foot regiments. The term *troops* is not limited to cavalry, but extends to all kinds of soldiers, whether mounted or not.

TROPÆ'OLUM. (Lat. tropæum, *a trophy;* the leaves

resembling a buckler, and the flowers an empty helmet.) A genus of handsome trailing plants, some of whose species have pungent fruits, which have rendered them useful as condiments. Indian cress, the name given to *Tropæolum majus*, expresses their quality. They form a small group nearly allied to the Geraniaceous order, if not forming a part of it.

TROPE. (Gr. τρεπω, *I turn.*) In Rhetoric, literally any expression *turned* from its primary signification, and employed in a sense derived in some manner from that primary signification. In this sense, the general term trope comprises the various figures termed metaphor, allegory, metonymy, synecdoche (which see), and perhaps several others. By the natural progress of language, words or phrases at first employed as tropes become impressed so strongly with their new or derivative signification, that it finally supersedes the original; its *tropical* or *figurative* being lost in its *simply indicative* character.

TRO'PHI. (Gr. τρεφω, *I nourish.*) A name given by Kirby to the different instruments of, or organs contained in the mouth, or closing it, and employed in manducation or deglutition. They include the *labrum*, *labium*, *mandibulæ*, *maxillæ*, *lingua*, and *pharynx*.

TROPHO'NIUS, in Greek Mythology, son of Erginus, king of Orchomenos, together with his brother Agamedes, built the temple of Apollo at Delphi; and having prayed for a reward from the god, it was promised him on the seventh day, on which he and his brother were both found dead. The story is told in other ways. He had a temple at Lebadea, as Jupiter Trophonius. In this temple was the celebrated cave into which those who descended spoke oracularly on their return; and in this way responses were made. But the impressions produced by the descent were thought so to work upon the spirit of a visitor, that he remained a victim to melancholy the remainder of his life. Hence arose the proverb applied to a serious man,—that he looked as if he came out of the cave of Trophonius. Some thought that the priests had secret access to the cavern, and that those whose minds did not give way under the terror of the scene which they encountered were murdered by them. (See Bryant, *Anc. Myth.* vol. ii. p. 361.)

TRO'PHSPERM. (Gr. τρεφω, *I nourish*, and σπερμα, *a seed.*) A name given by some French botanists to the placenta of a plant.

TRO'PHY. (Gr. τροπαιον, from τρεπω, *I turn.*) A monument consisting of some of the arms of slain enemies, hung upon the trunk of a tree, or a stone pillar, by a victorious army in token of its victory and the flight of the enemy; whence its name. Trophies were always dedicated to some deity, and especially to Jupiter, whence it was deemed sacrilegious for any one to injure or demolish them; while at the same time it was esteemed an equal crime to repair them when decayed. This custom was common to all the Greeks, except the Macedonians, who were forbidden to raise trophies by a law of one of their ancient kings. Perhaps the most celebrated trophies of ancient times were those of Marius at Rome, which were of marble, and were restored by Cæsar after their destruction by Sylla, contrary to all the usages of the times. (See as to Roman trophies, *Mém. de l'Ac. des Inscr.* xxiv. 32.)

TROPICAL HIEROGLYPHICS. *See* HIEROGLYPHICS.

TRO'PICAL YEAR. (Gr. τροπη, *return.*) The time between the sun's leaving a tropic and returning to it; popularly it means the time from the longest day in one year till the longest in the next. *See* YEAR.

TRO'PICS, in Astronomy, are the parallels of declination, between which the sun's annual path in the heavens is contained, their distance from the equator being equal to the sun's greatest declination. The northern tropic is called the tropic of Cancer, and the southern one that of Capricorn, from their touching the ecliptic in the first points of those signs.

The distance of the tropics from each other is equal to the difference between the greatest and least meridian altitudes of the sun, observed at any place whose latitude is greater than the obliquity of the ecliptic. *See* ECLIPTIC.

TROPICS, in Geography, are the two parallels of latitude on the earth, over which the sun is vertical when his declination is greatest, or when it is the longest day in the hemisphere in which the tropical circle is situated over which the sun is, and the shortest in the other hemisphere.

TRO'PIDONO'TUS. (Gr. τροπις, *a keel*, and νωτος, *the back.*) A genus of non-venomous serpents, nearly allied to the true Colubers; but with bodies thicker in proportion to their length, the back more keel-shaped, and the abdomen more expanded and convex; the head is large and conical, with a slender and short muzzle. The species seldom exceed three or four feet in length; they live near fresh-water streams, and are good swimmers: they are confined to the old world continents, and are replaced in South America by the genus *Homalopsis*. The *Coluber scaber*, Linn., a serpent of the Cape of Good Hope, remarkable for the presence of teeth in the œsophagus, and their absence from the mouth, is referred to the genus *Tropidonotus* by Schlegel.

TROU'BADOURS, *i. e.* Inventors. (Ital. trovar; Fr. trouver, *to find.*) A school of poets who flourished from the 11th to the latter end of the 13th century, principally in the south of France, but also in Catalonia, Arragon, and the north of Italy. They wrote in varieties of the Provençal or Romance language, also called in the middle ages Langue d'oc. They flourished under the lines of the Counts of Toulouse, Barcelona, and Provence; and their minstrelsy and peculiar spirit declined from the time of the crusade against the Albigenses, when the former of these noble houses was vanquished and humiliated, and their land overrun by the sterner adventurers of the north. The most renowned among the Troubadours were knights, who cultivated poetry as an honourable accomplishment; but their art declined in its later days, when it was chiefly cultivated by minstrels of a lower class. The names and some of the productions of more than 200 Troubadours have been preserved, and among their numbers are to be found kings, dukes, counts, and warriors of historical celebrity. The most remarkable characteristics of the Provençal poetry were its almost entire devotion to the subject of romantic gallantry, and the very complicated character, in general, of its metre and rhymes. The principal species of composition cultivated by the Troubadours were *tenzones*, or poetical contests between two minstrels; sometimes breathing satire or defiance, sometimes rivalling each other in the praise of their ladies, sometimes aiming at mere exertions of verbal ingenuity; *sirventes*, pieces devoted to martial and other serious subjects; short songs, or *chanros;* and a variety of other lyrical strains, *soulas*, *lais*, *pastourelles*, *arbades*, *serenades*, *retronage*, and *redondes*. The earliest Italian poets framed their style of thought and versification closely after the model afforded them by the troubadours. (See Sismondi, *Literature du Midi de l'Europe*, vol. i.; the works of M. Raynouard; *Mr. Lewis's Researches into the Romance Language;* Schlegel, *Obs. sur la Langue et Lit. Provençale.*)

TROUGH OF THE SEA. The ship is said to be in the trough, when she lies parallel to the hollows between the waves.

TROUT. (Lat. trutta.) This name is restricted properly and specifically to the *Salmo fario* of Linnæus; but is applied in a generic sense to other native species of *Salmo*, the *S. eriox* of Linnæus, which is the *S. salar* of Rondeletius, being called the bull-trout and grey trout; the *Salmo ferox*, the great grey trout, or lake-trout; the *S. trutta*, the salmon-trout, &c. The common trout inhabits most of our lakes and rivers, and is subject to many varieties of colour, proportions, and even of internal structure, as in the stomach of the gillaroo-trout, according to the variations of soil and food. The season of spawning with the trout is generally in the month of October, at which period the gravid fish make their way up the stream to the shallows. Trouts are in finest condition from the end of May to September.

TRO'VER. In Law, is an action of tort. It is a species of action on the case (*see* ACTION), which is employed to try a disputed question of property in goods and chattels. The declaration in trover assumes (by a fiction) that the plaintiff lost, and the defendant found and converted to his own use, the goods in question.

TROWELLED STUCCO. In Architecture, stucco left ready for the reception of paint.

TROY WEIGHT. An English weight chiefly used in weighing gold, silver, diamonds, and other articles of jewellery. The pound troy contains 12 ounces or 5760 grains, the pound avoirdupoise containing 7000 of such grains. The name is supposed to have reference to the monkish name given to London, of Troy Novant. *See* WEIGHTS.

TRUCE. (Mod. Lat. treuga, from the Teutonic treue, *truth.*) An agreement between states, or those representing them, for the suspension of hostilities. Such an agreement, when made by officers of the state in the general exercise of their duty, and not authorized for the purpose expressly, or by necessary implification, ranks among that class of conventions which jurists term sponsions, and which are binding only if ratified. (*See* SPONSION.) A general armistice or truce differs from a partial, which is limited to particular places; as between two armies, or between a besieged fortress and the besieging army. The former, in general, requires ratification: power to include the latter is held to be implied in the general authority of military and naval officers. (See *Vattel*, book iii. ch. 16.; *Wheaton on International Law*, vol. ii.)

TRUCE OF GOD, *Treuga Dei*. A suspension of arms, which occasionally took place in the middle ages, putting a stop to private hostilities. The right to engage in these hostilities was jealously maintained by the inferior feudatories of the several monarchies of Europe. But it was restrained by the repeated promulgation of these truces, under the authority of the church. Thus, in the

county of Roussillon, A. D. 1027, it was determined in a synod of the clergy, that no man should attack his enemy from the hour of nones on Saturday to the hour of prime on Monday. In 1041, a general " truce of God " was accepted by the barons, first of Aquitain, and then of all France, to last from the Wednesday evening of every week to the Monday morning following. This regulation was admitted by Edward the Confessor in England, in 1042, with some additions of great festivals and other days. It was confirmed by many councils, especially the Lateran council of 1179. The observation of it was sworn by knights, burgesses, and peasants, of the age of fourteen and upwards; and the penalty of its infringement was excommunication, which, however, was quite insufficient to maintain it. Philippe Auguste introduced a new species of truce, termed the quarantine, by one of his ordinances. It restrained the family of an injured or murdered person from the commencement of hostilities until forty days after the act done, under penalty of high treason.

TRUCK. The small wooden cap at the extremity of a flag staff, or at the mast head. Also a small circular piece of wood with a hole bored through it for a rope to run through.

TRUCK SYSTEM. A name given to a practice that has prevailed, particularly in the mining and manufacturing districts, of paying the wages of workmen in goods instead of money. The plan has been for the masters to establish warehouses or shops; and the workmen in their employment have either got their wages accounted for to them by supplies of goods from such *depôts*, without receiving any money; or they have got the money, with a tacit or express understanding that they were to resort to the warehouses or shops of their masters for such articles as they were furnished with. (For the advantages and disadvantages of this system, see *Com. Dict.*)

TRU'FFLE. A subterranean fungus, of a roundish oblong form, and a blackish brown colour, much employed in cookery. It is found by dogs and pigs, trained for the purpose, in soil beneath trees, especially beeches and oaks; it is, however, very local. It is propagated by spores included in sinuous chambers in the interior; but has never yet been cultivated with success, notwithstanding many attempts that have been made. Botanists recognize several kinds of truffles, the commonest being the *Tuber cibarium*.

TRU'MPET. In Acoustics, an instrument used for the purpose either of conveying articulate sounds to a great distance, or for applying to the ear, in order to collect the sonorous rays, and render sounds more distinct. In the former case, the instrument is a *speaking-trumpet;* in the latter, a *hearing-trumpet.*

Speaking-trumpet. — The object of the speaking-trumpet is to increase the intensity of speech, and transmit it to considerable distances in a particular direction. In order to obtain this effect, it is necessary that the aërial undulations which would disperse themselves in all directions be confined by the sides of the trumpet, and reflected so as to take, as nearly as possible, a direction parallel to the axis. This is accomplished by giving the trumpet such a form that its diameter becomes greater towards the extremity furthest from the mouth. A cylindrical or prismatic tube, of equal diameter throughout, assists powerfully in conveying sound from one extremity to the other, but contributes in no degree to give a direction to sound, or transmit it through free air.

The theoretical explanation of the effects of the speaking-trumpet is attended with considerable difficulty. Assuming that the reflexion of sound takes place according to the laws of catoptrics, Lambert (*Berlin Memoirs for* 1763) shows the best form of the instrument is a truncated cone, for the rays successively reflected from the interior surface of this figure make smaller angles with the axis after each successive reflexion. Cassegrain (*Journal des Savans*, tom. iii.) recommends the surface formed by the revolution of a hyperbola about its asymptote; and Kircher had previously proposed a truncated parabolic conoid, the mouth-piece occupying the focus. Some authors suppose that the trumpet should be formed of a very elastic material, in order to strengthen the sound by its vibrations. Others are of opinion that it should be without elasticity, to avoid the confusion that might be caused by the vibrations of the tube. Hassenfratz (*Journal de Physique*, tom. lvi.), who made a number of experiments on the power of the trumpet, by fixing a small watch in the mouth-piece, and observing the distance at which the beats ceased to be audible, found that the effects were precisely the same with a trumpet of tinned iron, whether used in its naked form, or tightly bound round with linen to prevent vibration, or when lined with woollen cloth, whereby reflexion was entirely prevented. It would appear, therefore, that neither the shape of the instrument, nor the material of which it is formed, is of much consequence. Leslie (*Experimental Inquiry into the Nature and Propagation of Heat*) supposes the effect of the trumpet to be owing to the more condensed and vigorous impulsion given to the air from its lateral flow being checked. " The tube," he observes, " by its length and narrowness, detains the efflux of air, and has the same effect as if it diminished the volubility of that fluid, or increased its density. The organs of articulation strike with concentrated force; and the pulses, so vigorously thus excited, are, from the reflected form of the aperture, finally enabled to escape, and to spread themselves along the atmosphere." p. 225.

The invention of the speaking-trumpet is commonly ascribed to Sir Samuel Moreland, who, about the year 1670, proposed the best form of the speaking-trumpet as a question to the Royal Society, and exhibited some instruments, constructed according to his own views. These were, in general, large conical tubes, spreading suddenly, at the extremity, to a greater width. They were tried in St. James's Park; and it is stated that their effects were such that the king (Charles II.), speaking in his ordinary colloquial pitch of voice, through a trumpet of only five feet and a half long, was distinctly heard at the distance of 1000 yards. Another person was perfectly understood at the distance of four miles and a half. Kircher claims the credit of having made such experiments previously; but his remarks apply rather to hearing than to speaking trumpets.

Hearing-trumpet. — The hearing-trumpet, or ear-trumpet, may be considered as a reversed speaking-trumpet, with which it generally corresponds in form, though, for the sake of portability, it is often made curved or spiral. Lambert recommends the parabolic figure as the most advantageous; but, in order to give the greatest effect, the apex of the paraboloid must be cut off, and the mouth of a small tube inserted in the focus, to convey the sound concentrated at that point to the auditory organ. Various other forms are adopted in practice; and, of late years, flexible India rubber tubes have been brought into use, having a conical mouth-piece of ivory or silver at one extremity, and a small tube of like material, to be applied to the ear. A trumpet of this kind may be used advantageously, not only for remedying the defects of the organ of hearing, but for assisting the observer to collect feeble and distant sounds. (See *Moreland on the Speaking-Trumpet*, 1671; Chladni, *Traité des Sons;* Gehler, *Physikalisches Worterbuch*, art. " Hörrohr.")

TRUMPET. A musical wind instrument usually made of brass, but sometimes of silver. This instrument formerly possessed but few notes; but in later times it has, by means of slides and keys, been vastly extended in its inflexions. Its compass will be seen by referring to the synoptical view of the different instruments at the end of the article MUSIC.

TRU'NDLE. In Mechanics, a pinion having its teeth formed of thick cylinders or spindles; otherwise called a *lantern wheel*, or *wallower*.

TRUNK. (Lat. truncus.) In Architecture, the same as *shaft*. In the application of this word to a pedestal, it signifies the die, dado, or body of the pedestal.

TRUNK, in Entomology, signifies the intermediate section of the body which lies between the head and the abdomen.

TRU'NNIONS. The pivots or short cylinders projecting from the sides of a piece of ordnance, by which it rests on the cheeks of the carriage. The *trunnion ring* is the ring on a cannon next before the trunnions.

TRUSS. (Fr. trousser.) In Architecture, a framed assemblage of pieces of timber for the purpose of tying up or suspending a principal beam or piece. *See* ROOF.

TRUSS. A rope confining the middle of a lower yard to the mast.

TRUSS, in Surgery, is an apparatus by which in cases of rupture the intestine is retained in the abdominal cavity. This is usually effected by the aid of a steel spring resting upon a small pad or cushion, which is kept in its place by a proper bandage.

TRUSSED ROOF. In Architecture, one so constructed as to support the principal rafters and tie beam at certain points where bending of the timber is likely to occur. *See* ROOF.

TRUST. In Law, is a term commonly used to designate any equitable right or interest, as distinguished from a legal one: properly, that class of equitable rights supposed to be founded in the confidence placed by one party in another; the name *trustee* denoting the person in whom confidence is placed; *cestuy que trust*, the person who trusts, — in other words, the party who enjoys a beneficial interest in the objects of which the trustee has the legal property.

The origin of conveyances in trust may be traced to the *fidei commissum* of the Romans, which was a gift by will to a person capable of taking in trust for another incapable by the Roman law of taking such benefit, whose claim under such gifts was for a long time precarious, and merely fiduciary, but came at length to be recognized and enforced by law. With us in the same manner, the original motive for the introduction of the fiduciary right, which was certainly borrowed from the Romans,

was the wish to escape from the disabilities affecting certain persons, or bodies, or the liabilities attached to property in its direct and simple shape. Such was, in particular, the disability of corporations to purchase land at common law; and on this account, as it is commonly said, the ecclesiastics, who were chiefly interested in this matter, introduced this new species of property, which was willingly recognized by the chancellors, then usually ecclesiastics, and in other respects inclined to adopt the principles of the civil law. The clergy were, however, soon themselves deprived of the benefit of the invention, the disability of corporations to take land being extended by statute to the new right so created. But there still remained many liabilities arising from feudal tenure, incident to property at common law; such as, for instance, dower, escheat, wardship, restraint upon alienation by will, which it was desirable and possible either to evade by this mode of conveyance in trust, or to transfer to a quarter less likely to be affected by them: and there were also many modifications of property for the benefit of families, which could only be given to it in this manner. It must be admitted, further, that there were less honest purposes, such as the defrauding *bonâ fide* purchasers by secret alienation, sought to be attained by the same means. For these, among other reasons, conveyances in trust were still resorted to; and the Court of Chancery, which had once, for whatever reason, originally recognized, continued to enforce them.

There were also two other means of creating a trust, or rather raising a use, not by actual conveyance: the one by agreement for money; the other by covenant under seal in consideration of near *relationship*.

The right so created was called indifferently a *trust* or *an use*; more commonly the latter, from the actual enjoyment of the rents and profits annexed to it in equity. Indeed, the benefit of the use or trust was in the first instance confined to this; but the cestuis que use, or parties beneficially interested, soon acquired the right of directing a conveyance by the holders of the legal estate, legally termed the feoffees to uses, and also of calling upon them to use the legal title in their defence in a court of common law.

Several statutes were passed at different times, giving to the owner of the use or trust partial legal rights, and partially also subjecting interests of that sort to legal liabilities, before the celebrated statute, commonly called the Statute of Uses, which was passed in the 27th year of Henry VIII. The general object of this statute, as stated in the preamble, was to prevent those secret and fraudulent transfers occasioned by the separation of the real from the apparent ownership, and to restore those rights of the feudal lord, and of the crown, which had been in a great measure evaded, by keeping the legal title to which alone they attached in a course of succession; where it was likely to be forfeited by treason, and where it was less frequently subject by descent to an infant heir to the burden of wardship and relief. The general effect of the statute, as stated in the title, was the transferring or changing the use into possession, that is, annexing to the use the legal right of possession, whereby the real owner would be made manifest to all, and the real ownership would become subject to all the liabilities incident to the legal title: in short, the distinction between equitable and legal rights would be abolished, and the adjudication on all questions of property, except in particular cases of fraud or accident, would be restored to the courts of common law.

The statute, however, was so worded as not to apply either to copyholds or leaseholds, nor indeed to personal property of any description, which at that time was little thought of; so that equitable rights in copyholds and personalty remained as before, merely equitable; and they arose again, very shortly afterwards, in every species of real property, it being held by the courts of common law that such uses or trusts only were executed and transferred into possession by the statute, as were raised or declared upon what was *before* the statute the legal seisin or estate; so that where a new legal estate taking effect as such by virtue of the statute was created or conveyed in trust, such trust right not being within the purview of the statute, and not being recognized by the courts of common law, was adopted and enforced in equity, for reasons altogether similar in kind to those which originally led to the introduction of uses. Hence a new system of equitable rights grew up under the name of trusts, commensurate with the new system of legal rights or uses (for the use henceforth denoted the legal estate), created by the statute; and though some of the peculiar advantages of the old trust were, by the effect of the statute, transferred to the new legal ownership, such as the capability of modification for the benefit of different parties upon different events, and though the right of disposition by will was shortly afterwards extended to it by special statute, and though whatever advantages were still possessed by the *trust*, as a means of evading the burdens of tenure or other liabilities now attached to the use, were gradually removed either by the abolition of those burdens or the extension of those liabilities, trusts still continued and continue to be habitually resorted to for various purposes. These are, generally, either to protect the interests of married women and children, by placing in the hands of trustees for them the legal rights which they would be incapable of exercising; or to secure the rights of those in remainder, by severing from the usufruct of property for a life the power of disposing of the whole; or, lastly, the convenience of management, where many parties are interested in the same subject. These observations can apply only, at least with one or two exceptions, to express trusts. An express trust supposes a legal transfer of the property actually completed, and a declaration in the same instrument, or having reference to the same instrument (as an appointment under a power thereby created) of the trust upon which the property so transferred is to be held. Such trusts may be declared in or by a reference to any instrument, either deed or will, that is sufficient to pass property at law; the ground upon which they rest is the express confidence that is placed in the trustee, by the person who transfers the property to him, no consideration of money or blood between the trustee and those for whom he holds being required as an inducement for the interference of equity. Trusts are most commonly raised by marriage-settlements, or by will. The usual trusts in the former case, as to real estate, are upon legal estates in terms of years, to arise upon certain events, to be held in trust, in the first place, for securing to the wife payment of her pin-money during marriage, and of her jointure after the husband's death; then for the raising, by sale or mortgage of the term, the stipulated provisions for younger children, and also for providing for their maintenance during minority. The ultimate trust of such terms, whether expressed or not, is for the person entitled to the corpus of the estate, subject to those charges which the terms are created to secure. Similar trusts, also, are commonly raised in wills, for the maintenance or advancement and portioning of younger children. In all such cases, the legal rights vested in the trustees most commonly remain in their hands, as a means only of compelling the person actually in possession to discharge those claims subject to which he holds his estate. But there are other trusts of frequent occurrence, both in marriage-settlements and in wills, which require a more active interference on the part of the trustees, and which, therefore, carry with them a greater degree of responsibility. These are trusts for the sale of land and investment of the proceeds upon security, or in the purchase of other land, or trusts for the investment of what was originally personalty; in which cases, it is important for the trustees to consider, in the first place, how far the trust for sale or conversion is imperative and immediate, lest by delay they become liable for any loss that may ensue from the alteration in the value or price of land securities; in the next place, what are the securities in which they are directed to invest, as they will be answerable for the failure of any security a resort to which has not been authorized by the terms of the trust. Where these securities are private, or where a purchase of land is made with trust moneys, they are further bound to see that the usual professional inquiries are in either case instituted into the validity of the title. It is obviously their duty, also, to look to the due appropriation or distribution of the proceeds. Where there is a conversion absolute, or, as it is called, *out and out*, of realty into personalty, or of personalty into realty, either agreed to or directed by deed or will, land is in equity considered as money, and money as land, for all the purposes of succession or transmission; but it rarely happens that a conversion by will is in terms sufficiently absolute to exclude the right of the heirs, or, where it is personalty, the rights of the personal representative, to such part of the real or personal estate, whether actually converted or not, as shall not be required to fulfil the purposes for which the conversion was directed.

The system of trusts is still more generally prevalent in limitations of copyhold and personal property, particularly personal chattels, as money or stock in the funds, to neither of which classes of property the Statute of Uses applied, and in which, therefore, the legal interest remained, at least for a time, subject to the narrow rules of the common law; and copyhold property is therefore, for this as well as for other reasons, more commonly settled upon trust than is property of freehold tenure. Personal property, though once held incapable at common law of partial or shifting limitations, has long, by a somewhat forced though ingenious rule of construction, been released from that restriction; and therefore in the settlement of chattels real, of which the title is distinct from the possession, the creation of a distinct equitable title is not more often resorted to than in the settlement of real property of freehold tenure. But it is in regard to that sort of personal property, the title to which, or rather the power of conferring a title to which, is annexed to the possession, either from the nature of the thing itself, as in the case of money, or for reasons of

public convenience, as in the case of bills of exchange, and in regard also to stock in the funds (a class of property over which the holder, whether it be in trust or not, has by the regulations of the bank absolute power of alienation), that the utility of trusts is more particularly conspicuous. Whenever it is sought to create in any such property shifting or partial interests, nothing in such cases can secure future or contingent rights from the dishonesty of the tenant for life or partial owner but the intervention of trustees, in whose hands the whole legal interest, that is to say, the whole power of alienation, resides; and though a similar danger is sometimes to be apprehended even at their hands, yet their number itself, and the discretion that may be exercised in their appointment, afford a greater security than is to be found in the integrity of a single individual.

Duties of Trustees.—It is only in cases of express trusts, whether such in the origin, or become such by the acceptance and acknowledgment of the legal owner undertaking to act as trustee, that the rules respecting the duties, liabilities, and rights of trustees are applicable. As to their liabilities, they are liable not only for such sums as they actually have received, but for such also as they might, but for their wilful neglect or default have received. Where there are several trustees, each is generally liable for his own acts and receipts only; but where all concur in empowering either one of themselves, or a third party, to do or receive that which he could not do or receive but by virtue of such authorization, all are responsible for his acts and receipts under such joint authority. It is the duty of trustees, besides being faithful accountants, to apply and distribute rightly the property they are entrusted with according to the various rights of the parties entitled to it; and they are liable for any misapplication, arising either from ignorance of facts which they ought to have known, *i.e.* might by common diligence have known, or from ignorance of the law in any case. It is their business, then, as to the first, to inquire diligently into all the circumstances of the trust; and as to the second, where upon consulting professional advisers there appears to be any reasonable doubt, to refer it to the opinion of the court by instituting a suit for the fulfilment of the trust. The rights of trustees are confined to the reimbursement of their proper expenses out of the trust property. An express trust will not fail for the want of trustees; where none are nominated, the court will take upon itself the appointment. To the same class of trusts proper, that is to say, equitable rights arising from confidence reposed, may be assigned implied or resulting trusts, in which the confidence is not expressed, but implied by courts of equity from the want of consideration or motive apparent in such cases, to give away the whole, or, as it may be, any part of the beneficial interest. Such trusts arise, in the first place, upon the conveyance or transfer, by deed or will, of property real or personal upon some trust expressly declared, which does not exhaust the whole beneficial interest, or expressly upon trust, though no trust be declared; in the first of which cases, the surplus of the beneficial ownership, after satisfaction of the express purpose or trust, and in the second case, the whole of the ownership, results to the party making such conveyance or transfer. To the former class of partial resulting trusts belongs the equity of redemption upon a mortgage, which is an equitable right resulting to the mortgagor after all right of redemption is forfeited at law, to recover back the thing mortgaged upon payment of the capital and interest of the money borrowed upon the security of such pledge. This equity of redemption subsists in favour of the real or personal representatives of the mortgagor against the real or personal representative mortgagee, till it is destroyed either by twenty years of the adverse possession, *i.e.* possession without any acknowledgment whatever of any rights in the mortgagor, or, which is the most common case, by decree of foreclosure in equity, by which a peremptory day is fixed.

Trusts of a similar nature frequently arise upon devises of real property for payment of debts, in which cases a trust results in the surplus, either for the heir, or the residuary devisee, where there is one; but it should be observed, that where any specific purpose for which a trust is created by devise in the produce of land fails of taking effect, such as a legacy charged upon land by predecease of the legatee, or a similar legacy void under the Statute of Mortmain, the benefit of the lapse results to the heir, and not to the residuary devisee, who takes by such devise not that which ultimately is not applicable to the purposes of the will, but that only which the testator expresses no intention of otherwise disposing of. But where a legacy, payable out of the personalty, fails of taking effect, the lapse shall enure for the benefit of the residuary legatee, where there is one, in preference to the next of kin; the reason of the difference being that previous to the late Wills Act a devise of land spoke from the time of the will, a bequest of personalty from the death of the testator.

A trust is implied in the *whole* beneficial ownership upon the conveyance or transfer by deed of the legal interest in real or personal property; *i. e.* where it is either chattels real or stock, or where the corpus of the property is not actually delivered to a person from whom no motive or consideration moves, and in whose favour no declaration of trust is contained in such deed or instrument; in which case a trust is implied, either for the party making such conveyance or transfer, or for the person from whom it is shown aliunde that the consideration for such conveyance or transfer, as, for instance, the money with which the purchase was made, actually moved. The implication of resulting trusts has, perhaps, arisen through an unwise departure from the Statute of Frauds, as it is a reliance upon parol evidence in opposition to the legal title. It should, however, be observed, that the parol evidence, upon which such trusts may be *raised*, must be evidence, not of declarations or intention, but parol evidence of facts; as, for instance, of the payment of money by a person not the nominal purchaser; but to repel a presumption of a trust parol evidence of a declaration of intention is admissible, because such evidence is corroborative of the legal import of the deed.

TRUTH. In the Fine Arts, a faithful adherence in representation to the models of nature, or the prototypes on which the principles of art are founded.

TRY'ING, or A-TRY. In Naval Language, a word somewhat obsolete for *heaving* or *hove to*.

TRY'SAIL. A small gaff sail of strong or storm canvass, set in bad weather.

TUBE. (Lat. tubus.) A pipe or long hollow body. A tube is generally understood to signify a hollow cylinder, but the cylindrical form is not essential.

TUBER. In Botany, a kind of fleshy stem, formed underground, and filled with starch. It is commonly looked upon as a root, as in the potato. Also the systematical name of the truffle.

TU'BERCLE. In Morbid Anatomy, this term is applied to certain diseased structures, as *tubercles* of the lungs: small hard superficial tumours of the skin are also called tubercles.

TUBERCLE OF LOWER. An eminence in the right auricle of the heart where the two venæ cavæ meet; it was first described by Richard Lower, in 1665.

TUBE'RCULA QUADRIGEMINA. Four white oval tubercles in the brain, two of which are situated on each side, over the orifice of the third ventricle and the aqueduct of Silvius. The old anatomists called them *nates* and *testes*.

TU'BICOLES, *Tubicola*. (Lat. tubus, *a tube*, colo, *I inhabit*.) The name of an order of Anellidans, comprehending those which live in tubes, and which are Cephalobranchiate; also the name of a family of Lamellibranchiate Acephalous Mollusks, including those which have a tubular calcareous sheath in addition to the two shelly valves.

TU'BICORNS, *Tubicornia*. (Lat. tubus, cornu, *a horn*.) The name of a family of the order of Ruminants comprehending those in which the horns are composed of a horny axis covered with a horny sheath.

TU'BIFERS, *Tubifera*. (Lat. tubus; fero, *I carry*.) The name given by Lamarck to an order of the class *Polypi*, comprising those which are united upon a common substance fixed at its base, and whose surface is wholly or partially covered with retractile hollow tubes.

TUBIPORES, *Tubipora*. (Lat. tubus, porus, *a pore*.) The name of a family of Zoophytes, comprehending those in which the animals are isolated and contained in elongated cylindrical calcareous cells, attached by their base, and strengthened by cross bars at definite distances.

TUBULA'RIA. The name of a genus of Corallines, with simple or branched horny tubes, from the extremities of which the polypes are protruded; these have two rows of tantaces, of which the external is expanded in a radiated manner, the internal one raised into a tuft.

TUBULIBRA'NCHIANS, *Tubulibranchiata*. (Lat. tubus; branchiæ, *gills*.) The name of an order of Hermaphrodite Gastropodous Mollusks, comprehending those which have the shell in the form of a more or less irregular tube in which the branchia are lodged.

TUBU'LICOLES, *Tubulicola; Polypes à Tuyaux*. (Lat. tubus; colo, *I inhabit*.) A name applied by Cuvier to a family of Polypes, including those which inhabit tubes of which the axis is traversed by the gelatinous flesh, and which are open at the summits or sides to give passage to the digestive sacs and prehensile mouths of the polypes.

TU'ESDAY. In the Calendar, the third day of the week, named after Tuisco, the Saxon god of war; whence the astronomical symbol is the same as that for the planet Mars. As to the god Tuisco, or Tuisto, see *Mem. de l'Ac. des Inscr*. vol. xxiv.

TU'FA. (Italian.) A volcanic rock, composed of an agglutination of fragmented scoriæ.

TU'FO. In Architecture, a species of porous, light, sandy, calcareous stone, suited to the construction of vaults. The *travertino*, with which the cupola of St. Peter's is constructed, is of this species.

TU'GENDBUND. (Germ. *union of virtue.*) A patriotic association formed in Prussia after the treaty of Tilsit in 1807. Its object was to prepare the people of that country by moral instruction and discipline for better times. It was abolished at the instigation of the French; but its spirit survived, and it had great effect in promoting the national war against Napoleon in 1813.

TU'LIPA. (Turkish toliban.) A gay flower inhabiting the warmer parts of Europe and Asia Minor. It is well known for the gaudiness of its colours, which have made it a favourite with gardeners, who have converted its cultivation into a system of gambling, which the Dutch have been obliged to repress by sumptuary laws. It is a genus of the Liliaceous order.

TUMBLE HOME. The term describing the falling or bending inwards of the upper timbers of the ship's side.

TU'MBREL. (Old Fr. *tumerel.*) A low carriage with two wheels, occasionally used for the most ordinary purposes by farmers; but it is chiefly used for carrying the implements of the pioneers attached to trains of artillery.

TU'MULI. *See* BARROWS.

TUN. A measure of capacity. The English tun contains 252 gallons, or 4 hogsheads. *See* TON.

TUNE. (Gr. τονος.) In Music, the relation of notes to each other and the distances between them, wherefrom arises melody. In other words, it is a certain succession of different single sounds arranged according to art.

TU'NGSTATES. Compounds of the *tungstic acid. See* TUNGSTEN.

TU'NGSTEN. (Swedish tung sten, *heavy stone.*) The ores of this metal are the native tungstate of lime, and the tungstate of iron and manganese; the latter mineral is known under the name of *Wolfram.* Tungsten is a white, hard, and brittle metal, very difficult of fusion, and having the high specific gravity of 17·4. Heated to redness in the open air, it burns into the *peroxide*, or tungstic acid. The equivalent of tungsten is probably about 100; and the tungstic acid consists of 1 atom of metal and 3 atoms of oxygen ($8 \times 3 = 24$), and is represented by the equivalent 124. This metal was discovered by Messrs. Delhuyart. It is sometimes called *Wolframium*, and also *Scheelium*, in honour of Scheele, who first examined the nature of tungstate of lime.

TUNIC. (Lat. tunica.) A garment worn by the ancient Romans of both sexes, under the *toga* (which see), and next to the skin. It was generally of wool, of a white colour, and it reached below the knee. The senators wore their tunics with a broad stripe of purple sewed on the breast: the equites had narrow stripes; hence the epithets *lati*clavii and *angusti*clavii, applied respectively to these orders.

TU'NICARIES, *Tunicata.* (Lat. tunica, *a tunic.*) The name of an order of Acephalous Mollusks, comprehending those in which the exterior covering is uncalcified, soft, and elastic: it is equivalent to the *Ascidies* of Savigny, and the *Acephales sans Coquilles* of Cuvier.

TUNKERS, or DUNKERS. A religious sect, a subdivision of the Baptists: chiefly found in Pennsylvania. Their name is said to be derived from tunken, Germ., *to dip;* because in baptism they plunge the person head foremost into the water. They differ little in doctrine from other Baptists; but every brother is allowed to speak in their churches. This society was originally founded by one Conrad Beissel, in 1720; who founded a colony called "Ephrata," sixty miles from Philadelphia. They wear long beards.

TU'NNEL. (Sax. ꝑœnel.) In Engineering, a subterranean passage cut through a hill or under a river, for the purpose of carrying a canal, road, railway, &c.

In the construction of railways and canals, it is sometimes absolutely necessary, and very frequently expedient, to have recourse to tunnelling, either to preserve the requisite level, or shorten the distance, or to lessen the expense of open cutting. The circumstances on which the question of expediency depends are often of a very complicated nature; but generally speaking, it must be decided by considerations of economy, for in the present state of engineeering, a tunnel may be made of almost any length, and through materials of any description, from a granite rock to a quicksand. The nature of the ground can hardly be said to interpose any farther obstacle than what may be occasioned by the expense.

On account of the peculiar nature of the difficulties to be overcome, the tunnel which has recently been carried under the bed of the Thames, from Rotherhithe to Wapping, may perhaps be regarded as the most remarkable work of the kind which has ever been executed. A short account of this operation will probably be the best mode of conveying a notion of the extent and difficulty of such works generally.

Some previous attempts had been made to carry a tunnel under the river below London bridge. In 1799, one was projected at Gravesend; but the project was soon abandoned. In 1804, another was attempted from Rotherhithe to Limehouse. A shaft of 11 feet in diameter was sunk to the depth of 42 feet, and continued at a reduced diameter of 8 feet to the depth of 76 feet, whence a drift was carried 923 feet under the river, and to within 150 feet of the opposite shore, where difficulties of so formidable a nature arose that the engineer reported farther progress to be impossible. The scheme, however, continued to be agitated; and in 1823, Mr. Brunel proposed a plan which has at length been carried successfully into execution.

The act of parliament authorizing the operation was obtained in June, 1824, and shortly after the work was commenced at Rotherhithe. The shaft at this place is 150 feet from the river. It was formed by building a cylinder of brickwork 50 feet in diameter, 42 feet in height, and 3 feet in thickness, on the top of which a steam engine was erected for raising the water and earth. The cylinder was let down bodily into the ground, forcing its way through a bed of gravel and sand 26 feet deep, and full of land water. The shaft was sunk to the depth of 65 feet, and from this level another smaller shaft 25 feet in diameter was sunk, destined to be a well or reservoir for the drainage of water. The excavation for the body of the tunnel was commenced at a depth of 63 feet, and was carried on at a declivity of 2 feet and 3 inches per 100 feet, in order to have sufficient thickness of ground to pass safely under the river. The excavation is 38 feet in breadth, and 22½ feet in height, presenting a sectional area of 850 feet; and the base, at the deepest part of the river, is 76 feet below high-water mark. The body of the tunnel is of brickwork in Roman cement.

The means by which this extensive excavation was effected, consisted of a powerful apparatus of iron, which has been called a shield. It was formed of twelve great frames lying close to each other, and severally provided with the mechanism necessary to move them forward, and to secure them, when stationary, against the brickwork. The frames were 22 feet in height, and about 3 feet in breadth, and each divided into three stages or stories; the whole thus presenting thirty-six compartments or cells for the workmen. These compartments were open at the back; but in front small boards, which could be separately removed and replaced at pleasure, were pressed firmly against the ground to be excavated by screws. Each workman in his cell operated upon the surface opposed to him, taking out one of the small boards at a time, cutting the ground away to the depth of a few inches, and then replacing the board before he proceeded to the next; and when from 3 to 6 inches were thus removed over the whole surface of the shield, the frame was moved forward, and the work secured by immediately adding so much more of brickwork to the body of the tunnel. By this means, the excavation and the structure were carried forward simultaneously.

The tunnel consists of a double and capacious archway, one side being appropriated to carriages passing in one direction, and the other to those passing in the contrary, with paths for foot passengers by the sides of the carriage roads. The middle wall between the two archways was first built solid for greater strength, but openings were afterwards cut at short distances, so that each has a ready communication with the other. The two shafts at the extremities will contain easy flights of steps for foot passengers; and the access for carriages is intended to be by circular roadways 200 feet in diameter, the declivity of which will not exceed 4 feet in 100. The entire length of the tunnel is 1300 feet, and the expense is said to have been about 1200*l.* per yard.

In the course of the work, two irruptions of the river took place, the first on the 18th of May, 1827, after the excavation had been advanced to the distance of about 400 feet; and the second in January, 1828. These accidents were repaired by filling the chasms in the river with bags of clay; and on clearing the tunnel of water, the structure was found, on both occasions, to be in a perfectly sound state, and to have sustained, in fact, little or no injury. After the second irruption, however, the works, from want of funds, remained suspended for seven years; but assistance having at length been obtained from government, they were resumed in 1835, and proceeded without further interruption till the tunnel reached the termination on the Wapping side of the river, early in the present year, 1842. This extraordinary work, which during its progress was visited by multitudes of persons from all parts of the world, is, doubtless, destined to remain for ages a proud monument of the genius and perseverance of the engineer by whom it was contrived and successfully executed.

The establishment of railway communication in this country has given rise to some stupendous undertakings in the way of tunnelling. One of the most remarkable, perhaps the most remarkable of all, is the Box Tunnel, on the Great Western Railway, an account of which is given in the *Companion to the British Almanac* for 1842, and the *Railway Times* for July 10, 1841. This tunnel pierces through Box Hill, between Chippenham and Bath, part of which is 400 feet above the level of the railway. "It is 9680 feet long, 39 feet high, and 35 wide to the outside of the brickwork. The shafts for making

and ventilating it are thirteen in number, and vary in depth from 80 to 306 feet. The excavation amounted to 414,000 cubic yards, and the brickwork and masonry to more than 54,000 cubic yards. The number of bricks used was 30,000,000; a ton of gunpowder and a ton of candles were consumed every week for two years and a half, and 1100 men and 250 horses were kept constantly employed." For a considerable distance, the tunnel passes through freestone rock, from the fissures of which there was at times an immense influx of water, whereby on one occasion the works were interrupted for a period of nine months. On a subsequent occasion, after an irruption, water was for some time discharged by the engine at the rate of 32,000 hogsheads a day. This tunnel occurs on an inclined plane of 1 in 100.

The extent of brickwork or other structure which may be necessary to secure the excavation in works of the class now mentioned will depend, of course, on the nature of the materials through which the tunnel is driven; and in deciding this question, it is important to attend to the geological formation of the locality. In the unstratified rocks an excavation may be made with perfect safety and will require no support, while in those whose strata are nearly vertical, danger may he apprehended from slipping. In the chalk, oolite, marl, lias, and similar formations, the tunnel requires to be lined with brick-work throughout, as the materials cohere so imperfectly, that even the vibration arising from the passage of the carriages may cause the fall of parts of the roof.

The following table of the dimensions of a few railway tunnels will enable the reader to form an accurate notion of the gigantic scale on which such operations are conducted: —

	Length in Yards.	Height in Feet.	Width in Feet.
Box Tunnel, — Great Western - -	3,227	39	35
Wapping to Edge Hill, — Liverpool and Manchester - - -	2,200	16	22
Lime Street - - - -	1,760	19	25
Kilsby, — London and Birmingham -	2,420	27	23½
Primrose Hill, — Ditto - -	1,250	25	22
Canterbury and Whitstable - -	880	12	12
Leicester and Swannington -	1,760	13½	10¾

TU'NNY. *See* THYNNUS.

TU'RBAN. The usual head-dress of the Turks, Persians, and most other eastern nations. It varies in form in different nations, and in different classes of the same nation. It consists of two parts: a quilted cap, without brim, fitted to the head, and a sash, scarf, or shawl, usually of cotton or linen, artfully wound about the cap, and sometimes hanging down the neck. The Grand Signior's turban contains three heron's feathers, and is ornamented with diamonds.

TU'RBO. (Lat. turbo, *a whirling.*) The name of a Linnæan genus of the *Vermes Testacea*, characterized by having a shell of a regular turbinated form, with an entire and rounded mouth. The species grouped together by this specific character form a family of Pectinibranchiate Gastropods in the system of Cuvier, which is subdivided into the genera *Turbo* proper, Cuv.; *Delphinula*, Lam.; *Pleurotoma*, Defrance; *Scissurella*, D'Orb; *Tornatella*, Lam.; *Scalaria*, Lam.; *Cyclostoma*, Lam.; *Valvata*, Müll.; *Littorina*, Ferussac, &c.

TU'RBOT. The best, and, excepting the halibut, largest of our flat fishes; it is the type of the subgenus *Rhombus* of Cuvier. It is taken either by the troll-net, or, in deep water, by the many-hooked line baited with the common smelt, or small gar-fish. A preference is given in the London markets to the turbots caught by the Dutch, who are estimated to have drawn for this supply not less than 80,000*l.* a year.

TURF. The surface of grass lands, of a smooth and uniform texture, covered with pasture grass. The term is also sometimes applied to peat cut out of bog. *See* PEAT.

TU'RKEY RED. A fine and durable red dyed upon calico and woollen cloth; the colouring matter used in its production is madder, but the process for producing it in perfection is tedious and complicated. (See *Bancroft on Permanent Colours.*)

TU'RLUPINS. (A word of which no satisfactory derivation has been found. See *Du Cange's Glossary.*) In French Ecclesiastical History, one of the numerous popular by-names by which the sectaries of the 14th century, the precursors of the Reformation, were distinguished: called elsewhere Beghards, Picards, Beguins, Lollards, &c.

TU'RMA. In the Roman Legion, a company of horse, of which ten formed the whole complement of the legion. According to Varro, it consisted of thirty horsemen, ten answering to each of the three original equestrian tribes, the Tatienses, Ramnenses, and Luceres. But in addition to the ten, there seem to have been two file leaders; and as the word turma was sometimes indiscriminately used for the subdivision or third part of the full turma, the following lines of *Virgil's Æneid* seem to describe the arrangement: —

> Tres equitum numero turmæ, ternique vagantur
> Ductores: pueri bisseni quemque secuti.

(See M. Le Beau's 8th Dissertation on the Roman Legion, *Mém. de l'Ac. des Inscr.* vol. xxxii.)

TU'RMERIC. The root of the *Curcuma longa*. This root yields a fine yellow powder, which is occasionally used as a dye stuff in medicine; it also forms one of the ingredients of *curry powder*. Paper stained with turmeric is often used in the chemical laboratory as a test of the presence of free alkalies and their carbonates, by which its yellow colour is converted to brown.

TURN. In Music, a grace thus marked ∾; indicating that the note above it, one degree higher, must be struck before it shortly, then passed quickly through the note itself, and *turned* from the note a degree below into the note itself, over which the mark is placed.

TU'RNIP-FLY. As different insects prey, in the larva state, upon the leaves of the growing turnip, the most destructive, and consequently the most important and interesting of these, will be noticed under the present head. They are the turnip-flea, as it may be called from its power of agile leaping (*Haltica nemorum*), and the turnip-fly (*Athalia centifolia*). The turnip-flea belongs to a genus (*Haltica*) of minute Coleopterous insects, of the section *Tetramera*, and family *Galerucidæ*; in which genus the species are all remarkable for the large size of the femora or thighs of the hindmost pair of legs. The species in question does not exceed the twelfth of an inch in length; it is of an oval form, with the elytra of a greenish tinge, each ornamented with a broad longitudinal stripe of a pale brimstone colour; but there are other species of the same genus, perhaps equally destructive, and not characterized by the longitudinal elytral bands. The perfect insect shelters itself in the rough uncultivated margins of fields, feeding upon the hedge-weeds; and appears to be ready at any time, provided the weather be warm, to commence the work of destruction on the young turnip shoots. Late sowing of the turnip seed does not therefore obviate the attacks of the *Haltica*. The first precaution obviously is to clear away all the weeds in the neighbourhood of the turnip grounds that may afford food or shelter to the little enemy. When the turnip-flea has made its appearance in the crop, the ground should be dusted with quicklime, and this repeated as often as rain or wind beats it off, and the flea reappears. The other enemy to the turnip (*Athalia centifolia*) belongs to the order *Hymenoptera*, and family *Teuthredinidæ*, or saw-flies.

TU'RNSOL. *See* LITMUS.

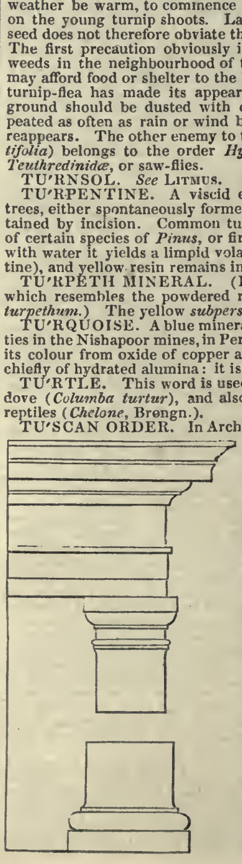
TU'RPENTINE. A viscid exudation from certain trees, either spontaneously formed upon the bark, or obtained by incision. Common turpentine is the produce of certain species of *Pinus*, or fir trees. When distilled with water it yields a limpid volatile oil (oil of turpentine), and yellow resin remains in the still.

TU'RPETH MINERAL. (From its yellow colour, which resembles the powdered root of the *Convolvulus turpethum.*) The yellow *subpersulphate of mercury*.

TU'RQUOISE. A blue mineral found in great quantities in the Nishapoor mines, in Persia. It appears to derive its colour from oxide of copper and of iron, and consists chiefly of hydrated alumina: it is admired in jewellery.

TU'RTLE. This word is used to signify a species of dove (*Columba turtur*), and also a genus of Chelonian reptiles (*Chelone*, Brongn.).

TU'SCAN ORDER. In Architecture, one of the five orders, and the simplest of them all. It is not found in any ancient example. Palladio has given two examples of this order, from one of which the profile here given is adopted, though by some that composed by Vignola has been preferred. The base, as will be seen on inspection, consists of a simple torus with its fillet, accompanied by a plinth. Sir William Chambers assigns to the column, with its base and capital, a height equal to seven of its diameters. Vitruvius speaks of this order with little praise, but Palladio commends it for its great utility. It does not allow the introduction of ornament; and it is to be



observed, that its columns are never fluted. By some architects it has been varied on the shaft with rustic cinctures; but such taste is perhaps very questionable. Though not suitable to every application of the order, the most perfect profile in this country to which we can refer is that of the portico of St. Paul's, Covent Garden, by Inigo Jones.

TU'TENAG. An alloy of copper, zinc, and nickel, made in China; the term is also sometimes applied to a pale brass, and to bell-metal. (*See* PACKFONG.) In India, zinc also sometimes goes under this name.

TUTORS. *See* UNIVERSITIES.

TU'TTI. (It. *all.*) In Music, a notice to the performer that, from the place to which it is affixed, all the parts are to play together. This word is generally used to contradict the word *soli*, or *solo*, which see.

TUTTY. An impure oxide of zinc collected from the chimneys of the smelting furnaces.

TWELF HINDI. In the old Saxon Commonwealth, the highest class of citizens were so called. They were valued at 12,000 shillings, and enjoyed many special prileges.

TWELFTH-DAY. The festival of the Epiphany, or Manifestation of Christ to the Gentiles; being the twelfth day, exclusive, from Christmas. (*See* EPIPHANY.) For the customs peculiar to this day in England, see *Brande's Popular Antiquities.*)

TWELVE TABLES, LAWS OF THE. The celebrated laws of the Roman republic, framed by the decemvirs appointed A. U. C. 303, on the return of three commissioners who had been sent to Greece to examine into foreign laws and institutions. The tables, as set up by the decemvirs, were originally ten in number; two were added in the second year of the decemvirate, and bore a more aristocratic stamp than the original ten (according to Cicero, the prohibition of marriages between patricians and plebeians was among the number). The text of the Twelve Tables were preserved down to the latest age of Roman literature, and formed the basis of the greater part of the Roman jurisprudence: they are called by Livy, "fons omnis publici, privatique juris." The authentic remains of them are given by Haubold (*Institutionum juris Romani privati Lineamenta*, Leipsig, 1826). There is a valuable chapter on the early Roman law, as founded on the Twelve Tables, in *Dr. Arnold's History of Rome*, vol. i.

TWI'LIGHT. (Germ. zwielicht.) In Astronomy, the faint light which is perceived for some time after sunset and before sunrise.

The twilight is produced by the reflexion of light from the atmosphere. When the sun descends below the horizon, the rays of light no longer reach the earth directly; but as they pass through the atmospheric strata a portion of them are reflected towards the earth, and illuminate its surface. At first the light, falling on the lowest and densest strata, is reflected in great abundance; but as the sun descends to a greater distance below the horizon, his rays fall on strata at a greater height, and consequently less dense. A smaller number of them, therefore, suffer reflexion; and as this number is constantly diminishing, the vivacity of the twilight diminishes in the same proportion, till at length the solar rays fall on strata so rare as to be incapable of reflecting light, and the twilight accordingly disappears. In the morning, the change from darkness to light takes place by the same gradations.

From this theory it is evident that twilight must begin and end when the sun's depression below the horizon attains a certain limit. The limit, however, cannot be fixed with any precision. It is usually estimated according the time which elapses from sunset till the smallest stars which are seen by the naked eye become visible. But this mode of estimating the duration of twilight is uncertain and arbitrary; and it will be reckoned greater or less according to the goodness of sight of the observer, and the temperature and pressure of the atmosphere. Accordingly, the sun's depression at the beginning and end of twilight has been fixed at various limits by different observers; by Alhazen, at 19°; by Tycho, at 17°; by Rothman, at 24°; by Stevinus, at 18°; by Cassini, at 15°; and by others at different quantities; but the limit usually assigned is 18°. Assuming this limit, the duration of twilight in different latitudes, and at the different seasons of the year, is computed as follows:—

In the spherical triangle Z P S, let P S = $90° - d$ be the distance of the sun from the pole, Z P = $90 - p$ the distance of the pole from the zenith of the observer, and Z S = $90° + 18°$; S being the place of the sun when he reaches the circle parallel to and 18° below the horizon. Now as d, the sun's declination, is known, and also p, the latitude of the place, the three sides of the triangle are given; whence the hour angle Z P S is found (*see* TRIGONOMETRY) by the formula.

$$\cos Z P S = \frac{-\sin 18° - \sin p \sin d}{\cos p \cos d}.$$

If, therefore, we make A = the semidiurnal arc of the sun, or the angle at the pole when the sun is in the horizon, and consequently his zenith distance = 90°, we shall have from the same formula

$$\cos A = -\tan p \tan d;$$

whence the angles Z P S and A are known, and their difference expressed in time gives the duration of the twilight.

At the equator $\sin p = 0$, $\cos p = 1$, and A = 90°. We have, therefore, $\cos Z P S = \frac{-\sin 18°}{\cos d}$. 1st, Suppose the sun to be in the equator; in this case we have also $d = 0$, and Z P S becomes equal to Z S = $90° + 18°$; whence the duration of twilight is equal to the time in which an arc of 18° on the equator passes over the meridian, or equal to 1 hour and 12 minutes. 2d, Suppose the sun to be at the tropic; in this case $d = 23\frac{1}{2}°$, and the duration of twilight is found by computing from the formula to be 1 h. 19 m.

By computing from the above formula, the duration of twilight, at the time of the equinox, is found to be 1 h. 55 m. at the latitude of 50°, and 2 h. 32 m. at the latitude of 60°. At the shortest day, its duration at different latitudes is as follows:—

1 h. 26 m. at latitude 25°,
2 h. 6 m. at latitude 50°,
2 h. 57 m. at latitude 60°;

and at 70°, when the sun no longer rises above the horizon, it continues about 5 h. 12 m. after the sun has passed the meridian of the place.

When the angle Z P S = 180°, we have $\cos Z P S = -1$. But in order that the hour angle may have this value, the sun must be on the lower semicircle of the meridian; and consequently, as his depression below the horizon is by hypothesis = 18°, the twilight will not entirely disappear, or will continue through the whole night. The formula in this case becomes

$$\cos p \cos d = \sin 18° + \sin p \sin d;$$

or $\cos (p + d) = \sin 18°$, whence $p + d = 72°$. When, therefore, the sun's declination $d = 72° - p$, the twilight will continue through the whole night at the place whose latitude is p. Hence, by giving different values to p, we find the declination, and consequently the day of the year on which twilight begins to continue through the whole night. Suppose $p = 50°$; then $d = 22$, which corresponds to the 1st of June. In the latitude of London (52°) perpetual twilight begins about the 20th of May. At 60° latitude it begins about the 22d of April; at 70° about the 26th of March; at 80° about the last of February; and at the pole itself about the 29th of January. It is scarcely necessary to remark, that as no account has been taken of the refraction, these expressions are only approximative.

One of the problems most frequently proposed respecting the twilight, is to find the day of the year when its duration is the least possible at a given latitude. This problem, which is the same as to determine the sun's declination when his zenith distance increases from 90° to 108° in the least time possible, was first solved by John Bernoulli (*Opera*, t. i. p. 64.). Solutions of it are given in most works on Practical Astronomy. (See Delambre, *Astronomie*, t. i.)

TWO-COAT WORK. In Architecture, plasterer's work that is either laid and set, or rendered and set.

TYMPANI'TIS, or TYMPANY. An elastic distension of the abdomen, arising from a morbid collection of gas in the intestines. The disease is sometimes termed *drum belly*, and arises occasionally from air secreted into the abdominal cavity, in which case it is usually fatal.

TY'MPANUM. (Lat. *a drum.*) The drum of the ear; the cavity behind the membrane of the tympanum, surrounded by the petrous portion of the temporal bone, and terminating at the cochlea of the labyrinth; it contains the four small auditory bones, and the Eustachian tube opens into it.

TYMPANUM, in Architecture, the space in a pediment enclosed by the cornice of the inclined sides and the horizontal fillet of the corona.

TYMPANUM, in Botany, is a membrane stretched across the mouth of the threa of a moss.

TYPE. (Gr. τυπος.) In the Fine Arts, the model or pattern in nature of an object used. Thus, in architecture, the types of columns are said to be trees, &c. &c.

TYPE. Properly, the figure stamped upon a coin: hence, a figure, sign, or symbol, especially those by which Christ was prefigured to the Jews, as the Brazen Serpent, the Lamb of the Passover, the Sacrifice of Isaac; or persons whose character and history are considered as embodying an anticipatory representation of the Saviour, as Moses, David, the prophet Jonah, &c.

Many types are referred to as such by the writers of the New Testament: and hence we learn to look for such intentional meaning in what we might otherwise,

in particular instances, pass over as mere coincidences and analogies. It is the great sum of such analogies, and the fulness with which they pervade the whole of Scripture, which seem most strikingly to evince the unity of design.

TYPE METAL. The alloy of lead and antimony used in casting printers' types. One part of antimony to three of lead are the usual proportions. This alloy takes a sharp impression from the mould or matrix, and is hard enough to stand the work of the press, without being brittle or liable to fracture.

TYPES. By this term is understood the letters, from the smallest size to the largest, with which books and other articles are printed. A single type consists of the shank, the beard, and the face. The shank is the body of the letter; the beard is that part between the shoulder of the shank and the face; the face is the shape of the letter, from which the impression is taken.

The following are the English names of the different sizes in their regular order; with the addition of the Dutch, French, German, and Italian names:—

1. Diamond, the smallest.
2. Pearl. (*Fr.* La Parisienne ou Sedanoise; *Ger.* Perl; *Ital.* Occhio di Mosca.)
3. Ruby.
4. Nonpareil. (*Dutch*, Nonpareil; *Fr.* La Nompareille; *Ger.* Nonpareille; *Ital.* Nompariglia.)
5. Emerald.
6. Minion. (*Fr.* La Mignione; *Ger.* Colonell; *Ital.* Minione.)
7. Brevier. (*Dutch*, Brevier; *Fr.* Le Petit Texte; *Ger.* Petit, or Jungfer; *Ital.* Piccolo Testo.)
8. Bourgeois. (*Dutch*, Bourgeois; *Fr.* La Gaillarde; *Ger.* Burgeois; *Ital.* Gagliarda.)
9. Long Primer. (*Dutch*, Garmond; *Fr.* Le Petit Romain; *Ger.* Corpus, or Garmond; *Ital.* Garamone.)
10. Small Pica. (*Dutch*, Dessendiaan; *Fr.* La Philosophie; *Ger.* Brevier, or Rheinlænder; *Ital.* Filosofia.)
11. Pica. (*Dutch*, Mediaan; *Fr.* Le Cicero; *Ger.* Cicero; *Ital.* Lettura.)
12. English. (*Dutch*, Augustyn; *Fr.* Le Saint Augustin; *Ger.* Mittel; *Ital.* Silvio.)
13. Great Primer. (*Dutch*, Text; *Fr.* Le Gros Romain: *Ger.* Tertia; *Ital.* Testo.)
14. Paragon. (*Dutch*, Paragon; *Fr.* Le Petit Parangon; *Ger.* Paragon; *Ital.* Parangone.)
15. Double Pica. (*Dutch*, Dubbelde Dessendiaan; *Fr.* Le Gros Parangon; *Ger.* Text, or Secunda; *Ital.* Due Linee Filosofia.)
16. Two Line Pica. (*Dutch*, Dubbelde Mediaan; *Fr.* Les Deux Points de Cicero; *Ger.* Doppelcicero.)
17. Two Line English. (*Dutch*, Dubbelde Augustyn; *Fr.* Palestine; *Ger.* Doppelmittel; *Ital.* Canoncino.)
18. Two Line Great Primer. (*Dutch*, Kanon; *Fr.* Petit Canon; *Ger.* Kleine Canon; *Ital.* Grosso Testo.)
19. Two Line Double Pica. (*Dutch*, Groote Kanon; *Fr.* Trismegiste; *Ger.* Grobe Canon.)
20. Trafalgar.
21. Canon. (*Dutch*, Parys Romeyn; *Fr.* Le Gros Canon; *Ger.* Kleine Missal; *Ital.* Canone.)

Canon is the largest size with a specific name; Pica then becomes the standard to distinguish them, and the next size to Canon is Four Line Pica, then Five Line Pica, and so on, to the largest size used in posting bills.

1. To enable the reader to form an opinion of the comparative sizes of
2. types, and the proportions they bear to each other, there is given
3. in this paragraph a line of each size, from Diamond, the
4. smallest type in general use in England, up to Great
5. Primer, inclusive, numbered to correspond with
6. the preceding list, in order to distinguish
7. them by their names. There is a smaller
8. type than Diamond lately introduced,
9. but it is as yet little used. The
10. French have one so small that
11. it cannot be read by the
12. naked eye, even by
13. young persons.

TYPHŌ'EUS. One of the Titans, said to have been overthrown in the war against Jupiter, and imprisoned under the weight of Ætna; a circumstance in mythological romance well known from the descriptions of Virgil, Pindar, and Æschylus. And see *Bryant's Anc. Mythol.* iv. 318.

TY'PHON. The Evil Genius of Egyptian Mythology. According to Sir G. Wilkinson (*Ancient Egyptians*, vol. iv. p. 417. &c.), they seem to have acknowledged two deities, who answered to the description given by the Greeks (especially Plutarch, *De Is. et Os.*) of Typho. "One, who was the brother of Netpe, and opposed to his brother Osiris, as the bad to the good principle; the other bearing the name of Typho, and answering to that part of his character which represents him as the opponent of Horus:" the true evil genius Ombte, whom the Greeks seem to confound with Typho. "He is figured under the human form, having the head of a quadruped, with square-topped ears, which some might have supposed to represent an ass with clipped ears, if the entire animal did not too frequently occur to prevent this erroneous conclusion." In his Egyptian names is "Ombte," in which Sir G. Wilkinson thinks he traces a connection with Antæus, the son of Earth. There appears to have been a general propensity to erase his figure and titles from the monuments at some remote epoch. (See also Bryant, *Anc. Myth.* vols. ii. and iii.)

TYPHOO'N. The name given to a violent tornado or hurricane in the Chinese seas. *See* STORMS.

TY'PHUS. This term (implying to burn with a concealed and smothered flame) is applied to certain continued fevers, attended by great debility and a tendency to putrefaction. It is contagious or infectious, and often epidemic, and is most prone to attack debilitated persons, especially where aided by want of cleanliness, good food, and fresh air; so that it often spreads in hospitals, jails, camps, and other situations where such causes assist its progress. This form of fever is liable to several modifications, commonly termed low fever, putrid fever, nervous fever, jail fever, &c. Its attack is generally characterized by inordinate muscular and nervous debility, and by great depression of spirits, weariness, flying pains, sighing, and a frequent, small, hard, and fluttering pulse; the tongue is foul and brown, and the taste impaired, and not unfrequently nausea and bilious vomiting prevail, constituting that variety of typhus which is sometimes called *bilious fever*. As the disease advances, the debility increases; the mouth becomes very foul, and the breath fetid; the urine deposits a brown sediment, and, together with the motions, is fetid, and rapidly putrefies; all these symptoms increase in intensity; the speech becomes inarticulate, muttering, and delirious; there is a tendency to bleeding from the nose, mouth, and bowels; petechiæ, or livid spots, appear upon the surface; the pulse sinks and intermits; the mind wanders; hiccup comes on; the hands and feet become cold; and, under these horrible symptoms, the patient dies. Such is an outline of the progress of a typhus fever to a fatal termination. In this climate it may endure for three weeks or a month; but in hot countries the symptoms follow each other more rapidly and violently, and it is not of more than eight or ten days' duration. When it does not terminate fatally, the symptoms begin to assume a more favourable aspect about the twelfth or fourteenth day; the pulse improves, the patient gets some tranquil sleep, perhaps perspires; the urine deposits a red sediment; bilious stools are passed; he becomes more tranquil in mind and body, and his symptoms gradually disappear till health is restored; but it is a disease the event of which must be anticipated with the utmost caution, for attacks apparently mild sometimes terminate fatally, and in other cases the constitution has rallied under the most alarming and malignant features. At the very commencement an emetic and a mild aperient are proper, followed up by aromatic opiates, with camphor and ether. It is possible that some particular symptom, indicative of local congestion, may call for bleeding or blistering: the former, except in some very rare cases, should be local only, and very limited as to quantity. Serpentaria, Peruvian bark, cascarilla, and colombo are the tonics which are most relied on; and, with these, camphor, aromatic confection, opiate confection, and ether; or, if agreeable to the stomach and bowels, sulphuric and muriatic acids, in small doses, and acidulous drinks. Wine and brandy, and, in some cases, bottled ale and porter, are requisite to keep up the general powers of the system; but care must be taken lest their use should be followed by over-excitement, and the quantity in some measure regulated by the previous habits of the patient. Broths, jellies, and the varieties of farinaceous food, may constitute the diet; and, in all cases, the utmost attention must be paid to extreme cleanliness, frequent change of linen, ventilation, and the due use of chlorine fumigation. On the first attack of typhus, the effusion of cold water, performed two or three times a day, often affords much relief; and afterwards, when the shock of such a remedy would be too great, sponging the head and body with cold or with slightly tepid water is productive of infinite comfort.

TYPO'GRAPHY. The art of printing. *See* PRINTING.

TY'RANNY. (Gr. τυραννος, *a tyrant*.) In the original sense of the word, a citizen who acquired sovereignty by violence or other usurpation is called, in the language of Greek political writers, a tyrant; and where the power thus acquired became hereditary, the title of

tyrant is still given to his descendants in the generations immediately following. A tyrant in this sense is opposed to basileus, a rightful king, with power either limited by the laws or sanctioned by ancient usage. (See, as to the Greek tyrannies, Wachsmuth, *Historical Antiquities*, vol. i. ch. 6.; and the explanation of the difference between the ancient and modern sense of the word given by Mitford, *Hist. of Greece*, i. 250. ed. 1829.)

TY'THING. A tything was a subdivision, *i.e.* a tenth part, as its name indicates, of the hundred, with which it was probably coeval in institution, as it was certainly identical in object, as far at least as regards the prevention of offences by the condition of liability for the production of offenders, or in default thereof reparation of the mischief, in the case of offences committed within the district. For this purpose, all free persons above the age of twelve years were required by the Saxon law to belong to some tything. No jurisdiction seems to have belonged to the tything; and the office of tythingman, or constable, seems always to have been confined, as it is now, to the preservation of the peace, and the apprehension of offenders. The limits of a tything were in most cases coextensive with those of a parish, with which it is now commonly, for practical purposes, identical.

U. and V.

U and V were long considered the same letter, and were used indiscriminately the one for the other; but at the beginning of the 16th century their peculiarities came to be marked, and *u* has since been used as a vowel and *v* as a consonant.

UBI'QUISTS, or UBIQUITA'RIANS. (Lat. ubique, *every where.*) In Ecclesiastical History, a school of Lutheran divines; so called from their tenet that the body of Christ was present in the Eucharist in virtue of his divine omnipresence. Luther is said to have maintained this argument, as a mode of reconciling the doctrine of transubstantiation with reason, for two years. Brentius, one of his diciples, passes for its principal supporter. Melanchthon opposed it; but it seems to have obtained great credit among the Lutherans of the sixteenth and seventeenth centuries.

U'CKEWALLISTS. In Ecclesiastical History, a sect of rigid Anabaptists; so called from one Uke Wallis, a native of Friesland. They appear to subsist still, independent of other Anabaptists and Mennonites, in Friesland and Groningen. (See *Mosheim*, vol. v.)

UKA'SE. An ordinance of the emperor of Russia, having the force of law in his dominions.

U'LCER. (Lat. ulcus.) A solution of continuity in any of the soft parts of the body, attended by a purulent or other discharge. The several kinds of ulcers are divided by surgeons into *local* and *constitutional*, but these often run into each other. They have been termed *simple* and *specific* sores or ulcers; the former resulting from accidental injuries, the latter from specific poisons or particular habits of body. (See *Cooper's Surgical Dictionary*.)

ULE'MA. (Turk. *learned men.*) The college or corporation composed of the three classes of the Turkish hierarchy: the imans, or ministers of religion; the muftis, or doctors of law; the cadis, or administrators of justice. This organization, according to D'Ohisson (*Tableau de l'Empire Ottoman*), was first framed by the caliphs, and adopted, along with the other principles of their government, by the Ottoman sultans. Candidates for admission into the Ulema are educated at the different colleges (medressés) of the empire. The *Sheikh ul Islam*, or mufti of Constantinople, is the president of the whole body. (See *Ed. Rev.* vol. 50.)

ULLAGE. In Gauging, what a cask wants of being full, is so called.

ULMA'CEÆ (Ulmus, the principal genus), are woody plants, usually timber trees, inhabiting temperate climates. They are apetalous Exogens, nearly allied to the Urticaceous order, from which they principally differ in having a two-celled fruit. The various kinds of elm trees are the best known species; but the thin papery fruit of these plants is by no means characteristic of the order; it is merely a character of the genus *Ulmus*.

U'LMIN. (Lat. ulmus, *the elm tree.*) A black or dark brown substance which exudes from the bark of the elm and several other trees, and which appears to be contained in most barks. It may be obtained by digesting elm-bark in boiling alcohol, and afterwards in cold water, by which various more soluble substances are removed; the residue is then digested in an aqueous solution of carbonate of potash: it acquires a brown colour, and yields a precipitate when neutralized by muriatic acid, which, after having been washed and dried, is *ulmin*. It is very sparingly soluble in water, but readily soluble in solutions of the alkaline carbonates. According to Boullay (*Annales de Chim. et Phys.* xliii. 273.), it is a compound of 567 carbon and 433 hydrogen and oxygen in the ratio to form water. He terms it *ulmic acid*, and considers it identical with the brown matter of vegetable mould and turf, and as contributing materially to the nutriment of growing plants.

U'LNA. The larger of the two bones of the forearm. It forms the point of the elbow, and is articulated by a species of hinge-joint to the humerus, and to the radius; and below to the radius, and to the bones of the wrist.

U'LTIMATE ANALYSIS. This term is applied in Chemistry to the resolution of substances into their absolute elements; and is opposed to the *proximate analysis*, by which they are merely resolved into secondary compounds. The ultimate analysis of crystallized blue vitriol, for instance, teaches us that its true elements are sulphur, copper, oxygen, and hydrogen; its proximate elements are sulphuric acid, oxide of copper, and water; the ultimate elements of sulphuric acid are sulphur and oxygen; of oxide of copper, copper and oxygen; and of water, hydrogen and oxygen. The terms *ultimate analysis* and *ultimate elements* are, however, most generally used in reference to organic products: gum resin, starch, and other compounds, are often found associated in a vegetable, and are called its *proximate* principles, and they are separated by proximate analysis; but all these are resolvable into carbon, hydrogen, and oxygen. These three elementary substances, therefore, are their *ultimate* components. The accurate determination of their relative proportions in the various products of vegetables is almost always a difficult chemical problem.

ULTIMATE RATIO. The ratio of evanescent quantities. *See* Prime and Ultimate Ratio.

ULTIMA'TUM. (Lat.) In Diplomacy, the final conditions offered by a government for the settlement of its dispute with another.

ULTRA. In Modern Politics, those who carry to their farthest point the opinions of the party to which they belong are so termed. The name was applied in 1793 to the more violent revolutionists; it has since been bestowed on the extreme section of all parties in turn.

ULTRAMARI'NE. (Lat. ultra, *beyond*, and marinus, *belonging to the sea.*) The blue colouring matter of the lapis lazuli. This substance is much valued by painters, on account of the beauty and permanence of its colour, both for oil and water painting. In its preparation the finest lapis lazuli is selected, heated to a dull red heat, and quenched in water; it is thus rendered friable, and is ground down into an impalpable powder. This is then mixed with a tenacious paste made of linseed oil, wax, resin, turpentine, and mastic; and the mixture being kneaded in warm water gives out the blue particles, which are afterwards collected by subsidence. Chemists have long in vain endeavoured to imitate this colour, but till lately its nature even had not been determined. It appears from the experiments of Gmelin that sulphuret of sodium is the principle to which the blue colour is owing, and he has succeeded in preparing an artificial ultramarine by heating sulphuret of sodium with a mixture of silica and alumina. (See the *Annales de Chimie et Physique*, vol. xxxvii. p. 409.)

U'LTRAMONTANE, or TRA'MONTANE. A name applied by Italian writers to theologians and jurists of other countries beyond the Alps, especially France. In ecclesiastical law, ultramontane tenets are those least favourable to the supremacy of the popes. As to ultramontane jurists, see Savigny, *Hist. of Roman Law*, vol. vi.

U'MBEL. In Botany, a form of inflorescence in which all the pedicels proceed from a single point, as in *Astrantia*. If there is no subdivision, the umbel is called simple; but if the pedicels produce other umbels, as in parsley, the umbel is compound.

UMBELLI'FEROUS PLANTS (Umbel), are a race of great frequency in all cool or temperate climates, and even occur in hot ones, though much more rarely. They are known in general by their flowers being disposed in an umbel. They have a herbaceous stem; leaves usually much divided, often inflated when they join the stem; and they have universally a dry fruit, which divides into two seed-like pieces. Some of them are poisonous, as hemlock and water dropwort; others are esculents, as celery, carrots, and parsnips; many yield aromatic fruits, as caraway, coriander, and anise; a few secrete a fœtid gum resin, of which assafœtida, ammoniacum, and galbanum are examples. The species are extremely numerous, and difficult to recognize with accuracy; and, unfortunately, no general rule has yet been discovered for distinguishing those poisonous from the harmless kinds.

U'MBER. Two distinct substances are used as pigments under this name: one is a variety of peat or brown coal, large beds of which are worked near Cologne; it is said to be largely used in the adulteration of snuff: the other, called *Turkish umber*, is a variety of ochraceous iron ore, composed, according to the analysis of Klaproth, of 48 peroxide of iron, 20 peroxide of manganese, 13 silica, 5 alumina, 14 water. The term umber

is said to be derived from Ombria, or Spoleto, in Italy, where it was first obtained.

UMBI'LICAL CORD, in Botany, is an elongation of the placenta in the form of a little cord, as in the hazel nut.

UMBI'LICATE. (Lat. umbilicus, *a navel.*) In Zoology, when a pit, tubercle, or granule has a depression in its centre.

UMBILI'CUS. (Lat.) Properly the navel; whence it was metaphorically applied to the two ends of the roller on which the manuscripts of the ancients were rolled, and which were usually adorned with ornamental knobs, while the ends of the parchment were filed with pumice-stone, in order that the folds might lie smooth and neat.

UMBILICUS. In Conchology, the aperture or depression in the centre, round which the shell is convoluted.

UMBILICUS. The scar by which a seed is attached to the placenta, frequently of a different colour from the rest of the seed, and not uncommonly very dark-coloured. It is more commonly called *hilum*.

UMBILICUS. In Geometry, used by the older geometers synonymously with *focus*.

UMBO. (Lat.) A protuberance or boss. In Conchology it is that point of a bivalve shell immediately above the hinge.

UMBRA. A shadow. In Astronomy, this term is applied to the dark cone projected from a planet or satellite on the side opposite to the sun. *See* ECLIPSE.

U'MPIRE. This word appears to be properly derived from the Fr. "impair," *uneven in number;* an umpire being a third party to whom a dispute is referred. An umpire is properly a person whom two referees, each chosen by his client, being unable to agree, jointly choose to determine between them.

UNBEND. In sea language, to take the cable from the anchor, a sail from its yard, &c.; to untie one rope from another.

UNCIÆ. The name given by the old writers on algebra to the coefficients of the letters in the expansion of any power of a binomial. Thus, the expansion of $(a+b)^4$ gives $a^4 + 4\,a^3\,b + 6\,a^2 b^2 + 4\,a b^3 + b^4$, in which the numbers 1, 4, 6, 4, 1, are the *unciæ*, or coefficients.

UNCIA'LES LITERÆ. (Lat.) Uncial letters or writing. In Diplomatics, a species of character compounded between the capital and the minuscule or small characters; some of the letters resembling the former, others the latter. It is supposed to have been employed in Latin MSS. as early as the third or fourth century, but was seldom used after the tenth.

U'NCIFORM BONE. (Lat. uncus, *a hook.*) The last bone of the second row of the wrist bones; so called from its hook-like process, which projects towards the palm of the hand, and gives origin to the great ligament which binds down the tendons of the wrist.

UNCOMMON CHORD. In Music, another term for the chord of the sixth; not so called, however, because it is unusual or improper, but to distinguish it from the *common chord*, wherein the lowest note is the root or fundamental bass. *See* MUSIC.

UNCONFORMABLE STRATA. A term applied by geologists to strata not lying parallel with the subjacent ones, or having a different line of direction or inclination.

UNCTION, EXTREME. *See* EXTREME UNCTION.

UNDE'CAGON. (Lat. undecim, *eleven*, and Gr. γωνια, *angle.*) In Geometry, a plane figure of eleven sides or angles. The area of a regular undecagon is found by multiplying its side into $\frac{11}{4}$ of the tangent of $73\frac{7}{11}$ degrees; hence if the side be 1, the area is 9·36564.

UNDERTOW. A current below different from that at the surface.

UNDERWOOD. The low woody growths produced among timber trees: sometimes called coppice wood; though the term *coppice wood* is more especially applied to woods in which low growths of shrubs, or the stools of trees, are more abundant than timber trees. *See* COPPICE WOOD and STOOL.

UNDI'NES, or ONDINES. (Lat. unda, *water.*) The name given by the Cabalists to one class of their spirits of the elements, namely, those residing in the waters. The ancient Greeks believed springs and lakes to be haunted by a peculiar race of supernatural nymphs (*see* NAIADS); and this belief passed down unimpaired to the middle ages. The ancient Saxons adored the female deity of the Elbe; and the belief in undines is still scarcely eradicated in that region. The Saxon peasants report that an undine is often met in the market-place of Magdeburg, dressed as a girl of their own class, but always to be known by having one corner of her apron wet. Near Toulouse many objects of value were once discovered on draining a large artificial lake, which are supposed to have been thrown in as offerings to the spirits of the water. The *nixe* of the northern countries is of the same family, and the Scottish *kelpies* are creatures of a similar superstition.

UNDULA'TION. (Lat. unda, *a wave.*) A waving motion; applied, in physics, to the vibratory motion of an elastic fluid, as the atmosphere.

UNDULATORY THEORY, in Optics, is the hypothesis according to which the impression of light is conveyed to the eye by the undulations of an elastic medium. This theory supposes the universe to be filled with an ether or medium of great elasticity, but so extremely rare as to offer no resistance to the motions of the planets. For an explanation of the phenomena of light and colours according to this theory, see LIGHT.

UNEVEN NUMBER. In Arithmetic, the same with *odd* number; a number not divisible by 2.

UNFORMED STARS, in Astronomy, are such as are not included in any of the constellations.

UNGUI'CULATES, *Unguiculata.* (Lat. unguis, *a claw.*) The name of a primary division of the class Mammalia, including those which have the digits armed with claws, but free for the exercise of touch upon their under surface. *See* MAMMALIA.

U'NGUIS, or CLAW. The narrow part of the base of a petal, taking the place of the footstalk of a leaf, of which it is a modification. The term is also used as a term of measure equal to a nail, or half an inch, or the length of the nail of the little finger.

U'NGULA. (Lat. *a hoof.*) In Geometry, a solid formed by cutting off a part from a cylinder, cone, or other solid of revolution, by a plane passing obliquely through the base. The ungula is, consequently, bounded by the plane of the base, the intersecting plane, and the portion of the surface of the cylinder, &c. included between them. The name is derived from its resemblance to the hoof (ungula) of a horse.

U'NGULATES, *Ungulata.* (Lat. ungula, *a hoof.*) The name of a primary division of the class Mammalia, including those species which have the digits inclosed in hoofs, the under surface not being left free for the exercise of touch. *See* MAMMALIA.

U'NICORN. (Lat. unus, *one;* cornu, *horn.*) The beast called unicorn, in our version of scripture (Heb. rem), is now commonly understood to be the rhinoceros. But the fabulous unicorn, which has passed into heraldry, is represented with the figure of a horse, and a single horn issuing from its forehead. The unicorn of Pliny, however, has the head of a hart, the feet of an elephant, the tail of a boar, and the rest of the body resembling a horse. Aristotle, Ælian, and all the classical writers on animals, mention the unicorn. The traveller Ludovicus Romanus asserts that he saw *two* unicorns, kept alive in the temple of Mecca. Altogether there is perhaps no fabulous beast for whose existence there is so much appearance of evidence, and some seem to imagine that it may yet be discovered in the interior of Thibet. Many strange virtues were attributed of old to the horn of the unicorn, particularly against poison; but the horns preserved in collections, and to which that name was given, were either of the rhinoceros, or of the narwal or sea-unicorn.

UNIFO'RMITY. (Fr. uniforme.) In the Fine Arts, resemblance in shape between the correspondent parts of a subject.

UNIFO'RMITY, ACT OF. In English History, the first act of uniformity is the 1 Eliz. c. 2.; that at present subsisting, 13 & 14 Car. 2. c. 4. It regulates the form of public prayers, administration of the sacraments, and other rites of the Church of England.

UNIGE'NITUS. The celebrated constitution, in the form of a bull, issued by Pope Clement XI. in 1713, in condemnation of Père Quesnel's *Réflexions Morales sur le N. Testament.* It is so called from its beginning, "Unigenitus Dei Filius." Father Quesnel was a friend of the celebrated Jansenist leader Arnauld, and became chief of that religious party after the death of the latter. He died in exile at Amsterdam, in 1679. The bull was procured by the Jesuits, especially Father le Tellier; it condemned 101 propositions selected from Quesnel's work. Its publication created great discord in France. Most of the bishops accepted it, but with explanations which they gave to the public. Cardinal de Noailles and others refused to accept it all. As soon as the Duke of Orleans became regent, Father le Tellier was banished, and the party opposed to the bull came into power; but the strength of Rome prevailed, and eventually the Duke of Orleans himself compelled de Noailles to accept the bull, in 1720. After that event the Jansenist party only survived in small fragments, especially among the commonalty of Paris. *See* JANSENISTS.

UNILO'CULAR. (Lat. unus, *one;* loculus, *partition.*) In Conchology, shells which are not divided into chambers. In Botany, seed vessels not separated into cells.

UNION. In British History. The union of the crowns of England and Scotland took place on the accession of James I. to the former. The scheme of uniting the kingdoms was afterwards several times taken up; and commissioners were appointed to consider it in the reigns of Charles II. and James II. But it was finally carried

into execution in 1706; the statute passed on that occasion being the 5 Anne, c. 8. By this enactment laws relating to trade, customs, and excise were to be the same in both countries; other laws to remain in force in each respectively. The parliament of the United Kingdom, called Great Britain, was to have 16 Scottish peers, and 45 members of the House of Commons. The mode of election of peers was subsequently regulated. (*See* PARLIAMENT.) Since the union, acts of parliament, in general language, are held to extend to Scotland; a proviso being inserted where it is to be excepted. The union of Great Britain and Ireland took place in 1800, by the statute 39 & 40 G. 3. c. 67. of the British, and 40 G. 3. c. 38. of the Irish statutes. It admitted 4 Irish lords spiritual, 28 temporal, and 100 commoners to the united legislature; the lords temporal elected for life, the lords spiritual sitting by a certain rotation. By article 5. the churches were united. For the changes which have since taken place in the number of Scottish and Irish members in the House of Commons, see PARLIAMENT.

UNIPE'LTATES, *Unipeltata*. (Lat. unus, *one*, and pelta, *a buckler*.) The name of a family of Stomapodous Crustaceans, comprehending those in which the carapace is composed of a single shield-like plate.

U'NISON. (Lat. unus, *one*, and sonus, *sound*.) In Music, a consonance of two sounds equal in gravity or acuteness, produced by two bodies of the same matter, length, thickness, tension, &c. equally struck at the same time, so that they yield the same tune or sound.

UNIT, UNITY. In Arithmetic, the number one; an individual of discrete quantity. Euclid defines number to be a multitude or collection of units.

UNITA'RIANS. Those who confine the Godhead to a single person; in which general sense the term may be taken to represent the Arians and Socinians, as well as the sect which is more strictly denominated Unitarian. These last are the descendants of the religious communities which adopted, in the 16th century, the opinions of Socinus; but in the course of years they have gone considerably further towards reducing Revelation to a mere ethical system. They have been supplied with an abundant stream of converts from the Presbyterians and Independents in this country, many congregations of whom became first Arian, and latterly Unitarian in sentiment. The principal Unitarian authorities are Drs. Priestley, Belsham, and Channing, who have either entirely rejected or neutralized the doctrine of the atonement, and represent the language of the apostles upon this and other mysterious points as either intentionally accommodated to the ideas current among their hearers, or derived from erroneous conceptions of their own. The revelation of the New Testament is thus reduced to the assertion of a mere historical fact— that of the existence of the man Jesus as a moral teacher. But with respect to what he taught, great latitude of interpretation is allowed to Unitarians, since it appears that in their view the exposition of the first disciples is not to be implicitly relied on; nor do they allow infallibility to the Author of the religion himself. The Unitarians were subjected to severe penalties, as deniers of the Trinity, long after other dissenters had been relieved by the Act of Toleration: the laws against them were not repealed by statute till the year 1813.

In this country they do not constitute a numerous body: the number of their congregations has been stated at something more than 200; but they are principally composed of persons of the educated classes. In Geneva the pulpits of the established church are mostly occupied by professors of these opinions; and in the northern states of America they form one of the most influential of Christian denominations.

UNITED BRETHREN. In Ecclesiastical History, a body of reformers in Bohemia, who separated themselves from the Catholics and Calixtines (according to some writers) about 1467. It is also said that they received episcopal ordination from the Vaudois. According to others (Bossuet, *Variations des Eglises Protestantes*, chap. ii.), they were an offshoot from the Taborites or Thaborites (see that article). At all events, it appears certain that there already existed a considerable body of persons professing the tenets of the Reformation in Bohemia at the period of Luther.

U'NITIES, in the Drama, are three,—of time, place, and action. The latter only is strictly adhered to in the dramatic compositions of classical antiquity; but what is termed by moderns the *classical* drama (in opposition to the *romantic*) requires all three. *See* DRAMA.

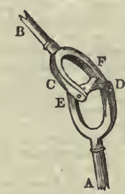
UNIT JAR. A small insulated Leyden jar placed between the electrical machine and a larger jar or battery, so as to announce by its repeated discharges, which may be counted, the number of them which have passed into the larger jar. This is among the many valuable additions made to electrical apparatus by Mr. Snow Harris.

U'NIVALVE. (Lat. unus, *one*; valva, *a valve*.) This term is applied to those Mollusks, the shell of which is composed of one piece, and which is generally convoluted spirally. Latreille also thus denominates a family of Lophyropodous Crustaceans.

UNIVE'RSAL. In Logic. A universal proposition is that which has the subject distributed, so that the predicate is declared concerning every thing comprehended in it; *e.g.* "All men (subject) are mortal (predicate)." In universal negative prepositions the predicate is distributed also; *e.g.* "No men are immortal."

UNIVE'RSALISTS. A name by which the Arminians are sometimes characterized, expressing the universality which they attribute to the operation of grace, conceiving it to be given to all men without favour or reserve. On the other hand, the Calvinists, or those who hold the particular election of individuals, are designated as Particularists.

UNIVERSAL JOINT, or HOOKE'S JOINT. In Machinery, an ingenious contrivance of Dr. Hooke for the purpose of communicating motion obliquely. It is single or double. In the single universal joint, the two



shafts or axles, A and B, between which the motion is to be communicated, terminate in semicircles, the diameters of which are fixed in the form of a cross, their extremities moving freely in bushes placed at the extremities of the semicircles. Thus, while the central cross remains unmoved, the shaft A and its semicircular end may revolve round C D as an axis; and in the same manner B, with its semicircular end, will revolve round E F. If the shaft A be made to revolve without changing its direction, the points C D will move in a circle whose centre is at the middle of the cross. The motion thus given to the cross will cause the points E F to move in another circle round the same centre, and hence the shaft B will be made to revolve. (*Mechanics*, *Cabinet Cycl.* p. 253.)

When the shafts are inclined to each other under an angle of 40°, it is necessary to employ a double universal joint, as represented in the annexed figure. In this

manner the motion may be transmitted from one shaft to another at right angles. Instead of employing a cross in the manner now described, the joints may be constructed with four pins, fastened at right angles upon the circumference of a hoop or ball. Universal joints are of great use in cotton mills, where the tumbling shafts are continued to a great distance from the moving power; for, by applying a universal joint, the shafts may be cut into convenient lengths, and so be enabled to overcome a greater resistance. (See *Gregory's Mechanics*, vol. ii. p. 9.; *Willis's Principles of Mechanism*, p. 272.)

UNIVE'RSITY. In the middle ages, the Latin term universitas signified the whole body of students, or of teachers and students, assembled in a place of education, with corporate rights, and under by-laws of their own; in later times, also, the name was held to imply that all branches of study were taught in a university. In the modern sense of the term, a university signifies an establishment for the purposes of instruction in all or some of the most important divisions of science and literature, and having the power of conferring certain honorary dignities, termed degrees. It is generally understood that the authorization of the sovereign power in the state is necessary to enable such an establishment to confer degrees; and, in most European countries, there are various offices and professional situations for which a person is qualified by having taken a certain degree at one of these establishments. Hence universities, although in many instances they are composed of private foundations, are justly regarded as national institutions. The University of Paris, the most celebrated of those of the middle ages, and which served in some degree as a model to the rest, was formed about 1200 by the union of the various schools of rhetoric, theology, and philosophy, with which that city abounded, under one head, styled the rector. That university was divided into four nations,—French, Picard, Norman, and English: the first comprehended students from Italy and Spain; the last from the north of Europe generally. The subjects taught were arranged under faculties; viz. theology, law, medicine, and that of the seven liberal arts,—rhetoric, logic, grammar, geometry, arithmetic, astronomy, music. (*See* TRIVIUM, QUADRIVIUM.) These faculties were corporate, and elected each a dean; and these last, with the procuratores of the nations, represented the university. The lowest degree was that of bachelor; the next licentiate; the third magister (this degree at Paris corresponded with that of doctor at Bologna). The colleges were royal or private foundations for the benefit of poor students, whose board was,

in some instances, found for them, and who received stipends or other emoluments. The faculty of theology at Paris was well known by the name of the Sorbonne (*q. v.*). This slight sketch of the constitution of the famous University of Paris may serve for similar establishments in other Continental countries during the middle ages, and down to a comparatively late period. In England, the two national universities have been established, from a period of considerable antiquity, at Oxford and Cambridge. The original constitution of these universities much resembled that of the Parisian, with the exception of the division into four nations, which was wanting. But their subsequent history was much modified by the growth of the colleges, or individual foundations, into a much higher degree of consequence. These were originally destined by their founders merely to entertain a certain number of junior students (generally termed scholars), and a higher body (named in most cases fellows), and furnish them with assistance in the prosecution of their studies; while the great body of independent students lodged in the numerous halls, and attended only on the public university lectures. But by degrees the colleges likewise became receptacles for independent students, under the tuition of the fellows; the halls were for the most part abandoned, and such as remained partook of the collegiate character; and, in the modern system (which has subsisted for more than two centuries), nó student is admitted to take a university degree unless he has completed his studies in a college, or collegiate hall, under the superintendence of its tutors. But the original division into independent and foundation students still subsists; although the fellowships in many instances, instead of being filled up from the junior foundation members in each college, are left open as prizes for the competition of the whole university. The degrees, in Oxford and Cambridge, are differently named, or arrived at in different succession, in the several faculties; but degrees in theology and medicine can only be obtained after the acquisition of certain degrees in arts. In Spain, the universities are arranged on a system somewhat resembling that which prevails in England, the students being entered of their respective college in each. In Germany, as in England, the earliest universities (Prague, founded in 1348, and Vienna, in 1365) were framed on the model of that of Paris. Germany has now a far more numerous list of universities than any other country. From the Bursæ (charitable establishments resembling our collegiate foundations for the benefit of poor students) was derived the term *Bursche*, by which the students of these universities are so generally known. But the collegiate system never prevailed in that country as among ourselves. On their present arrangement (which is pretty similar in all, Catholic as well as Protestant), the four faculties are retained. Professors in the various branches are appointed by government. These form the senate, at the head of which is the prorector, who is chosen annually or biennially. Besides these, there are extraordinary professors, who receive small salaries; and an inferior class of licensed teachers, or licentiates, who receive none. The professors are obliged to give public lectures in the branch of study to which they are appointed; but they, as well as the other two classes, may give also private lectures on whatever subject they please; and from the fees of attendance at these their principal income is derived. The student is for the most part left at liberty to attend what lectures he pleases; but licences to practise various professions, benefices in the various churches, &c., are only given, especially in Prussia, to those who have studied a certain number of years by attending lectures in the requisite branch of study. The constitution of the Scotch Universities has a great resemblance to those of Germany; and the same observation is applicable to the two universities established in the metropolis within the last few years, — London University and King's College. In France, the old university system may be said to have been entirely done away with by the Revolution. As to the universities of the middle ages, see Savigny, *Hist. of Roman Law*, vol. iii. For an elaborate defence of the English system, see *Quart. Rev.* vols. lii. lix. The history of the great change effected in it by the substitution of collegiate for professorial instruction, has been traced in a series of recent papers in the *Edin. Rev.*

UNI'VOCALS, or SYNONYMS. In the Aristotelian Logic (as used by the schoolmen), generic words; *i. e.* words of which both the genus and the difference are predicable of many different species: *e. g.* the genus "animal" is "univocum univocans" with respect to "man" and "brute," both of which are comprehended under any definition which can be given of the word "animal," and are called with reference to it "univoca univocata." Universal terms are also such as have only one signification; opposed to equivocal.

UNMOOR. To take up one of the two anchors by which the ship is moored.

UPAS TREE (Upas, the Javanese name), is a plant common in the forests of Java and some of the neighbouring islands, to which extraordinary stories, for the most part fabulous, have been attached. Upon the authority of Dutch writers, it has been asserted that it is a most deadly poison, employed in the execution of criminals; who are, however, pardoned if they succeed in reaching a tree and bringing back its venom. Birds were said to drop dead while flying over it, and the whole country round it was asserted to be desolated by its pestilent effluvia. The truth is, that the Upas tree is merely a tree with poisonous secretions, and nothing more; there is nothing deleterious in its atmosphere. It is an Urticaceous plant, called *Antiaris toxicaria*, and is very nearly related to the fig, some of whose species are also deadly poisons.

UPHERS. In Architecture, fir poles chiefly used in scaffolding; they run from twenty to forty feet in length, and from four to seven inches in diameter.

U'PLANDS. Lands on hills or steep declivities, which in general require a different kind of management from lands in plains or comparatively flat surfaces. Uplands are generally kept in pasture or underwood.

U'PUPA. (Lat. upupa, *a hoopoe.*) A genus of Tenuirostral Passerine birds, distinguished by an ornamental head-crest formed of a double range of feathers, which can be erected at will. The common hoopoe (*Upupa epops*) is an occasional but rare visitant of England.

U'RACHUS. The ligamentous chord which arises from the base of the urinary bladder, and terminates in the umbilical cord.

URA'NIA. In Mythology, the muse of Astronomy. She is generally represented with a crown of stars, in a garment spotted with stars, and holding in her left hand a celestial globe or a lyre.

URA'NIUM. A metal discovered by Klaproth in 1789, who named it after the planet Uranus, discovered about that time. It occurs only in two native combinations, — the *pechblende* of Saxony, and the *uranite;* of the latter, fine specimens have been found in Cornwall. Little is known of the properties of metallic uranium: it appears to be a brittle gray metal, of the specific gravity about 9. From the experiments of Berzelius and Arfwedson we deduce the number 217 for its equivalent; that of its protoxide being 225, and of its peroxide (sesquioxide) 229. The salts of the oxides of uranium are of a fine grass green or yellow colour: the persalts have been most examined. Ferrocyanate of potassa produces in them a very characteristic rich brown precipitate, not unlike that formed by the persalts of copper. They are also precipitated brown by infusion of galls.

U'RANOSCOPUS. (Gr. οὐρανος, *heaven;* σκοπεω, *I explore.*) A genus of fishes was so called by Linnæus, because both eyes were placed on the superior surface of the head, which presents a nearly cubical form. The mouth is cleft vertically at the anterior part of the head, and, like the eyes, is directed upwards. The species of of this genus, commonly called "star-gazers," belong to the *Percoid* family of Acanthopterygian fishes in the Ichthyological system of Cuvier.

U'RANUS. (Gr. οὐρανος, *heaven.*) In Mythology, a divinity, the first king of the Atlantic nation, and the father of Saturn.

URANUS. In Astronomy, the remotest known planet belonging to our solar system. The mean distance of Uranus from the sun is 19·18239, that of the earth being considered as unity, whence its real distance is upwards of 1800 millions of miles. Its sidereal revolution is performed in about 84 Julian years. The orbit is inclined to the ecliptic in an angle of only 46′ 28·44″; and the eccentricity of the orbit is 0·046679, half the major axis being taken as unity. The apparent diameter of Uranus (which, on account of the great magnitude of its orbit in comparison of that of the earth, undergoes very little variation) is about 4″; whence the real diameter of the planet must be about 35,000 miles, or nearly four and a half times that of the earth; and its bulk about eighty times that of the earth. Uranus presents the appearance of a small round and uniformly illuminated disk, without rings, belts, or discernible spots. From analogy we infer that it revolves about its axis; but of this there is no direct proof: the great distance of the planet, indeed, precludes our obtaining much knowledge of its physical state. Two satellites at least are known to attend Uranus. Sir William Herschel thought he could discern six; but the existence of more than two has not been clearly made out. In fact, with the exception of the two inferior satellites of Saturn, those of Uranus are the most difficult objects to obtain a sight of in the solar system. The two satellites which are in some degree known have this remarkable peculiarity, that, instead of advancing from west to east round the centre of the primary, the planes of their orbits are nearly perpendicular to the ecliptic, and their motion is retrograde.

Uranus was discovered by Sir William Herschel, at Bath, on the 13th of March, 1781. It had been previously observed by Flamsteed, Bradley, Mayer, and Lemonnier; but, owing to the inferiority of their telescopes, not one

of these astronomers suspected it to be a planet. Sir W. Herschel called it the *Georgium Sidus*, in honour of George III. Foreigners for some time called it the *Herschel;* and it is now, in some English works, called the *Georgian.* *See* PLANET.

URE'A. A peculiar crystallizable substance held in solution in the urine. When dried in vacuo it consists, according to Dr. Prout, of

	Atoms.	Equiv.	Theory.	Experiment.
Nitrogen -	2	28	46·67	46·65
Carbon -	2	12	20.00	20·07
Hydrogen -	1	4	6·67	6·65
Oxygen -	4	16	26·66	26·63
	1	60	100·00	100·00

Urea is readily soluble in water, tasteless, inodorous; and when mixed with the other contents of the urine very prone to putrefaction, the principal result of which is carbonate of ammonia. Urea has been artificially obtained by the action of ammonia on cyanate of lead; oxide of lead is precipitated, and colourless crystals of urea obtained by carefully evaporating the solution.

URE'DO. (Lat. uro, *I burn.*) A genus of microscopical Fungi, whose presence is known by the burnt appearance of the part they infest. They consist of extremely minute brown spores, which multiply with great rapidity, and appear to injure plants by absorbing their juices. Smut and brand, diseases too well known to the farmer, are caused by their ravages. Steeping corn in lime-water is the best means of repelling their attacks.

U'RETER. The membranous tube which conveys the urine from the kidney to the urinary bladder.

U'RE'THRA. The membranous tube or canal by which the urine is voided.

U'RIA. A genus of web-footed birds, belonging to the short-winged family *Brachypteres* of Cuvier, and, like the rest of that family, admirable divers. The species of *Uria* are all marine, and generally known by the name of "Guillemots." They resort in vast numbers to breed among the rocks of the Orkney and Shetland Isles, and are a source of profit to the adventurous inhabitants.

URIC ACID. An acid peculiar to the urine of certain animals; it is always present in human urine, and in the excrements of many birds of prey and of serpents, especially of the *Boa constrictor*, which is voided in white nodules, consisting of little else than urate of ammonia. Uric acid also forms one of the commonest varieties of urinary calculi, and of the red gravel or sand which is voided in certain morbid states of the urine. Pure uric acid is obtained in the state of a very insoluble white powder by digesting powdered uric calculus, or the excrement of the boa, in potash, and dropping the solution into weak muriatic acid: the precipitate which falls is to be well washed, and dried at 212°. Its most distinctive chemical character, by which it is at once easily recognized, is, that when moistened with nitric acid and heated it dissolves, and upon evaporation to dryness leaves a red compound, which, upon the addition of a drop or two of a solution of caustic ammonia, becomes of a fine crimson (*purpurate of ammonia*). The following is the composition of uric acid: —

	Atoms.	Equiv.	Theory.	Experiment.
Nitrogen -	2	28	31·11	31·125
Carbon -	6	36	40·00	39·875
Hydrogen -	2	2	2·22	2·225
Oxygen -	3	24	26·67	26·775
	1	90	100·00	100·000

U'RIM. A word connected in its signification with the word *thummim*, being the plural of the Hebrew aur, *a light, a luminary;* whence it has come to signify fire. *Thummim*, which is the plural of thom or tam, means *fulness* or *perfection*. See *Wilkinson's Ancient Egyptians*, as to the connection of this word with the title of the Egyptian god Thauth, or Thoth.

The two words, conjointly, signify light and perfection; but the Septuagint render it literally δήλωσις και αλήθεια, *manifestation and truth*. The urim and thummim were the precious stones on the high priest's breastplate, which made known the will of God by casting an extraordinary lustre, and thereby *manifested* the success of events to those who consulted them.

The high priest alone could officiate at this solemn ceremony; and the urim was to be consulted only at the instance of public persons, such as the king, the president of the sanhedrim, and the general of the Israelitish army; and only on such public matters as related to the common interest of the twelve tribes.

The manner in which the high priest consulted the urim was as follows: — Having entered into the sanctuary or holy place, being fully invested with his robes and breastplate, and with his face turned towards the ark of the covenant, upon which the divine presence reposed, he brought the matter to be consulted; the person for whom he consulted standing behind him, and in humility and reverence awaiting the answer. The high priest then fixed his eyes on the pectoral, and those letters which formed the answer shone with more than ordinary lustre, and were significantly raised out of their places. So when David inquired of God, by means of the urim, whether he should go up to one of the cities of Judah, three letters came out of their places as it were, and gave the answer.

While the Hebrews were under a theocracy, or immediately governed by Jehovah, it was necessary there should always be means at hand to consult him; but when this theocracy ceased, and the kingdom became hereditary in the person and family of Solomon, and Israel became divided into two monarchies, under Rehoboam and Jeroboam, the consulting of the urim and thummim appears to have ceased.

URINE. (Gr. *οgουειν, to rush out.*) The fluid secreted by the kidneys, whence it passes by the ureters into the bladder. The variable appearance of the urine announces, even to the casual observer, corresponding fluctuations in its composition; these have long been studied by physicians and medical chemists, as furnishing useful prognostics in disease. The chemical analysis, however, of the urine is attended by many difficulties, chiefly arising out of the great number of different substances which are found in it, the variations in quantity and quality to which they are liable, and the facility with which they are modified by the analytical reagents which it is necessary to employ. The substances always found in healthy urine are water; carbonic acid; phosphoric acid, or superphosphate of lime; uric acid, or superurate of ammonia; phosphates of lime, soda, magnesia, and ammonia; sulphate of soda; chloride of sodium (common salt); urea, albumen, and mucus; colouring and odorous matter. To these may probably be added fluoric, benzoic, and lactic or acetic acids; gelatine; acetate of ammonia; sulphate of potassa; fluoride of calcium; muriate of ammonia; sulphur; silica. In certain diseases other products make their appearance, which are not discoverable in healthy urine; such as oxalic acid, or oxalate of lime; nitric acid; sugar; carbonate of lime; cystic oxide; and occasionally some anomalous organic compounds, the nature of which has not been very satisfactorily ascertained.

It is almost impossible, in consequence of the circumstances above mentioned, to give a correct notion of the relative proportions of the component parts of healthy urine; but the following statement, from Berzelius, will serve to give an idea of the average composition of this complicated fluid.

Water - - - - - -	933·00
Urea - - - - - -	30·10
Sulphates of potash and soda - -	6·87
Phosphate of soda and of ammonia - -	4·59
Chloride of sodium - - - -	4·45
Muriate of ammonia - - - -	1·50
Free lactic acid (acetic?) } Lactate of ammonia } Animal matter } - - -	17·14
Earthy phosphate and a trace of fluoride of calcium - - - - - -	1·00
Uric acid - - - - - -	1·00
Mucus and albumen - - - -	0·32
Silica - - - - - -	0·03
	1000·00

When the urine is in a healthy state, there are many circumstances of mind and body which materially influence its appearance and quantity. It is often little else than water, as after very copious draughts of diluting and diuretic liquids; at other times it is saturated with its solid contents, and even deposits part of them as it cools. If turbid at the time it is voided, it may always be considered as in a morbid state. Sometimes it contains foreign matters which have been taken as medicine or food. The peculiar odour imparted to it by asparagus, the colour by spinach, rhubarb, &c., and the passage of certain saline substances by the kidneys, are familiar cases of these modifications to which the urine is subject. The daily average voided under ordinary circumstances, by healthy individuals, is not less than 30 nor more than 40 ounces; and its specific gravity should not exceed 1030; though in some cases of disease, as in diabetes, and occasionally in some diseases of the liver and of the kidneys (as in cases of albuminous urine described by Dr. Bright) it rises to 1040. The usual average is 1020. It always reddens the vegetable blues which indicate free acid. In cases of suppressed perspiration its quantity is usually increased; and in hot weather, and when the perspiration is copious, it is diminished, for it is one of the great outlets of mere water from the system. We may also observe, that a large quantity of nitrogen is thrown off by the same channel, for that element constitutes 20 *per cent.* of urea.

Urinary Calculi.—When the uric acid of the urine, which we have already stated to be one of its most insoluble contents, is secreted in any extraordinary proportion, it is passed in a solid state, generally in minute red crystals, or *red sand;* and these not unfrequently agglutinate, so as to form small *calculi* from the size of a pin's head upwards. These, passing with more or less pain from the kidney along the ureter into the bladder, produce what is termed a *fit of gravel;* and if one or more of them remain in the bladder, it then increases in size, and becoming too large to be passed with the urine, gives rise to symptoms of *stone in the bladder*. The increase of this nucleus will be more or less rapid, according to the state of the urine; but if the inordinate formation of uric acid continues, that substance will frequently be deposited upon it in successive layers, and it will sometimes thus attain a considerable size, and consist almost entirely of uric acid. But if the uric attack in the kidney is transient, the small uric calculus in the bladder usually becomes encrusted with a white deposit, composed of *ammonio-magnesian phosphate*, perhaps with more or less *phosphate of lime*, this mixture forming what has been termed the fusible calculus; and this gives rise to a second and frequent species of urinary calculus, namely, that in which a uric nucleus is enveloped in the phosphates. The natural tendency of the urine is to deposit the above-mentioned difficultly soluble phosphates upon any extraneous matter or nucleus which may chance to be in the bladder; but the rapidity with which it is deposited is very different in different individuals, and accordingly the increase in size of such a calculus is sometimes very slow, and sometimes extremely rapid; and as the violence of the symptoms generally depends (but not always) upon the size of the concretion, they will be subject to great consequent irregularity. It does occasionally happen that calculi are formed in the bladder independent of any morbid state of the urine itself, or of any uric nucleus sent down from the kidneys; but these cases are rare, and appear to depend upon the accumulation of sand and mucus in certain disordered states of the bladder, which is gradually indurated into a nucleus, and which then goes on to increase in the phosphates; so that, on cutting such a calculus through the centre, we do not, as in the majority of cases, observe a uric nucleus, but the whole concretion is white and more or less crystalline, and usually consists of little else than ammonio-magnesian phosphate. This outline of the formation of calculi includes by far the greater number of cases; but it occasionally happens that not only the nucleus, but the bulk of the stone, is made up of *oxalate of lime*, a substance which we have above alluded to as not belonging to healthy urine. When these calculi come direct from the kidney, they often are grey and smooth, and look almost like a hempseed; or, when more carefully examined, are found to be a congeries of little rounded particles; but when they have increased in the bladder, they are then generally rough and dark brown on the exterior, whence they have acquired the name of *mulberry calculi*. Another, and more rare substance, which forms gravel and calculi, is the *cystic oxide;* and in some very rare cases small concretions of *carbonate of lime* have been voided, most probably originating in the prostate gland. Lastly, minute grains of *silica* are said to have been detected in the urine, and this substance has also been found in calculi; but it is rare, and in small quantity. In concluding this sketch of the history of the urine and urinary calculi, we cannot too strongly insist upon the importance of attending to the early symptoms of the disease, and to its first announcement, which *generally* consists in habitual turbidness and deposits in the urine. All persons are subject to occasional appearances of this kind; but when they are *constant*, they ought to be considered as alarming indications of further mischief. These, in their early stages, are almost always curable, either by diet, medicine, or both; but when once a stone has formed in the kidney or bladder, all hope of its removal, except by an operation (and even that not admissible in the case of kidney calculi), is vain, nothing having been yet discovered to which the term *solvent* is properly applicable. The removal of the stone from the bladder is effected by operation in two ways: either by an incision into the bladder, and the removal of the stone by a forceps,—this constitutes *lithotomy;* or by *lithotrity*, in which certain instruments are introduced by the urethra, so as to grasp the stone, and enable the operator to reduce it to fragments sufficiently small to allow of being voided by the usual passage.

URN, in Mosses, is the hollow urn in which the spores or false seeds are lodged.

URN, CINERARY or SEPULCHRAL. (Lat. uro, *I burn.*) A species of vase used among the ancients to receive and preserve the ashes of the dead. The form of the urn was derived by the Romans from Greece; but the Greeks did not employ their urns for sepulchral purposes. Among the Romans these vessels were especially consecrated to retaining the ashes of the dead. Similar vessels were used by the ancient Teutonic and Slavonic tribes, who likewise burnt their dead. Sir T. Brown's celebrated work, *Hydriolaphia, or Urn Burial*, contains a strange collection of learned fragments and philosophical reflections on this subject. Numerous descriptions of cinerary urns, both Roman and British, discovered at different periods in this country, will be found in the *Archæologia*.

UROCE'RATA. (Gr. ουρα, *a tail*, and κερας, *a horn.*) The name of a tribe of *Terebrantia*, or boring Hymenopterous insects, in which the *terebra* or borer of the females is sometimes very long and prominent, and composed of three filamentary processes, sometimes capillary, and coiled in a spiral form in the interior of the abdomen.

U'RODELES, *Urodelæ*. (Gr. ουρα, and δηλος, *manifest.*) The name of that tribe of Caducibranchiate Batrachian reptiles which preserve the tail through all the stages of their existence.

URO'PTERANS, *Uroptera*. (Gr. ουρα, and πτερον, *a wing.*) The name of a family of Amphipodous Crustaceans, including those in which the tail is terminated by enlarged appendages in the shape of fins.

UROPY'GIUM. (Gr. ουρα, *a tail*, and πυγη, *behind.*) The base of the tail in mammals and birds.

URO'SCOPY. The judgment of diseases founded upon an inspection of the urine.

U'RSA MA'JOR. The Great Bear; one of the forty-eight constellations of Ptolemy, in the northern hemisphere, and near the pole. It is often alluded to in the most ancient histories, sacred and profane, under the various denominations of Arctos, Bootes, Helix, Callisto, Megisto, the Waggon, the Plough. It contains seven very conspicuous stars, called *septemtriones;* whence *septemtrio*, the north.

URSA MINOR. The Lesser Bear; also one of the forty-eight constellations of Ptolemy. It was called by the Greeks *Cynosura;* that is, the *Dog's Tail*. The pole star is in this constellation.

U'RSULINES. In Ecclesiastical History, an order of nuns, of which the origin is ascribed to Angela di Brescia, about 1537; but which derived its name from St. Ursula (a lady of the family of Benincasa at Naples). The Ursulines were bound to perform charitable offices to the sick, poor, and penitent. They were erected into an order by Gregory XIII., in 1577, at the solicitation of St. Charles Borromeo. They take, in addition to the three ordinary vows, a fourth,—to devote themselves to education. (See Waddington, *History of the Church*, p. 401.)

U'RSUS. (Lat. ursus, *a bear.*) A genus of Plantigrade Carnivora in the system of Cuvier, restricted to those species which have three large tuberculate molars on each side of both jaws, the anterior lower and the posterior upper one being the largest. They are preceded by a tooth a little more trenchant, representing the carnassial tooth, and by a variable number of small premolars. In accordance with this dentition, the bears are omnivorous or frugivorous. They are heavy, stout-bodied animals, with thick limbs, and a very short tail: the cartilage of the nose is moveable, and sometimes very long, as in the labiated bear, commonly called the ursine sloth. The bears of the northern regions pass the winter in a state of somnolency in dens or other hiding places, and it is in these retreats that the female brings forth her young. The species best known are the common brown bear (*Ursus arctos*), the black bear (*Ursus Americanus*), the grisly bear (*Ursus ferox*), the polar bear (*Ursus maritimus*), the *Ursus labiatus*, *Ursus Thibetanus*, *Ursus Malayanus*, and *Ursus Syriacus*.

URTICA'CEÆ (Lat. urtica, *the nettle*), form a very large and natural order of plants, with apetalous flowers, a lenticular simple fruit, and a seed whose embryo always directs its radicle towards the top of the cavity. The stinging properties of the common nettle are participated in by many others whose acridity is intense. Others are provided with a poisonous juice, which in its most concentrated form gives the upas tree of Java its formidable qualities. A narcotic principle is highly developed in hemp, and the toughness of the fibre of that plant occurs in many others of the order. Nevertheless the fig, the bread-fruit, the mulberry, and hops, in which nothing deleterious is remarked, are the produce of some species; and even the milk tree of the Caraccas, whose bland juice feeds the natives of the country, is an Urticaceous plant. Many species furnish caoutchouc, which, in *Ficus elastica*, is of the finest quality.

URTICARIA. *See* NETTLE RASH.

U'SANCE. In Commercial Law. A foreign bill is often drawn at one, two, or more "usances," meaning thereby certain periods of time which it is the usage of the countries between which the bills are drawn to allow for payment thereof. Thus, the "usance" between London and Paris is one calendar month; a bill drawn here "at one usance," on the 2d January, is payable there on the 5th February, allowing three days of grace.

USE, in its original sense, signified the equitable right one had to take the rents and profits of land whereof the

legal ownership was in another. It was very nearly the same as the trust of the present day, and created in the following manner: — The owner of land conveyed it by feoffment to some friend, on the understanding that the feoffee should hold it for the sole use and benefit of the feoffor, or such persons as he might nominate. In this way the seisin or legal property of the land became vested in the feoffee to uses as trustee; while the feoffor, or other person nominated by him, who was called the cestui que use, had the substantial use and enjoyment of it. The simplicity of the common law, however, recognized but one person in connection with the soil, namely, its real owner, and repudiated the idea of any use as separated from the seisin; so that if the trustee, abusing the confidence placed in him, refused to let cestui que use take the rents and profits, there was no redress for the grievance. But the Court of Chancery, as a court of equity, considered the agreement entered into by the trustee as binding on his conscience; and after calling on him by writ of subpœna to appear and make a disclosure on oath of the particulars of his trust, compelled him to perform it.

The system of uses was transplanted from the civil law, and introduced into this country about the time of Edward III. by the ecclesiastics, who procured conveyances to be made, not directly to themselves, but to lay persons as trustees for them, in order to evade the statutes of mortmain. Once known, it was generally adopted; and though crushed in its infancy, so far as regarded religious houses, continued to flourish without disturbance in other respects, and was found admirably adapted to the wants and convenience of the people at large in softening the rigours of feudal tenure, and facilitating the alienation and settlement of property. The laws and policy of feudal tenure required the vassal to render certain fruits and services to his lord; and if these were not duly rendered, or any act were done in derogation of the lord's title, the estate was forfeited. The tenancy of the freehold could not be interrupted or suspended for an instant; and to every transfer of it actual and public delivery of possession, in the presence of witnesses, and accompanied by much solemn ceremonial, was absolutely indispensable; so that the lord might always have some person to perform the services due to him, and always know with certainty who that person was. The lord was entitled to sell his ward in marriage, to take the profits of the land during the wardship, and on the descent or alienation of the land heavy fines were payable to him. The tenant had no power of directing the destination of the land by will; such a mode of disposition would at once have been wanting in notoriety, and have deprived the lord of his fruits upon a descent.

When, however, the equitable interest in land, as distinguished from the legal property in it, became recognized and enforced in the Court of Chancery, the principal hardships of tenure were easily avoided. A. conveyed land to B. to A.'s own use; the terms upon which B. took the land were said, in equity, to affect his conscience, and to impose upon him a moral obligation to fulfil them honestly. But it was in equity only that A. had any claim: there he might call upon B. to allow him to take the profits of the land, and to make such conveyances of it as he might from time to time direct. At law A. had no control over or connection with the land any longer remaining to him. His use, therefore, altogether evaded the grasp of tenure, which rested entirely upon the common law. It was held of no one; it was the creature of his own declaration, operating upon the conscience of the person in whom he confided. It might be transferred at any time without any public solemnities by a secret declaration. At law A. could not carve out for himself a portion of the whole fee, and limit the residue of it to others, without first of all going through all the formalities of a conveyance to B., and then taking back a reconveyance, with the same formalities, of that portion of the fee which he might wish to retain to himself. Husband and wife being one person in law, he could not carve out a portion for her without conveying to B., in order that B. might afterwards convey to her. He could not convey the fee, or any portion of it, to B.; so that it should, on the happening of any named event, or the expiration of any named period, shift either wholly or in part from him to any other person. He could not even convey to B. at all without giving him immediate possession: a conveyance to him in futuro, as from Christmas next, would have been altogether void. He might, however, resorting to equity, and making a declaration of the uses to which he wished his property to be applied, effect all these and innumerable other arrangements by a single stroke of the pen, or a mere breath. The use, emancipated from the common law, had such a suppleness and pliability as almost to accommodate itself to his very whims. He might dispose of it by will, or it would descend to his heirs in the course of the common law; but no fine was payable upon its descent. It was not liable either to dower or to curtesy; it was not extendible for debts, nor forfeited for treason. Lord Bacon accordingly complains, that it "deceived many of their just and reasonable rights. A man that had cause to sue for land knew not against whom to bring his action, or who was the owner of it. The wife was defrauded of her thirds; the husband of his curtesy; the lord of his wardship, relief, heriot, and escheat; the creditor of his extent for debt; and the poor tenant of his lease." To remedy these and other inconveniences, the statute 27 Henry 8. c. 10. was passed, usually called the Statute of Uses; which enacts, that when any person shall be seised of lands to the use, confidence, or trust of any person, he shall thenceforth be seised and possessed of the land of and in the like estate as he had in the use, trust, or confidence.

The statute thus executed the use, as it is called, by transferring it into possession, and doing away with the distinction between the beneficial interest and legal property in land. Whoever had the use had now also the legal estate. Thus the use was not abolished, according to the probable intention of the legislature, but merely annexed to and incorporated with the legal estate; to which, therefore, it now superadded all the convenient ductility of its own nature. It had no longer a merely precarious existence in equity, but a firm locus standi in courts of law. It was shorn, indeed, of many of its old privileges, such as exemption from dower, curtesy, and forfeiture; but for this loss there was soon contrived a remedy. The judges, in their narrow construction of the statute, decided that its provisions did not extend to a use limited upon a use, as their phrase was. Accordingly, on a feoffment to A. and his heirs, to the use of B. and his heirs, to the use of (or in trust for) C. and his heirs; they held that the statute clothed the first use with the legal ownership, and that the second was a nullity. But as it was quite clear that C., and not B., was the person intended to enjoy the estate, this verbal pedantry of the common law judges drove C. into the Court of Chancery for relief, where he was immediately received as the substantial cestui que use; and the *use* which the statute had been in law held not to execute was considered a valid *trust* in equity. Thus by limiting two uses successively instead of one only as before the statute,—by making, in fact, the conveyance only three words longer than had been customary, the equitable interest and the legal estate were again disunited, and the use under its new name of trust was as popular and available as ever. In this manner the destructive qualities of the statute are virtually repealed, while its creative qualities are to this day in full operation; and the legislature, instead of paralyzing the use, has only given new form and flexibility to the legal estate.

Uses are of various kinds.

An *executed use* is one to which the statute applies by annexing to it the legal ownership. That to which the statute does not apply is called, as has been already mentioned, a *trust*.

Secondary or *shifting use* is one which takes effect in derogation of a use previously limited, as in a conveyance to A. to the use of B.; and if C. shall return from Rome or pay B. a certain sum of money, then to the use of C.

Springing use is one limited to arise on a future event, where no preceding use is limited.

Future or *contingent use* is one limited to a person not ascertained, or upon an uncertain event, but without derogation of an use previously limited, as to A. for life, and afterwards to his unborn son.

Resulting use. When the use limited expires or cannot vest, it is said, either after such expiration or during such impossibility, to result back to the grantor; as on a conveyance by A. to the use of his intended wife for life, then to her eldest son in tail: here, until the marriage, the use results back to A.; or results to him in fee in the event of his wife dying without issue.

U'SHER. (Probably from the Fr. huissier.) An officer who has the care of the door of a court or hall, &c. In the court of England, he is an officer of considerable rank, whose business it is to introduce foreign ambassadors or other high strangers to the sovereign.

USQUEBAUGH. A strong compound liquor, made in greatest perfection at Drogheda in Ireland. Brandy or other spirits, raisins, cinnamon, cloves, and various other spices are its ingredients.

USTRI'NUM, or USTRI'NA. (Lat. uro, *I burn.*) In Roman Antiquities, a public burning-place, enclosed by walls, in which bodies, mostly of the poorer sort of people, were consumed. An ustrinum, according to Montfaucon, was square, and in compass about 300 feet. In the *Archæologia* (vol. xxvi.) will be found a detailed account of the site of one recently discovered in Cambridgeshire, which appears to have been of rather large dimensions.

USTULATION. (Lat.) A term of old Pharmacy, implying the gradual desiccation and torrefaction of substances.

USUCA'PTION. In Civil Law, the acquisition of property in any thing by possession and enjoyment for a certain term of years; commonly considered as synony-

mous with prescription, although some have restrained the use of the former term to moveables only.

U'SUFRUCT, in the Civil Law, is defined to be the right of enjoying indefinitely something belonging to another without diminishing its substance. *Usufruct* differs from *use*; because he who has the use of a thing can only enjoy it personally, whereas the right of him who has the usufruct is alienable, and may be granted, sold, or hired to another. Usufruct may be constituted in four ways: by contract, by will, by judgment of a court (as where the judge, in effecting a division of common property, may, under certain circumstances, instead of dividing the inheritance, allot the usufruct to one, and the thing to another), and by operation of law. Usufruct is, properly speaking, confined to things real, and to incorporeal rights (whether they would be termed real or personal, according to the division of our law), such as debts; but a sort of usufruct (quasi usufruct) may exist in things liable to be consumed by use. The division between the fruit (which belongs to the usufructuary), and the thing itself (which belongs to the proprietor), affords room for a great variety of legal distinctions. Usufruct may be extinguished in several ways: by the death, natural or civil, of the usufructuary; by loss; by prescription, the right being extinguished if disused for a certain period; by forfeiture, where the usufructuary abuses his right; by expiration of time, if the usufruct have been granted for a term; and by the union of the usufruct with the property in the same hands.

U'SURY. The taking of interest for money: from the Latin word usura. The Jews were forbidden by the law of Moses to exact interest from one another. By the old Roman law of the twelve tables, the rate of interest allowed as legitimate was the usura centesima, which was strictly one per cent. a month; and has been supposed by some to have amounted to twelve, by others to ten per cent. in the year. Interest was also computed in the following manner: — Usura unciaria, being the lowest term, one per cent., or one twelfth of the usura centesima; usura semis, or semis, half the centesima (six per cent.); bes, quadrans, quincunx, &c., two third parts, a quarter, a fifth of the centesima (eight, three, two per cent.). The Roman laws against excessive usury were frequently renewed, and constantly evaded; but the same principle, additionally sanctioned by mistaken religious opinions, pervaded the laws of all countries in which the civil jurisprudence prevailed. The amount of legal interest has been fixed by various statutes in England. In the reign of Henry VIII. ten per cent. was allowed; by 21 J. 1., 8 per cent.; by 12 C. 2., 6 per cent.; by 12 Ann. 5 per cent. All contracts made for the payment of any principal to be lent on usury above this rate were utterly void. The question of usury, *i. e.* whether a contract is *bonâ fide*, or a colour for a usurious loan, was determined by the verdict of a jury. But the usury laws have been relaxed by several recent statutes. By the last, 2 & 3 Vict. c. 37., bills of exchange not having more than 12 months to run, and contracts for loans or forbearance of money above 10*l.*, are no longer affected by those laws. But 5 per cent. remains the legal interest recoverable on all contracts, unless otherwise specified.

UT. In Music, the name of the first of the musical syllables. The Italians, for the sake of softening the sound, use the syllable Do instead of Ut in the modern solfeggi.

U'TERINE. (Lat. uterus, *belly*.) In the Civil Law, an uterine brother or sister is one issued from the same mother.

UTILITA'RIANS. A name which has been given to a particular sect of modern politicians; those, namely, who profess to try the excellence of modes of government and usages simply by their utility. The celebrated Jeremy Bentham, regarded as the founder of this sect, introduced into the critical department of politics a closer logic than had been commonly applied to it; and aimed at applying his famous principle, "the greatest happiness of the greatest number," as an immediate test by which to affirm or deny the value of institutions. It is evident that all political sects, both of writers and statesmen, profess ultimately the same object. The real characteristic of the Utilitarians consists in the peculiar sense in which they understand it. They confine for the most part the proposed utility, so as to restrict it to that which is useful for the material and economical well-being of the multitude. Their tenets have been attacked in two celebrated articles in the *Edin. Review* (vols. 49 and 50.): *Mill's Essay on Government*, and *Austin on Jurisprudence*, may be referred to as containing the most intelligible summaries of them.

UTI POSSIDE'TIS. In Politics, a treaty which leaves belligerent parties mutually in possession of what they have acquired by their arms during the war is said to be based on the principle of *uti possidetis* — "as you possess."

UTO'PIA. A term invented by Sir T. More (from Gr. *ουτοπος*, *no place*), and applied in his celebrated work called *Utopia* to an imaginary island, which he represents to have been discovered by a companion of Amerigo Vespucci, and as enjoying the utmost perfection in laws, politics, &c., in contradistinction to the defects of those which then existed. The work was first printed in 1516, but Froben's edition, of 1518, is more correct. The word *Utopia* has now passed into all the languages of Europe, to signify a state of ideal perfection; and *Utopian* is used synonymously with *fanciful* or *chimerical*.

UTRI'CULUS. (Lat. uter, *a bladder*.) A term in Botany applied to a one-celled, one or few-seeded, superior membranous fruit, frequently dehiscing by a transverse suture, as in *Chenopodium*. It is also used to indicate a fruit with a thin skin and a single seed. Sometimes this word is employed to express a separate cell of the cellular tissue of a plant, which is usually a little vegetable bladder.

UVA URSI. The *Arbutus uva ursi*, *bear's berry*, or *whortleberry*. The leaves of this small shrub have a highly astringent and sweetish taste; their decoction or infusion is occasionally used in medicine, especially in certain disorders of the kidney and bladder.

U'VULA. (Lat. dim. of uva, *a grape*.) A small fleshy protuberance attached to the soft palate, and hanging over the tongue. It consists of the common integuments of the mouth, and a small vermicular muscle by the contraction of which the uvula is elevated. In some cases of enlarged or relaxed uvula which will not yield to local or other remedies, it becomes necessary to amputate a part of it, in consequence of the impediment to deglutition which then ensues, and the tickling cough and retching which it induces.

VACCINA'CEÆ. (Vaccinium, one of the genera.) A natural order of shrubby Exogens, chiefly inhabiting North America. Formerly combined with the Ericaceous order, from which they differ in their inferior ovary and succulent fruit. The berries of many are eaten, under the names of cranberry, bilberry, whortleberry, &c.; and some of the species are cultivated as objects of ornament.

VACCINATION. *See* Cow Pox.

VACU'NA, or VACI'NA. The ancient Italian goddess of leisure, to whom the husbandmen sacrificed at the close of harvest, or "harvest-home;" to which rustic festival Horace alludes in the words "fanum putre vacunæ." (See also *Ov. Fasti*, vi.)

VA'CUUM (Lat. vacuus, *empty*,) in Physics, is a portion of space void of matter. The possibility of the existence of a perfect vacuum has been a favourite subject of dispute with the schoolmen and metaphysicians. Its existence was maintained by the Pythagoreans, Epicureans, and Atomists; and denied by the Peripatetics, who ascribed the rise of water in a sucking-pump, and some other phenomena of the same kind produced by atmospheric pressure, to nature's abhorrence of a vacuum. Descartes made the essence of matter to consist in extension, and therefore denied the possibility of a vacuum; for if extension be the essence of matter, wherever extension is there matter must be. Those, again, who suppose all material bodies to be formed of the agglomeration of elementary particles, are compelled, by the phenomena of motion, to admit at least the existence of what was called by the schoolmen a *vacuum interspersum*, or of intervals devoid of all matter among the interstices or pores of bodies; for if there were no interstices, all space would be full of matter, in which case no body could be moved out of its place, inasmuch as there would be no unoccupied place into which it could move. For the arguments on this subject, see *Newton's Optics*.

The most perfect vacuum that can be produced artificially is the *torricellian vacuum*, or the space above the mercury in the barometric tube. But in this sense vacuum merely signifies the exclusion of atmospheric air; for this space in the barometer may be filled with the vapour of mercury, or with some other medium infinitely more rare than air, and inappreciable to our senses. It is obvious, from the nature of the pneumatic machine, that the vacuum produced by an air-pump, or the Boylean vacuum, as it has been called, can never be perfect, as some air must always remain in the receiver, however long the exhausting process may be continued.

The question of the abstract existence of a vacuum is not worth discussing; but there is another question of great interest with reference to physical astronomy connected with the subject, — namely, whether the spaces in which the planets move are so far void of matter as to offer no resistance to their motions, or are occupied by a medium of sufficient density to impede their motions in the long run in a sensible degree. Recent observations appear to give some countenance to the supposition that this is actually the case. It has been observed that after the most careful allowance has been made for the attractions of the planets, and all other known causes of disturbance, on Encke's comet, the successive returns of that body to its perihelion are accomplished in periods which are constantly diminishing. (*See* COMET.) Now this is precisely the effect that would be produced if the body moved in a medium which offered a small resistance to its motion;

and as this is the only obvious mode of explaining the phenomenon, it has been generally adopted. Nevertheless, it is extremely difficult to reconcile the supposition of an existing medium with the astronomical fact, that, during the last two thousand years of observation, it has produced no effect on the motions of the large planets capable of being appreciated by the most delicate instruments. This fact, however, though it proves the extreme feebleness of the resistance, does not furnish an absolute proof that such a medium may not exist, and that its effects may not ultimately become sensible even on the densest planets. If it does exist, the consequence seems inevitable that all the planets and satellites, as well as the comets, must be ultimately precipitated into the sun.

Another argument against the existence of a vacuum is furnished by the undulatory theory of light. If this hypothesis be true, and it is rendered probable by numerous phenomena, a medium of great elasticity must pervade all the parts of space through which light penetrates. There could in this case be no vacuum; unless, indeed, the term be understood to denote merely the absence of ponderable matter. *See* LIGHT.

VA'DE IN PACE. (Lat. *go in peace.*) In monastic communities offences were sometimes punished by the dreadful infliction of starving to death in prison; and bones have occasionally been found among the ruins of convents of victims who appear to have perished in this manner. The punishment acquired this name from the words in which the sentence was pronounced. The use which Walter Scott has made of this custom in his poem of *Marmion* is well known. But it is no romantic fiction. (See Fleury, *Hist. Eccles.* vol. xx. p. 102.; where, however, the *vade in pace* is described as perpetual solitary imprisonment. *Dict. de Trévaux.*)

VAGA'NTES. (Lat. vago, *I wander.*) The name of a tribe of spiders (*Araneidæ*), comprehending those which watch their prey concealed in a web; but also frequently run with agility, and chase and seize their prey.

VAGI'NA (Latin term for *sheath*), is applied by botanists to the leafstalk of those plants in which it becomes thin and rolls round the stem, to which it then forms a sheath: this is the case in grasses.

VAGI'NATES, *Vaginati.* (Lat. vagina, *a sheath.*) Sheathed Polypes. The name of an order of Polypes, comprehending those which are constantly surrounded by and attached to a calcareous or horny polypiary.

VA'GRANCY. (Lat. vagro, *I wander.*) In Law, a very miscellaneous class of offences against public police and order is comprehended under this title in English Law. Vagrants, under the present act of parliament in force on the subject (5 G. 4. c. 83.) are of three descriptions:—1. Idle and disorderly persons; including persons neglecting to maintain their families; paupers returning without certificate to parishes whence they have been legally removed; beggars, common prostitutes, pedlars without licence, &c.; all of whom may be summarily convicted and committed to gaol for a month by any single justice, subject to an appeal to the sessions. 2. Rogues and vagabonds including persons guilty of the former offences, who have been once already convicted of being idle and disorderly; fortune-tellers and other impostors; persons guilty of indecent exhibitions; procurers of charitable contributions under false pretences; playing at games of chance in public places; having in their possession housebreakers' implements, or offensive weapons, with intent to use them; reputed thieves frequenting public places to commit felony, and others; all of whom may be committed for three months. 3. Incorrigible rogues, viz. persons guilty of the last class of offences, having been already convicted; persons breaking out of legal confinement, &c., who may be committed to the next sessions, and there sentenced to a year's imprisonment. Under this act justices possess very extensive powers, such as to issue warrants to bring before them persons suspected of vagrancy, to search lodging houses reasonably suspected of harbouring vagrants, &c.

VAIR. In Heraldry, one of the furs employed in blazonry. It is supposed to represent the skin of a small squirrel. It is always white and blue, unless otherwise specified in the blazon; as vair of *or* and azure, vair of ermine and gules, &c. Vair appears to be derived from varius. *Vairy* is the pattern of vair with more than two colours.

VA'LENTINE. Feb. 14. is the day sacred to St. Valentine, a presbyter, who, according to the legend, was beheaded at Rome under Claudius. Mr. Brand (*Popular Antiquities*, vol. i. p. 47.) says that he cannot find in the life of the saint any circumstances likely to have given origin to the peculiar ceremonies of the day. It appears to have been a very old notion, however (for it is alluded to by Chaucer, as well as by Shakspeare in the *Two Gentlemen of Verona*), that on this day birds begin to couple. And the custom of "choosing Valentines" is of great antiquity in this country, as well as in France, where, however, it has been long disused. Lydgate mentions it (1476); Grose explains Valentine to mean "the first woman seen by a man, or man by a woman," on that day; but it does not appear where he picked up this explanation. There is also a curious French Valentine, composed by the poet Gower, in *Warton's History of English Poetry* (Additions to vol. ii. p. 31.). Herrick mentions the notion and the custom:—

> Oft have I heard both youths and virgins say,
> Birds choose their mates, and couple too, this day.

It appears that the Reformers attacked this as well as other legendary customs of their time; and that the Romanists themselves were so scandalized at it that devices were invented for turning the day to profitable use. St. Francis de Sales introduced the practice of drawing lots for patron saints on it, by way of substitute. According to others, this latter practice was of much older date, and substituted for a pagan custom by which boys and girls drew each other's names on the 15th February (day of Februata Juno). However this may be, it is certainly one of the few saints' days in the calendar popularly remembered in England, as the returns of the post office invariably testify.

VALENTI'NIANS. In Ecclesiastical History, a sect of the second century; so called from Valentinus, their founder. They were a branch of the Gnostics. *See* GNOSTICS.

VALE'RIAN. The root of this plant, the *Valeriana officinalis*, is used in the form of infusion, decoction, or tincture, as a nervous stimulant and antispasmodic.

VALERIANA'CEÆ. (Valeriana, one of the genera.) A natural order of herbaceous Exogens inhabiting temperate climates. They are distinguished from the Dipsaceous order by their flowers not being in heads, by the want of albumen, and the absence of an involucel. The roots of *Valeriana officinalis* are aromatic and antispasmodic; and the young leaves of the species of *Valerianella* are eaten as salad, under the French name of mâche, or the English one of lamb's lettuce and corn salad.

VALE'SIANS. An ancient sect of heretics mentioned by Epiphanius, and supposed to have become known about A. D. 240; said to have adopted the practice of eunuchism.

VA'LET, VARLET. Originally, the sons of knights, and afterwards those of the nobility before they had attained the age of chivalry. The name is sometimes written *vasletus*, and seems to be derived from the same root with vassal; probably the Celtic gwâs. (*See* VASSAL.) Valet in French, and varlet in English, degenerated in later times into the signification of servant.

VALHA'LLA, or WALHALLA. The palace of immortality, in the Scandinavian mythology, inhabited by the souls of heroes slain in battle.

VALKY'RIUR, or DISAS. The Fates of the Scandinavian mythology: the "choosers of the slain," who conduct heroes killed in battle to Valhalla.

VALLEY. (Lat. vallis.) In Architecture, the internal angle formed by two inclined sides of a roof. It is supported by a rafter called the *valley rafter*, or *valley piece*; on which lies a board for the reception of the lead gutter, called the *valley board*.

VA'LLUM. (Lat.) The rampart with which Roman armies enclosed their camps, and which was crowned with a breastwork of stakes.

VALVA'TA. (Lat. valvæ, *folding doors.*) A genus of fresh-water snails or Gastropods; so called from the valve-like form of the operculum or lid which covers the aperture of the depressed spiral shell. Of this genus several species are British; as *Valvata obtusa*, common in the ditches at Battersea; *Valv. spirorbis*, *Valv. planorbis*, *Valv. minuta*, &c.

VALVE. In Mechanics, a close lid affixed to a tube, or hollow piston, or opening in a vessel, by means of a hinge or other sort of moveable joint, in such a manner that it can be opened only in one direction. A spherical ball of metal laid on the end of a tube properly formed, and retained in its place by its weight alone, is sometimes used advantageously instead of a valve, as in the *hydraulic ram*. The *safety valve* of the steam engine is a valve attached to the boiler, to obviate the danger of its bursting in case the steam should become too strong. The valve is so loaded that its weight, added to that of the atmosphere, exceeds the pressure of the steam, when of a sufficient force. When the expansive force increases so far that its pressure preponderates over the pressure of the atmosphere and the weight of the safety valve, the valve opens, and the steam escapes from the boiler till its elastic force is sufficiently diminished, and the valve shuts by its own weight. By opening the safety valve the engine may be stopped at pleasure, for which purpose a particular apparatus is attached to the valve. As any accidental derangement of the safety valve might be attended with the most disastrous consequences, it has been proposed to make the valve of a metal which melts at a particular temperature, by which means the elastic force of the steam could never exceed that which corresponds to the temperature at which the valve would melt. This method has been adopted in France.

VALVES. In Botany, the pieces into which the fruit of a plant naturally separates when it bursts. The name is also applied to similar parts in any other organ, as the anther.

VA'MBRACE. (Fr. avant-bras.) In Plate Armour, the piece which served as a protection to the arm below the elbow.

VA'MPIRE. A blood-sucking spectre, the object of superstitious dread among various nations of Europe. The belief in vampires, *i.e.* in persons returning to the earth after death and burial, not as ghosts, but in actual corporeal substance, and sucking the blood of living men, appears to have prevailed in classical times. The Empusæ, Lamiæ, and Lemures were species of vampires. One of the most detailed stories of vampires is the tale of *Machates and Philinnion*, which Goëthe has made the foundation of his poem of the *Bride of Corinth:* in which the dead bride of a young man visits him at night, and withers him by her embrace. But in modern Europe, the populations among which vampire superstitions have prevailed appear to be of Sclavonic descent. The word vampire is said by Adelung to be of Servian origin; and although the modern Greeks have also their vampires, yet the barbaric names by which they call them (Vroucolachas, Vuroulachas, Vardoulachas) seem rather to indicate the Sclavonic, or perhaps Albanian source, from which they derived both the tradition and the word. In Crete they are called Katakhanâs, and firmly believed in. (See *Pashley's Travels.*) About a century ago, there prevailed in several districts of Hungary an epidemic dread of vampires, which lasted some years, and gave birth to many extraordinary stories. It was believed that in several places those among the dead who belonged to the class of vampires arose nightly from their graves and sucked the blood of the living, who fell into consumptions and perished; that those who had died in this manner became infected with vampirism; and that the only way of exterminating the plague was by disinterring all the suspected vampires, and, if it were discovered that they exhibited the tokens of their hideous character, burning them to ashes, or driving a stake through their middle. The attestations which these grotesquely fearful tales received, are among the most singular instances of human credulity recorded in all the annals of superstition. They are, in many instances, related on the authority of the pastors and other most credible persons of villages and towns, who depose to having been themselves witnesses of the scenes beheld on opening the vampires' graves. Some, indeed, had actually seen the spectres themselves on their nightly excursions; but more generally the subscriptions are by persons present at the inspection of the dead bodies; when, if the subject was a true vampire, he was generally found of a florid and hale complexion; his hair, beard, and nails had grown; his mouth, hands, &c. were stained with fresh blood; his eyes open and brilliant. Sometimes, when the stake was driven through him, he was heard to utter cries like those of a living person. It was believed that the consumption produced by the sucking of the vampire could be cured by eating earth from his grave. The popular name of the vampire-bat (*Vespertilio spectrum*), a small animal of South America which sucks the blood of persons asleep, is derived from these imaginary monsters.

VAN. In Naval language, the foremost division of the line of battle, which is also the weather division when the fleet is on a wind.

VANA'DIUM. (Lat. Vanadis, *a Scandinavian deity.*) A metal discovered in 1830, by Professor Seftström of Fahlun, in iron prepared from the iron ore of Taberg in Sweden. Vanadium has also been found in a lead ore from Wanlockhead in Scotland, and in a similar mineral from Zimapan in Mexico. Vanadium is a white brittle metal, very difficult of reduction; not oxidized by air or water; and insoluble in sulphuric, muriatic, and hydrofluoric acids, but soluble in nitric and nitromuriatic acids, with which it yields solutions of a fine dark blue colour. It is not acted upon by boiling caustic potash, nor by the carbonated alkalies at a red heat. The peroxide of vanadium is of an orange colour, and very slightly soluble in water; it unites with the salifiable bases; with the alkalis its salts are soluble, with the other bases sparingly soluble. These salts are orange or yellow coloured; in these and other respects there is a close resemblance between vanadium and chromium. Peroxide of vanadium, or vanadic acid, is distinguished from chromic acid by the action of deoxidizing substances, which give a blue solution with vanadium, but a green one with chromium. When heated with borax in the reducing flame of the blowpipe, both of the acids yield a green glass; but in the oxidizing flame the bead becomes *yellow* if vanadium is present, but the green colour is permanent if produced by chromium. According to the experiments of Berzelius, the equivalent of vanadium is about 68; and the protoxide, the deutoxide, and the vanadic acid, are composed respectively of 1 atom of vanadium, and 1, 2, and 3 of oxygen.

VANE. A contrivance for showing the direction of the wind. It consists usually of a thin slip of wood or metal, attached to a perpendicular axis, round which it moves freely; and is so shaped that it presents always the same extremity to the point of the horizon from which the wind blows.

VANE'LLUS. (Lat. *a lapwing.*) A name applied by Bechstein to a subgenus of the Linnæan *Tringæ*, including the true lapwings, which are distinguished from the *Squatarolæ* of Cuvier by their more distinct, though small, hinder toe, and their partially scutellated tarsi.

VANE'SSA. (Or better *Phanessa;* from φανης, one of the names of Venus or Love in the Greek as well as Egyptian mythology.) The term is applied to a genus of butterflies.

VANG. A rope for steadying the extremity or peak of a gaff to the ship's side.

VANGUARD. That part of an army which precedes the main body on the march, as a security against surprise.

VANI'LLA (Span. baynilla, *a small pod*), is the succulent fruit of a plant of the Orchidaceous order, climbing over trees in the tropical parts of America after the manner of ivy. Its fragrance is owing to the presence of benzoic acid, crystals of which form upon the pod if allowed to be undisturbed. It is an aromatic, employed in confectionary and the preparation of liqueurs, and in flavouring some kinds of chocolate, &c.

VA'POUR. (Lat. vapor.) When liquids and certain solids are heated they become converted into elastic fluids or *vapours*, which differ from *gases* in this respect, that they are not under common circumstances permanently elastic, but resume the liquid or solid form when cooled down to ordinary temperatures. The term *vapour* is frequently limited to water in the state in which it exists in our atmosphere and in other humid aëriform bodies; that is, in a perfectly invisible state. When very moist air is duly cooled, the vapour, previous to assuming the liquid state, becomes visible, as seen in mist and fog; it is observed in the same state when steam issues rapidly from the spout of a tea-kettle, when it escapes into the air from the surface of hot water. In this case it is sometimes called *vesicular vapour;* for, from its action on light, it seems in that *visible* state to exist in the form of minute vesicles. Different substances yield vapours with very different degrees of facility, or, in other words, are more or less volatile; a circumstance dependent, probably, upon the less or greater cohesion with which their particles adhere. Hence fluids are generally more volatile than solids, and hence solids generally pass into the liquid state before they assume the form of vapour. To both these statements there are, however, many exceptions; thus most of the expressed oils are very differently vaporizable, and are hence termed *fixed oils*. Common concentrated sulphuric acid is also a very fixed liquid, requiring a high temperature for its vaporization; and camphor and some other solids evaporate at common temperatures, and arsenic and sal ammoniac at high temperatures, without previously assuming the liquid state. The space which vapours occupy always exceeds that of the substances from which they arise. Thus, at the temperature of 212°, and under a pressure of 30 inches of mercury, a cubic foot of water produces 1696 cubic feet of vapour, of alcohol 660, and of ether 443. Hence it is obvious that different vapours differ very considerably in density, and that this property is not directly as that of the liquids which furnish them. Thus, if we assume the density of air as 1000, that of aqueous vapour or steam is only 625; the density of aqueous vapour to that of atmospheric air being as 1000 to 1694. Again, assuming the density of air as = 1000, that of alcohol vapour is 1613, and of ether no less than 2586; though alcohol and ether are both, in the liquid state, lighter than water. As water boils at a higher temperature than alcohol, and alcohol at a higher temperature than ether, it was supposed that the density of vapours was probably directly as the volatility of their respective liquids: but this law has exceptions; for bisulphuret of carbon yields a heavier vapour than ether, but its boiling point is higher. All pure vapours follow the same law of expansion, when heated, as gases; that is, for every degree of Fahrenheit's thermometer they increase by $\frac{1}{480}$th of the volume which they occupied at 32°.

VAPOUR, in Physics, denotes the condition of a body, when by the accession of heat its particles acquire a repulsive force, and it is reduced to the state of an elastic fluid. Every liquid possesses the property of boiling at a certain determinate temperature, under the mean pressure of the atmosphere. Water, for example, boils at the temperature of 212° of Fahrenheit's scale, when the pressure of the atmosphere is equal to a column of mercury 30 inches in height; but under a diminished pressure it boils at a lower temperature; and by increasing the pressure, the temperature of the boiling point is increased. In the course of ebullition an elastic fluid, or vapour, is generated; and it is only when the tension of the vapour becomes equal to the pressure that the action of boiling begins. But though ebullition and the

consequent rapid formation of vapour only take place at a given temperature under a given pressure, vapour will rise from the surfaces of all liquids in free contact with the atmosphere at much lower temperatures. Water, for example, exposed in an open vessel, undergoes a gradual diminution of bulk, and is dissipated at temperatures far below the boiling point; and ice itself soon wastes away in the same insensible manner. This dissipation has been shown by Dalton to be occasioned by the formation of vapour of the same temperature as that of the water from which it proceeds, and having an elastic force equal to that of the vapour of water boiling at that temperature under a diminished pressure. Some liquids, ether for instance, require to be carefully secluded from the atmosphere to prevent their rapid evaporation.

Tension of Vapour at different Temperatures.—Dr. Dalton of Manchester was the first who ascertained by accurate experiments the elastic force of vapours at different temperatures below that of the point of ebullition. (*Manchester Memoirs*, vol. v. 1802.) The method which he employed consisted in introducing a portion of liquid into the vacuum of a barometer, where it floats on the surface of the mercury, and part of it is immediately converted into vapour. The tension of the vapour causes the mercury to descend; and the force of the tension is measured by the space through which the mercury falls, or by the difference of the height of the mercury in the tube in which the experiment is performed and its height in the common barometer. Dr. Dalton employed two barometric tubes plunged in the same cistern of mercury; into one of these the liquid furnishing the vapour was introduced, the other serving the purpose of comparison; and in order that the experiment might be made at any determinate temperature, the two tubes were surrounded by another wider tube, into which water was poured of the temperature required. When the liquid on which the experiment was made was water, and the water surrounding the two barometric tubes was at the temperature of ebullition, the vapour formed in the tube caused the mercury to descend to the level of that in the cistern; whence it was inferred that at the temperature of ebullition the elastic force of aqueous vapour is precisely equal to the atmospheric pressure. A similar result was obtained when the experiment was performed with other liquids.

If the tube containing the portion of liquid be of considerable length, and the basin in which it is inverted of considerable depth, the pressure on the vapour above the mercury may be varied by raising or lowering the inverted tube. When the pressure is diminished in this way, it is found that so long as any liquid remains, new vapour of the same degree of tension will be generated, and the altitude of the mercury in the tube remain constant. On the other hand, an increase of pressure causes the condensation of a part of the vapour, and the mercury in the tube stands at the same height above that in the cistern. If the quantity of liquid in the barometric tube be so small that the whole is converted into vapour, it will be found that on raising the tube and increasing the space in which the vapour is contained, the elastic force diminishes in proportion as the space is increased. The law of Mariotte, therefore, applies to vapours as well as to the permanent gases (*see* PNEUMATICS); but with this distinction, that the vapours of all liquids, at a certain determinate temperature, have a maximum of density and tension which cannot be exceeded, and on attaining which they are condensed into the liquid form by any attempt to compress them further. It follows, therefore, that at a given temperature no more than a limited quantity of vapour can exist in a given space. This forms the criterion which distinguishes vapours from the permanent gases.

The results obtained by Dalton, in his experiments on the tension of aqueous vapour, are exhibited in the following table (*Manchester Memoirs*, 1802):—

Table showing the Maximum Tension of Aqueous Vapour at Temperatures below 212°, estimated in the Height of the Column of Mercury they are capable of supporting

Temperature.	Tension in Inches of Mercury.	Temperature.	Tension in Inches of Mercury.	Temperature.	Tension in Inches of Mercury.

62	0·560	137	5·29	212	30·00
67	0·655	142	6·05		
72	0·770	147	6·87		

From this table the following formula for the elastic force or tension (which is measured by the pressure p), in terms of the degrees of temperature t, reckoned from 32°, has been deduced, which nearly represents the table; namely,

$$p = \cdot 1718\,(1 + \cdot 006\,t)^7.$$

In order to determine the tension of vapour at a temperature above the boiling point, it is necessary to have recourse to a different method of experimenting. By far the most satisfactory experiments hitherto made on this subject are those of Dulong and Arago, which were undertaken at the instance of the French government, for the purpose of ascertaining the exact temperatures at which aqueous vapour acquires a given tension, with a view to establish such legislative regulations as might appear necessary to prevent accidents from the bursting of steam-boilers. As an account of these experiments, and a table of the results, have already been given under the term STEAM, (p. 1157.) it is here only necessary to remark, that the pressures or tensions were ascertained by direct experiment at different temperatures from 212° to 436° of Fahrenheit, between which they were found to vary from 1 to 24 atmospheres; and that the relation between the pressure and temperature (at least for all pressures exceeding four atmospheres) was found to be represented very nearly by the following empirical formula, viz.

$$p = (1 + 0\cdot 003974\,t)^5,$$

in which p denotes the tension or elasticity expressed in atmospheres, and t the degrees of temperature of Fahrenheit, counting from 212°.

It is evident from this empirical formula, as well as the numbers in the table, that the tension of aqueous vapour increases in a much faster ratio than the temperature. This result appears to be general, and applicable to the elastic force of the vapours of all liquids, at least so far as may be judged from the imperfect experiments which have hitherto been made on the vapours of mercury, alcohol, and ether. Dalton thought that he had discovered a law which would establish a very simple relation among the tensions of the vapours of different liquids. It consists in this, that at an equal number of degrees above or below the point of ebullition corresponding to each liquid the elastic force of their vapours is equal. Thus, water boils at 212°, alcohol at 175°, and ether at 100°, the tension of the vapour at the boiling point being in all cases the same, and equal to the pressure of the atmosphere. Now, from the experiments of Dulong it appears that the tension of aqueous vapour is doubled when heated under pressure to 251°; that is, by an increase of temperature of 39° above the boiling point. Hence, by the law of Dalton, the tension of the vapour of alcohol is equal to two atmospheres when its temperature is $175° + 39° = 214°$; and that of ether equal to two atmospheres when the temperature is $100° + 39° = 139°$. Dalton himself afterwards discovered that this law fails when the distances from the point of ebullition are considerable.

Density of Vapour.—The density of vapour may be determined by introducing a known weight of the liquid which yields it into a receiver containing mercury, and inverting the receiver in a vessel also containing mercury, and tall enough to contain, above the mercury, a sufficient depth of water to cover the receiver. The whole apparatus is then heated; and when the whole of the liquid in the inverted receiver has been evaporated, the space the vapour occupies and its temperature are noted. We have then a given bulk of vapour, the weight of which is the same as that of the liquid from which it has been produced, and consequently known. The temperature is also known; and the pressure given in terms of the column of mercury in the receiver, and the height of the surrounding fluid compared with the indication of barometer. In this manner the density is found; and when the density of a vapour at a given temperature and under a given pressure has been found, its density under any other pressure, and at its corresponding temperature, may be calculated in the following manner:—Let a = the constant coefficient of dilation = ·00208 (it being found by experiment that vapour out of contact with liquid expands or contracts at the same rate as permanently elastic fluids by variations of temperature, that is to say, by 1-480th part of its volume for each degree of Fahrenheit's scale), t = the number of degrees of Fahrenheit's thermometer above 32°, v = the volume, p = the pressure, and d = the density of a vapour at the temperature of 32°; and let v', p', and d' be respectively the volume, pressure, and density at another temperature, $32° + t$. We have then $v' = (1 + a\,t)\,v$. Now, when the pressure is constant, the density is inversely as its volume; and, by the law of Mariotte, the density of a gas or vapour is directly as the pressure; whence $\frac{d'}{d} = \frac{p'}{p} \times \frac{v}{v'}$, and consequently $\frac{d'}{d} = \frac{p'}{p\,(1 + a\,t)}$, or $d' = \frac{d\,p'}{p\,(1 + a\,t)}$.

If we compare the density of aqueous vapour at any temperature with its density at the boiling point of water, which is 180° above the freezing point, and put d'' = the density, and p'' = the pressure at the boiling point, the formula becomes $d' = \frac{d''\,p'\,(1+180\,a)}{p''\,(1+a\,t)}$. The following table, computed from this formula, with Dalton's values of the pressures, shows the density and volume of aqueous vapour, at its maximum tension, for every ninth degree of temperature from the freezing to the boiling point. The unit of density is water at the temperature of 32°; and the unit of volume the volume of an equal weight of water also at 32°. As the density is inversely proportional to the volume, the numbers in the two last columns are the reciprocals of each other. They differ slightly from the numbers given by Gay Lussac.

Temperature.	Density.	Volume.
32°	·0000053	188600
41	·0000073	137000
50	·0000097	103000

212	·0005896	1696

By means of this table the weight of water may be calculated that would be contained in the form of vapour of the maxium tension in any given volume,—a calculation which is frequently required in meteorological inquiries.

The phenomena of vapour have been studied with reference to two objects; the condition of the atmosphere as to moisture, and the properties of steam as a moving power in machinery. On the subject of vapour in connection with the first of these objects, see *Daniell's Meteorological Essays; Davy's Elements of Agricul. Chemistry:* also the terms Dew, Evaporation, Hygrometry. For experiments on the elasticity and density of aqueous vapour, see, in addition to the Memoirs of Dalton and of Arago and Dulong, already cited, *Robison's Mechanical Philosophy;* Ure, in the *Phil. Trans.* for 1818; Pouillet, *Traité de Physique;* Despretz, *Traité de Physique; Gehler's Physikalisches Worterbuch*, art. "Dampf," by Prof. Muncke; and the various recent works which treat of the steam engine. *See* Steam.

VARIABLE QUANTITY, in Analysis, is a quantity conceived to be in a state of increase or diminution, or or to have different values in the same equation. Thus, the abscissa and ordinates of a curve are variable quantities; because they have different values for every different point in the curve, and in passing from one point to another their values increase or diminish according to the law of the curve. In the equation of the circle $y = \sqrt{(2\,a\,x - x^2)}$, x and y are variables; for x may have any value whatever between 0 and 2 a, and there will be a corresponding value of y, which satisfies the equation. The quantity a is a *constant* quantity, and remains the same, whatever be the values of x and y. It represents, in fact, the radius of the circle. In mechanics, a *variable motion* is that which is produced by the action of a force which varies in intensity, or which continues to act after motion has been communicated.

VA'RIANCE. In Law, a difference of statement between two material documents in a cause; as where the plaintiff's declaration differed (formerly) from the writ, or where it differs from a deed on which it is grounded. And, in ordinary language, a departure in the oral evidence from the statement in the pleadings is termed a variance. This variance may be either immaterial or material; and, in the latter case, amendable or not, according to a great variety of distinctions. The powers of amendment given to courts and judges are greatly extended by 3 & 4 W. 4. c. 42. s. 23, 24.

VARIA'TION. (Lat. varius, *changing.*) In Music, a difference in performing the same air or melody, either by subdivision of its notes into several others of less duration, or by adding graces; but, nevertheless, in such a manner that the original melody is not lost in the decorations or alterations which it is thus made to undergo.

VARIATION OF CURVATURE, in Analytical Geometry, is the change which takes place in the curvature in passing from one point of a curve to another. The circle is the only curve in which the curvature is uniform at every point. The curvature of a curve line at any point is the same as that of the osculating circle at that point. But the curvature of a circle is inversely as its radius: hence the curvature of any curve is inversely proportional to the radius of curvature; and, consequently, the differential of the curvature is proportional directly to the differential of the radius, and inversely to the square of the radius of curvature. In the conic sections, the variation of curvature at any point is proportional to the tangent of the angle included between the diameter and normal, both passing through that point.

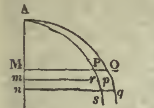
VARIATION OF THE COMPASS. The angle which the magnetic needle makes with the plane of the true meridian. It is otherwise called the *declination.* (*See* Declination of the Magnetic Needle.) For tables showing the variation of a great number of places, and its progressive, annual, and diurnal changes, see *Brewster's Treatise on Magnetism*, 1837, reprinted from the *Encyclopædia Britannica*.

VARIATION OF THE MOON. In Astronomy, an inequality of the moon's motion, depending on the angular distance of the moon from the sun. It arises from that part of the sun's disturbing force which is at right angles to the radius vector, and which accelerates the motion of the moon from the quadratures to the syzygies, and retards it from the syzygies to the quadratures. It is proportional to the sine of twice the angular distance between the sun and moon; and its maximum value, or the coefficient of its argument, is 35′ 41·9″. Hence it is represented by the formula (35′ 41·9″) sin. 2 A, A being the angular distance of the moon from the sun. The variation was discovered by Tycho Brahé. It had escaped the observation of Hipparchus and the ancient astronomers, though of sufficient magnitude to have been sensible to them; probably because they chiefly observed the moon in the syzygies and quadratures, and at these points of the orbit its value is nothing.

VARIATIONS, CALCULUS OF. An important branch of the modern mathematics, invented by Lagrange, the principal object of which is to resolve in a general manner certain classes of questions respecting *maxima* and *minima*, the solution of which cannot be obtained by the ordinary processes of the differential calculus. In solving problems of maxima and minima by the differential calculus, it is necessary to find the determinate values of the different variables which enter into a proposed finite function of those variables, in order that the proposed function may have the greatest or least value possible. Many problems of this nature are met with in the writings of the ancient geometers, particularly in the Conics of Apollonius; and the application of algebra to geometry gave rise, about the middle of the 17th century, to numerous others, proposed and solved chiefly by Fermat, Slusius, Hudde, &c. As no general method of solving such questions was known previous to the invention of the differential calculus, their solution was accomplished by particular artifices, and was frequently attained with very considerable difficulty. This difficulty was removed in respect of the class of questions now mentioned by the invention of the calculus; but as the instrument of investigation was improved, new views were opened up, and a more difficult class of questions was proposed, to which the known methods seemed inapplicable. It was proposed to find, among all curves subjected to a given law, that which best fulfilled a given condition: for example, to find the curve which, relatively to co-ordinates given in magnitude and position, encloses the greatest space; to find the curve along which a heavy body must descend in order to pass from one given point to another given point in the least time possible, &c. In such questions the relations between the variables is not given, as in the ordinary cases of maxima and minima; the object proposed is to find that relation, or to find the equation which must subsist between the variables in order that the condition of maximum or minimum may be fulfilled.

The first problem of this kind which was solved appears to have been that of the solid of least resistance. In the first edition of the *Principia*, published in 1687, Newton gave the equation of the curve by the rotation of which about its axis the solid is formed which, when moved through a fluid in the direction of the axis, is less resisted than any other body of the same specific gravity and bulk; but without demonstration or indication of the views by which he had been guided. About ten years later the famous question of the *brachystocrone*, or curve of quickest descent, was agitated between the two brothers James and John Bernoulli, in which Leibnitz and some of the other most illustrious mathematicians of the day took a part. The more general problem of *isoperimeters* was solved by James Bernoulli in 1701; and it was in the analysis which he gave on this occasion that the principle on which the solution of similar questions depends was first distinctly unfolded. Euler treated the whole subject in his peculiarly luminous manner in a treatise published in 1744, under the title *Methodus Inveniendi Lineas Curvas Maximi Minimive Proprietate Gaudentes.* And, lastly, the method was reduced to its utmost sim-

plicity by Lagrange, who supplied the algorithm and gave it the form under which it is now exhibited as the calculus of variations.



In order to give an idea of the nature and objects of this calculus, let us suppose a parabola A P referred to its rectangular co-ordinates A M $= x$, M P $= y$, and of which the parameter is a. The equation of this parabola is $y^2 = a\,x$. Now if $m\,p$ be drawn infinitely near M P, and P r parallel to the axis, the line M m or P r will represent $d\,x$, the differential of the axis x; and $r\,p$ will represent $d\,y$, the differential of the ordinate y; also the relation between those differentials is found by differentiating the equation $y^2 = a\,x$, which gives $2\,y\,d\,y = a\,d\,x$, whence $d\,y = \frac{a\,d\,x}{2\,y}$, or $d\,y = \frac{a\,d\,x}{2\sqrt{ax}}$.

Let us now suppose the parameter of the parabola also to vary, and to become $a + \delta\,a$ (the Greek letter δ being used to indicate the variation of a quantity, in the same manner as d is used to denote the ordinary differential). On constructing another parabola A Q, the parameter of which is $a + \delta\,a$, the variations which the co-ordinates undergo in consequence of this variation of the parameter will be represented as follows: — 1. Suppose the absciss A M to be the same in both parabolas. The ordinate M Q of the new parabola A Q will be equal to the ordinate M P augmented by the small quantity P Q, which, therefore, is the variation of y, and according to the notation of the calculus denoted by $\delta\,y$. In order to find the value of this variation, we must substitute $y + \delta\,y$ for y, and $a + \delta\,a$ for a in the equation $y^2 = a\,x$. This gives $(y + \delta\,y)^2 = (a + \delta\,a)x$, from which subtracting the original equation $y^2 = a\,x$, and neglecting quantities of the second order, as in the differential calculus, we get $2\,y\,\delta\,y = x\,\delta\,a$, whence $\delta\,y = \frac{x\,\delta\,a}{2\,y} = \frac{x\,\delta\,a}{2\sqrt{a\,x}}$.

2. Suppose the absciss also to vary, and to become A n. We have then M $n = \delta\,x$, and $s\,q = \delta\,y$. By substituting $x + \delta\,x$ for x, $y + \delta\,y$ for y, and $a + \delta\,a$ for a, in the original equation, it becomes $(y + \delta\,y)^2 = (a + \delta\,a)(x + \delta\,x)$; whence, by performing the multiplications indicated, subtracting the equation $y^2 = a\,x$, and neglecting quantities of the second order, we get $2\,y\,\delta\,y = a\,\delta\,x + x\,\delta\,a$, and consequently $\delta\,y = \frac{a\,\delta\,x + x\,\delta\,a}{2\,y} = \frac{a\,\delta\,x + x\,\delta\,a}{2\sqrt{a\,x}}$, for the value of the variation of y.

From this example we may see clearly the distinction between differentials and variations. The changes of the co-ordinates relative to the same curve are made by differentials; those which take place in passing from one curve to another of the same kind are made by variations. Each of the small quantities $\delta\,x$, $\delta\,y$, $\delta\,a$, is arbitrary, and we may make $\delta\,x = d\,x$; but this equality being established, we are no longer at liberty to suppose $\delta\,y = d\,y$, or $\delta\,a = d\,a$. It is also obvious that the variations of algebraic quantities are found exactly in the same manner as the differentials of those quantities; in fact, it is only necessary to substitute the characteristic δ for d, and to follow the rules of the differential calculus. This remark extends to variations of all orders, and to circular and exponential quantities.

The rules being entirely the same in both methods, it is evident that the variation of $d\,x$ is $\delta\,d\,x$, and reciprocally that the differential of $\delta\,x$ is $d\,\delta\,x$. These two quantities are also identical; for if we suppose x and x' to be two consecutive values of x, we have, by the principles of the differential calculus, $d\,x = x' - x$, whence $\delta\,d\,x = \delta\,x' - \delta\,x$. But in the same manner as x and x' are two consecutive quantities in the series of values of the variable x, so $\delta\,x$ and $\delta\,x'$ may be regarded as two consecutive values of the variable $\delta\,x$; whence $d\,\delta\,x = \delta\,x' - \delta\,x$, and consequently $\delta\,d\,x = d\,\delta\,x$.

Another principle of equal importance is, that the variation of the integral of any differential quantity is equal to the integral of the variation; that is to say, in any function P of different variables, as x, y, z, &c., and their differentials, we have $\delta\int \mathrm{P} = \int\delta\,\mathrm{P}$. To prove this let $\int \mathrm{P} = \mathrm{U}$. We have then $\mathrm{P} = d\,\mathrm{U}$ by taking the differentials; whence $\delta\,\mathrm{P} = \delta\,d\,\mathrm{U}$, and therefore, by what has been shown, $\delta\,\mathrm{P} = d\,\delta\,\mathrm{U}$. Integrating this last equation, we get $\int\delta\,\mathrm{P} = \delta\,\mathrm{U}$; whence, by restoring the value of U, $\int\delta\,\mathrm{P} = \delta\int\mathrm{P}$.

By means of these two principles we are enabled to find the variation of an indefinite integral expression $\int \mathrm{V}\,d\,x$, which, in fact, is the principal object of the method of variations. If this integral is a maximum or minimum, its variation must be made equal to nothing; and in this manner an equation is obtained which gives the required relations between the variable co-ordinates.

Lagrange, in his *Mécanique Analytique*, has founded a complete system of rational mechanics on the method of variations. The object of this important application may be understood from considering that the co-ordinates of the different points of a moving body may be used either for the purpose of comparing the positions of two different points at the same instant, or of two consecutive positions of the same point. In the former case, the only relation between the co-ordinates is that which results from the form of the surface of the body; in the latter the change of the co-ordinates is determined by the conditions of the motion, and a new variable is introduced which is the measure of the time. The co-ordinates, therefore, vary in two totally distinct modes, which it is necessary to indicate by different symbols. One of these modes becomes, in reference to the other, the calculus of variations, which, according to this view of the subject, may be described as a method of differentiating quantities conceived to vary in a particular manner, after having been already differentiated on the supposition that they vary in a different manner. See Lagrange, *Mécanique Analytique*; Id. *Leçons du Calcul.*; Lacroix, *Traité du Calcul. Diff. et Intégral*, tome ii.; Bossut, *Traité du Cal. Diff. et Integ.*; *Woodhouse on Isoperimetrical Problems*; *Airy's Mathematical Tracts*.

VARICE'LLA. *See* Chicken Pox.

VARICOCE'LE. (Lat. varix, *a distended vein*, and κήλη, *a tumour*.) A swelling of the veins of the spermatic cord.

VARI'ETY. (Lat. varietas.) In Zoology, this term is applied to individuals of the same species, which, from the operation of different causes, as age, climate, food, locality, domestication, &c., present deviations from the specific type in size, colour, form, and relative proportion of parts of the body; but have the capacity of reverting to the original typical form in successive generations, on the cessation of the influences under which the variety originated.

VARI'OLA. *See* Small Pox.

VA'RIOLITE. A porphyritic rock consisting of an imperfectly crystallized aggregate of felspar and quartz.

VARI'OLOUS. (Lat. variola, *small pox.*) In Zoology, when a part is beset with many shallow impressions like marks of the small pox.

VARIO'RUM EDITIONS. In bibliography, certain editions of the classic authors of antiquity, published chiefly in Holland, in the 17th and 18th centuries, and containing the notes of numerous commentators, are so called. These editions are chiefly valued by collectors.

VA'RIX. (Lat.) A dilatation or swelling of a vein.

VA'RNISH. (Fr. vernis.) A fluid which when spread thin upon a solid surface becomes dry, and forms a coating impervious to air and moisture. There are two kinds of varnish; namely, *spirit* and *oil varnishes:* rectified alcohol is used for the former; and for the latter fixed and volatile oils, or mixtures of the two. The solid substances dissolved in the above menstrua, and which constitute what is termed the body of the varnish, are almost exclusively resinous, and are chiefly the following: — 1. *Turpentine*, all the varieties of which are employed by the varnisher: they form an excellent body, and give strength and glossiness at a small expense; but they do not dry without other additions. 2. *Copal*, a peculiar resin, very difficult to dissolve, but forming a hard and durable ingredient. It is generally melted over a gentle fire previous to use. 3. *Lac*, which gives great toughness and hardness; but is often inadmissible, on account of its reddish brown colour. 4. *Mastic*, which yields a tough, hard, brilliant, and colourless varnish. 5. *Elemi*, a resin of a pale yellow green tint, and a valuable ingredient, on account of its toughness and durability. 6. *Sandarach*, a resin which imparts splendour, but which alone is not durable. 7. *Amber*, a valuable ingredient, on account of its hardness and durability; but difficult of transparent solution, and hence chiefly used in opaque varnishes. 8. *Benzoin*, added on account of its fragrancy. 9. *Anime*, which gives brilliancy and some scent. 10. *Gamboge*, for yellow varnishes. 11. *Dragon's blood*, for red varnish. These, together with turmeric, saffron, and annotta, are chiefly used on account of their colour, and to cover brass and copper under the name of *lacquers*. 12. *Caoutchouc*. This extraordinary vegetable product has of late been much employed in a variety of preparations used as varnishes. It is invaluable where materials are to be rendered air-tight, as balloons, for example, and where at the same time flexibility, and even elasticity, are required; but its principal application in this way is in the manufacture of various *water-proof* articles. 13. *Asphaltum*, the varieties of which are indispensable in black oil varnishes. In making spirit varnishes, the strongest alcohol of commerce should be used (of a specific gravity not exceeding 820), and its solvent power over some of the more intractable resins is sometimes improved by the addition of a little camphor; in order to prevent the agglutination of the resin, it is often requisite to mix it

with sand or pounded glass, by which the surface is much increased, and the solvent energy of the spirit facilitated. The proportions in which the several ingredients are used, and the selections for particular purposes, are infinitely various. The following are a few good varnishes, in illustration of their varieties: — 1. *Spirit varnish.* Sandarach 4 oz., seed lac 2 oz., elemi 1 oz.; digest the whole in a quart of moderately warm alcohol, and when dissolved add Venice turpentine 2 ozs. 2. *Lac varnish.* Seed lac 8 oz.; digest for four days in a warm place with a quart of alcohol, and then strain through flannel. 3. *Turpentine varnish.* Mastic 12 oz., mixed with 5 oz. of pounded glass, and digested in a quart of oil of turpentine, adding at intervals about half an ounce of camphor in small pieces. When the mastic is dissolved add to the warm fluid an ounce and a half of previously liquefied Venice turpentine, and stir the whole together. 4. *Copal varnish.* Copal which has been previously melted by a gentle heat 3 oz., oil of turpentine 20 oz. (measure): put the oil into a flask placed in boiling water, and add the powdered copal in small portions at a time, so that it may be gradually dissolved; let it stand a few days to clear, and then pour it off, and if too thick for use add to it a little warm oil of turpentine. This varnish dries slowly, but is very durable. 5. *Linseed varnish.* Melt 16 oz. of copal in an iron pot with as gentle a fire as possible, and when fused pour in 3 oz. of hot linseed oil; stir the mixture, remove it from the fire, and while yet warm gradually add a pint of warm oil of turpentine: when the whole is incorporated, strain it through a piece of linen into phials. This is a hard and durable, but also a coloured varnish. 6. *Amber varnish.* Melt 16 oz. of amber in an iron pot, then add 2 oz. of melted lac and 10 oz. of hot drying linseed oil; incorporate the whole by stirring; remove it from the fire, and before it cools add a pint of warm oil of turpentine. 7. *Black varnish.* Melt 16 oz. of amber in an iron pot, and add half a pint of hot drying linseed oil, 3 oz. of powdered rosin, and 3 oz. of powdered asphaltum; stir all together, and when removed from the fire and sufficiently cool add a pint of warm oil of turpentine. 8. *Lacquer.* Digest 3 oz. of seed lac, 1 oz. of turmeric, and 2 drs. of dragon's blood for six days in a pint of alcohol, frequently shaking the bottle, which should be kept in a warm place; strain the lacquer through linen. The above are samples of each of the principal varnishes; but every maker varies the proportions, and often the nature of the ingredients. In the preparation of varnishes, in consequence of the highly combustible nature of all the materials, the utmost care is requisite to avoid accidents by fire.

VA'RVICITE. An ore of manganese found at Hartshill in Warwickshire. It appears to be a compound of 2 equivalents of peroxide and 1 of sesquioxide of manganese with 1 of water.

VA'SCULAR SYSTEM, in Botany, is that portion of the tissue of plants which is destined for the conveyance of air. Vascular plants are those in which the vascular system occurs, or forms a principal feature. The air vessels are the tracheæ or spirals.

VASE. (Lat. vas.) In Sculpture, a vessel usually ornamented with sculpture of fruits, flowers, bassi-rilievi, &c.

VA'SES, ETRUSCAN. In Antiquities. These well-known and beautiful objects of ancient art have been discovered in great numbers, chiefly in the sepulchres of ancient Italian cities. Their material is terra cotta, and they are painted with figures and scenes. The most beautiful, and indeed the most numerous, were formerly obtained from Campania and Magna Græcia; and it was much controverted among antiquarians whether the workmanship was not originally Greek, which is maintained by Sir W. Gell. (*Topography of Rome*, vol. i.) Of late years, the great sources have been the sepulchres of Etruria Proper. Five thousand have been taken in twenty-five years from the ruins of Tarquinia alone; and it seems to be now generally admitted that the manufacture is rightly called Etruscan; that it is of extreme antiquity; that in its origin it is connected, in some way not easily explicable, with early Egyptian art; that in its progress Greek taste and style were introduced; that the art had fallen into disuse in the flourishing period of the Roman empire, which is evinced by this fact, among others, that none have been found in Pompeii or Herculaneum. "The most ancient vases are those called of the Egyptian style. They are particoloured, of red and black upon a pale yellow ground. *Black* vases, with friezes of animals and ornaments in bassi-rilievo, are also of very high antiquity. Those with *black* figures on a *red* ground come next in order; while the most modern are *black* with *red* figures: such of them, at least, as depart from the old stiff Etruscan style, and have the more natural shapes of Greek art; for example those of Magna Græcia in general, and Nola in particular." (Mrs. H. Gray, *Sepulchres of Etruria*, p. 45.)

VA'SSAL. (Derived, according to Sir F. Palgrave *on the English Commonwealth*, from the Welsh gwâs, *a young man or page;* gwasâeth, *the state of pagehood*, being rendered in Latin vassaticum.) The holder of a fief, by fealty and service, of a feudal superior or lord. (*See* FEUDAL SYSTEM.) From the Celtic origin of this word, it has been inferred that some portion of the feudal usages were derived from those of the tribes which possessed Gaul and Britain before their annexation to the Roman empire. In the ancient documents of the Carlovingian kings, the vassal is termed "vassus," or "homo fidelis;" the lord generally "senior." The term vassal was also more generally used, in common language, to signify all who were dependent on a superior lord, from those who held fiefs of him down to his serfs or villeins. (See Guizot, *Civilization en France*, vol. iv.)

VASTUS. A term applied by anatomists to two muscles of the thigh, the *external* and *internal vasti.*

VA'TICAN, the ancient palace of the popes, and the most magnificent in the world, stands at Rome on the right bank of the Tiber, and on the hill anciently called by the same name; derived, according to Aulus Gellius, from Vaticinium, or rather from an ancient oracular deity of the Latins, called by the Romans Jupiter Vaticanus, who was worshipped there. Some say that Pope Symmachus began the construction of the palace. It was inhabited by Charlemagne in 800; and the present irregular edifice has been raised by the gradual additions of a long series of pontiffs. Its extent is enormous, the number of rooms, at the lowest computation, amounting to 4422; and its riches in marbles, bronzes, and frescoes, in ancient statues and gems, and in paintings, are unequalled in the world; not to mention its library, the richest in Europe in manuscripts. The length of the museum of statues alone is computed to be a mile: here are the Sistine Chapel; the Camere of Raphael, painted by himself and his pupils; the museum of Pius VI., peculiarly rich in objects of ancient Italian workmanship; and other deposits of art and antiquity, each of which by itself would suffice to render a city illustrious.

VAU'DEVILLE. In French Poetry, a species of light song, frequently of a satirical turn, consisting of several couplets and a refrain or burden, introduced into theatrical pieces. The origin of the word is disputed; some derive it from Vau-de-Vire, a village in Normandy. Short comic pieces interspersed with such songs are also termed Vaudevilles.

VAU'DOIS. (Lat. Waldenses.) The inhabitants of some valleys in the Alps between Italy and Provence, from whence they derive their name; and who must be distinguished from the Waldenses, or followers of Peter Waldo, who acquired celebrity in the 12th century, and from whom some writers have deduced both their religious tenets and their appellation also. The Vaudois are celebrated for having maintained the purity of their doctrine for many ages before the Reformation; and it has been asserted by some theologians that the true spirit of the primitive Christianity was kept alive among them throughout the whole period of Romish corruption. This position, however, does not seem susceptible of proof. Another claim that they possess to a place in ecclesiastical history, is derived from the numerous persecutions to which they have been exposed on account of the witness they have so long borne against the erroneous doctrines of the nations by whom they are surrounded. Their extreme antiquity is certain at all events; and the numerous attempts which have been made by Romanist writers to fix on them the stigma of Manicheism seem unsupported by the evidence. For the last three centuries they have been viewed with displeasure by the dukes of Savoy and kings of Sardinia, their masters, and repeatedly visited with military execution, or more legal forms of violence. One great persecution, in the 17th century, is known to us by Milton's noble sonnet. Not long after it they were altogether expelled, and retreated into Switzerland, whence they returned by a celebrated march, and recovered their valleys by force; an event commemorated in the work of Arnaud, one of their pastors, *La Glorieuse Rentrée des Vaudois dans leurs Vallées.* At present they are by no means free from occasional vexations. Their number is about 30,000. (See *Faber on the Waldenses and Albigenses*, as to their tenets.)

VAULT. (Fr. voute; It. volta.) In Architecture, an arched roof, so contrived that the stones, bricks, or other materials whereof it is constructed, sustain and keep each other in their places. Vaults are circular and elliptical. When their section rises higher than a semicircle, they are said to be *surmounted;* when less, *surbased.*

VA'VASSOR. A word of uncertain derivation, although probably derived from the same root with vassal (gwâs, *a youth or page*, in some Celtic dialects). The vassals who held immediately of the higher nobility, under the feudal system in France, were frequently comprehended under this general name; the châtelains being such vavassaors as possessed castles or fortified houses. (See Hallam, *Middle Ages*, vol. i. p. 149.) The word, however, seems to have been of very loose application. Poor gentlemen are termed vavassors in old French romances. In England the title was not usual, although it

is mentioned in Bracton in contradistinction to baron, and sometimes appears to have designated persons who held land by military tenure of others than the king. (See *Archæologia*, vol. ii.)

VE'CTIS. (Lat. *the lever.*) In Mechanics, the same with *lever. See* LEVER.

VE'CTOR (Lat. vehere, *to carry*), or RADIUS VECTOR. In Astronomy, a straight line conceived to be drawn from the centre of a planet to the centre of the sun, by which the planet appears to be *carried* round the sun in its orbit. In geometry, the radius vector of a conic section is a straight line drawn from one of the foci to any point in the curve.

VE'DA. The name by which the Hindoos designate the collective body of their scriptures; sometimes called Vedam, Bedam, &c., according to various provincial pronunciations, by European writers. The four Vedas (Rig, Yajust, Saman, and Atharvan) are believed, according to the orthodox creed, to have been revealed by Brahma. But the subdivisions are infinite, as are also the connected works, — Upavedas, Angas, Upangas, &c.; some of which are considered by Mr. Colebrooke to constitute, according to received opinion, a fifth Veda. The arrangement is ascribed to one Vyasa, a sage of whom nothing positive can be ascertained. The Vedas chiefly consist of prayers, precepts or maxims, and stories; called respectively by different titles Thus a portion of the mythological histories are called Puranas; but these are not to be confounded with the poems of romantic mythology called by the same name. (*See* PURANAS.) The genuineness and antiquity of the Vedas have been matter of much dispute among western antiquaries. The chief chronological data are, that they were compiled before the supposed incarnation of Vishnu, as Rama and Krishna, under which titles he is now so commonly worshipped among the Hindoos; and also before the appearance of Buddha. Sir William Jones (*Asiat. Researches*, vol. ii.) gave them a conjectural antiquity of about 3000 years; and Mr. Colebrooke (Ib. vol. viii.) arrives at about the same conclusion.

VEDA'NTA. A sect among the Hindoos, whose theory of philosophy is professedly founded on the revelations contained in the Vedas. Its fundamental tenets appear to have a near connection with the opinions of Epicharmus, Plato, Pyrrho, and what is termed the Berkelian philosophy among ourselves; namely, that matter has no existence independent of mental perception; with the ordinary consequences of that doctrine, of which those practically most important are the maxims of Quietism. See, on the philosophy of the Vedas, *Ritter's History of Ancient Philosophy* (translation), vol. i. p. 66, &c.

VEER. In Naval Language, to give the ship more scope of cable. Also to let any thing drop astern by a rope. Also the old term for *to wear.*

VE'GETABLE EARTH. Soil in which decayed vegetable matter is in a much larger proportion than the primitive earths. In Horticulture, vegetable earth is called mould; and in Agriculture the term is applied to the surface soil of hollows, which contain alluvial soil beneath, and vegetable matter, generally of a black colour, on the surface.

VEGETA'TION. *See* BOTANY.

VEGETA'TION, CHEMISTRY OF. From the moment a seed begins to grow a series of chemical changes are induced, essential to the development of its germ. The process has been chiefly studied in regard to bicotyledonous plants, and a general outline of it is given under the word GERMINATION.

VE'HMIC COURTS. (Germ. vehm, or femgerichte.) Criminal courts of justice, established in Germany during the middle ages. These courts are commonly said to have originated in those held by the Missi Dominici, or imperial legates, sent by Charlemagne into the provinces of his empire; but many circumstances denote their descent from the more ancient tribunals of the German tribes, held in the open air in the primitive periods of their history. (See a curious account of the free field courts of the Germans in Sir F. Palgrave's work on the *English Commonwealth; Wigand's Femgericht Westphalens.*) But the character under which these institutions became formidable and important, about the beginning of the 13th century, arose from the disordered state of northern Germany after the dissolution of the duchy of Saxony. The Vehmic, or, as they were called, free courts, were then modelled on a secret system of organization. The president was usually a prince or count of the empire; his assistants (styled Freischöffen) were persons affiliated to the society by secret initiation, to the number, it is said, at one time of 100,000. All these were bound to attend the secret meetings of the courts when summoned, and to execute their decrees, if necessary, by taking the life of persons condemned. Westphalia, styled, in the language of the free courts, the Red Land, was the district in which their central authority was seated. These courts exercised a great power, which was occasionally serviceable in repressing the lawless violence of the nobles of that period, but which was also liable to be perverted to the gratification of private malice and tyranny. Various leagues were formed in the 15th century, by the nobles of the empire, for the purpose of destroying their influence; which was at last effected, chiefly by the introduction of a better system of public judicature and police in the several states. See also the publication of the Library of Entertaining Knowledge Society, *Secret Societies of the Middle Ages.* The romantic use of this history made by Goethe in his *Goetz von Berlichingen* is well known.

VEIL. A term used in describing fungi to denote the horizontal membrane connecting the margin of the pileus with the stipes.

VEINS. (Lat. vena.) In Anatomy, elastic tubes which convey the blood from the arteries back to the heart. *See* HEART.

VEINS, MINERAL. Cracks or fissures in rocks filled up with substances differing from the rock itself. When these are of a metallic nature, they form the chief repositories of the most useful metals, and are termed *metallic* veins: they often contain cavities lined with some of the most beautiful mineral products. Some veins are several yards wide; and they often branch off into smaller ramifications, which are gradually lost in the surrounding rock. *See* GEOLOGY.

VELE'LLA. (Diminutive of velum, *a sail.*) The name of a genus of Acalephes, characterized by a vertical crest or sail, by means of which they are wafted along the surface of the ocean.

VE'LITES. The light-armed infantry attached to a Roman legion were so called. (See *Mém de l'Ac. des Inscr.* vol. xxix.) They were equipped with bows, slings, and javelins, a light wooden buckler covered with leather, and a head-piece.

VE'LLUM. (Lat. velamen, or vitulinum.) A fine kind of parchment made of calfskin. The skins are limed, shaved, washed, and stretched in proper frames, where they are scraped with the currier's fleshing-tool, and ultimately rubbed down to a proper thickness with pumice-stone.

VELO'CE. (It. *swift.*) In Music, a term which, prefixed to a movement, indicates that it is to be performed in a rapid manner.

VELO'CIPEDE. (Lat. velox, *swift*, and pes, *foot.*) A vehicle invented at Mannheim in 1817, by M. Drais, consisting of a piece of wood about five feet long, and half a foot wide, resting on two wheels, one behind the other. On this an individual sits, as on horseback, his feet touching the ground, and thus propelling the machine. The front wheel may be turned at pleasure, so that the rider may give any direction to the machine. This species of vehicle never came into general use; but it was improved by Knight in this country, and a patent received for it.

VELO'CITY (Lat. velox, *swift*), is measured by the space which a moving body passes through in a given time. The velocity of a body is uniform when it passes through equal spaces in equal times; and variable when the spaces passed through in equal times are unequal. It is accelerated when the force by which a body is put into a state of motion continues to act after the motion has commenced; and retarded when the moving body encounters obstacles which tend to destroy the motion. Velocity is merely a relative term; for there is nothing, as Biot remarks (*Traité de Physique*, l. iii. p. 148.), which in itself is either swift or slow, any more than great or small. The velocity of a cannon ball appears very great, as it can scarcely be followed by the eye; yet it is slow in comparison of the motion of a point on the earth's equator carried round by the diurnal motion; and this, in its turn, is far inferior to the velocity of the earth in its orbit, which again is greatly exceeded by the velocity of light. (For the velocity of falling bodies, see ACCELERATION; for the velocity of a body moving in curve about a centre of force, see CENTRAL FORCES. *See also* GUNNERY, VIRTUAL VELOCITY, &c.

VELVET. A rich kind of stuff, extensively used for ladies' dresses and a variety of other purposes. Of velvet there are properly only two kinds, that with a plain, and that with a tweeled, or, as it is also called, a Genoa ground or back. When the material is silk, it is called velvet; when cotton, velveteen. The latter is a species of *fustian*, which, under a variety of names, is largely used for men's wearing apparel.

VENA CAVA. *See* HEART.

VENEE'R. In Architecture, a thin piece of material of a more valuable kind laid on another of a more common sort, by which the whole substance appears to be of the more valuable sort. Veneering is more usually applied to furniture than to strictly architectural purposes.

VENE'TIAN SCHOOL. In Painting. The distinguishing character of this school is colouring, and a consummate intellectual knowledge of chiaro-scuro; in both which all is grace, spirit, and faithful adherence to nature, so seductive as to lead the spectator away from any consideration of its defects. It is an exquisite bouquet of

well-arranged flowers; or a collection of pulpy, juicy, saccharine fruits. But it is not to be inferred that it is altogether wanting in still higher accomplishments; for the head of it was Tiziano de Vecelli; and in its ranks are to be found Tintoretto, Paul Veronese, Giorgione, and many other illustrious masters. *See* PAINTING.

VE'NIAL SIN. (Lat. venia. *forgiveness.*) In Theology, is defined, by Roman Catholic theologians, a sin which weakens sanctifying grace, but does not take it away: It is not necessary, although commendable, to mention such sin in confession. Reformed theologians altogether reject the formal distinction between venial and mortal sin.

VENI'RE FA'CIAS. In Law, a judicial writ, directed to the sheriff, to cause a jury to *come* or appear in the neighbourhood where a cause is brought to issue, to try the same. (*See* JURY.) A *venire facias de novo*, being a writ directing the sheriff to cause a jury to come and try a cause a second time, is granted where there has been a mis-trial; on the ground of irregularity, as, for instance, in summoning the jury; on the ground of misconduct by the jury; and also in certain cases where the verdict given is imperfect by reason of some ambiguity and uncertainty. The great rule of difference between a venire de novo in the latter case and a new trial is, that the former is only granted on matter appearing on the record.

VENI, SANCTE SPIRITUS. (Lat. *Come, Holy Ghost.*) The name given to a mass in the Roman Catholic church to invoke the assistance of the Holy Spirit.

VENTA'YLE, or AVENTAYLE. The visor of a helmet. *See* HELMET.

VE'NTER, (Lat.) in Entomology, signifies the lower part of the abdomen.

VENTILA'TION (Lat. ventus, *wind*) literally signifies fanning or blowing. In Domestic Economy, it is the art of conveying currents of fresh air through close apartments or confined places, so as to maintain the atmosphere in a state of purity.

Atmospheric air consists of two ingredients, oxygen and azote, blended together in the proportion of one part by measure of the former to four of the latter. When these proportions are altered, air becomes unfit for respiration; and when the oxygen is withdrawn or consumed, it is rendered altogether incapable of supporting animal life or combustion. But there are operations both of nature and art continually going forward in which the oxygen of the atmosphere is consumed, and gaseous products evolved which are destructive of life. Thus, in the act of respiration, a certain portion of the oxygen contained in the air inhaled into the lungs is converted into carbonic acid, a substance which acts as a narcotic poison; and hence, in a confined apartment, air is soon rendered, by breathing alone, not merely incapable of maintaining life, but highly destructive of it, in consequence of the evolution of a deleterious gas. In like manner, oxygen is consumed, and carbonic acid evolved, in the process of combustion; and the burning of a pan of charcoal in a close room is known to be a certain means of extinguishing life.

Although a decomposition and deterioration of air is thus continually going forward, nature has by various means provided so effectually for the restoration of the two constituent gases, that in whatever part of the world, and at whatever height in the atmosphere, air is taken, it is found, when chemically examined, to contain azote and oxygen in exactly the same proportions. *See* AIR.

Quantity of air required for Ventilation.— If the question were solely how to command a sufficient supply of fresh air, it would be easily solved; but as in our climates the temperature of the external atmosphere is in winter generally very much lower than is necessary for comfort, we have at the same time to provide for the maintenance of an artificial temperature in our apartments, by allowing the air to enter no faster than it can be warmed. One of the first points, therefore, to be considered, is the amount of the supply of fresh air which an individual requires for comfort and health. This, however, is a point on which, by reason of the great variety of circumstances concerned, it is extremely difficult to arrive at any satisfactory conclusion.

Dr. Henry estimates that an adult person makes, on the average, 20 inspirations per minute, and draws into his lungs at each inspiration 20 cubic inches of air. Peclet allows 40 cubic inches for each inspiration. Taking the mean of the two estimates, we have 600 cubic inches expired per minute. But, according to Dr. Arnott, air expelled from the lungs is found to vitiate, so as to render unfit for respiration, twelve times its own bulk of pure air; hence, the quantity of air spoiled every minute by the respiration of an adult, is 7200 cubic inches, or rather more than 4 cubic feet. Dr. Arnott, however, supposes the waste to be only half of this quantity. But there are several other causes of deterioration besides the production of carbonic acid from the lungs: the effluvia and vapour of animal matter exuded from the whole surface of the body is not less injurious than carbonic acid; and, according to M. Seguin, in a temperature of 60°, about 3½ cubic feet of air per minute is charged with animal vapour transmitted through the skin of an adult, and rendered unfit for respiration. When artificial lights are used, a further allowance must be made for the waste by combustion. Besides, air is required for various other purposes than those which have now been mentioned. It acts as a cooling power, and hence the supply requisite for comfort depends on its temperature. It likewise serves to carry off moisture from the skin, and therefore its state as to dryness or humidity must be considered. Dr. D. B. Reid found, from observations on a number of persons assembled in an experimental room, that not less than 10 cubic feet per minute should be allowed to each individual on the average, at an agreeable temperature; but that, to maintain the atmosphere in all its purity, a much larger supply would at times be desirable. On the whole, therefore, we may conclude that 10 cubic feet of fresh air per minute, for each individual, is the smallest allowance that should be made in order to ensure healthful ventilation.

Sources of Ærial Movement.—One of the most efficient means of ventilation is afforded by the action of heat. At ordinary temperatures, air suffers an expansion of about 1-500th part for each degree of Fahrenheit's thermometer by which the temperature is raised; and being rendered specifically lighter in the same proportion, the pressure of the surrounding atmosphere predominates, and the heated air is forced upwards. This principle is exemplified in the action of the ordinary chimney, which may be regarded as a tube open at both ends, and placed in any position except the horizontal. The air in the lower end of the tube, being heated by the fire, rises and passes out at the upper end, while its place is supplied by the pressure of the fluid surrounding the lower opening; and the circumstances of motion are the same as if another tube, filled with air of the original temperature, were adapted to the lower end of the chimney, which is filled with heated air, so that the current is established in the same manner as in an inverted siphon, in which two columns of air of different densities, but equal altitudes, press against each other. At the lower opening of the chimney, the draught or velocity of the current is expressed by this formula,

$$v = \sqrt{[2\,g\,h\,a\,(t' - t)]},$$

where v denotes the velocity in feet per second, g the accelerating force of gravity (= 32·2 feet per second), a the rate of expansion for one degree of increased temperature, t' the temperature of the heated air as it enters the chimney, and t that of the external air. It appears from this that the velocity of draught is as the square root of the height of the chimney, and the square root of the excess of temperature at the lower opening. But as the same quantity of air must be supposed to pass through every different section of the chimney in the same time, it follows that the velocity at every part must be inversely as the density, and, therefore, decreases from the bottom to the summit.

As the draught of a chimney depends on the difference of the temperature of the air at its lower and upper ends, it will afford a considerable power of ventilation, even when there is no fire, if the room be heated by any means (as by an assemblage of persons) above the temperature of the external atmosphere. In warm weather this may, however, be insufficient; but in this case a large shaft, communicating with the apartment at some distance, will afford, by means of a good fire, an exhausting power to any extent. This is the method by which the Houses of Parliament are at present ventilated, and the principle has been frequently applied in mines and manufactories. The impulsion of air into a chamber by mechanical means is often had recourse to in particular circumstances. In the printing-office of the Bank of England there is a ventilating apparatus consisting of a square box for a pump body, with a loose piston, and furnished with large valved openings, by means of which 1100 cubic feet of air per minute are driven through the apartments. For ventilating the holds of ships, cellars, &c., the windsail is usually applied, though sometimes a fanner is introduced for the same purpose.

The subject of ventilating is intimately connected with that of warming apartments; and the great difficulty to be overcome is, to provide for both objects at the same time. The open fire-place, so generally used for private buildings in this country, affords, beyond question, the purest and wholesomest source of heat; but it is attended with many serious defects. By far the greater part of the heat produced by the combustion passes through the chimney without contributing to warm the apartment, thus occasioning a great waste of fuel; while the air admitted into the room to supply the place of that which sustains the combustion is allowed to find its way through the imperfect fittings of the doors and windows, wherever accident leaves an aperture, under no regulation, and accordingly passes through the apartment to the fire-place, in offensive and injurious currents. Nor,

after all, is the ventilation by any means complete; for while currents of cold air are passing along a few inches or feet above the floor, they seldom rise above the level of the chimney-piece, and the air in the upper part of the room may exist in a greatly vitiated state by the products of respiration and the combustion of the lamps or candles. These evils might, indeed, be obviated to a considerable extent, and the currents in the room much diminished, by bringing an independent supply of air through tubes leading directly from the outer air to the fire-place, and provided with valves to regulate the quantity. Count Rumford recommended that the air should be conducted from the roof of the building through a pipe or canal placed in the interior of the chimney, and admitted into the apartment through a regulated ventilator in the chimney-piece. The object of placing the tube within the chimney was, that the air, in its passage through it into the room, should be warmed by the contrary current of air from the fire-place; thus economising the heat which in the ordinary arrangement is entirely lost. This suggestion has been improved upon in a great variety of ways, and the principle applied to close as well as to open stoves.

When apartments are warmed by other means than open fires, as close stoves, the circulation of hot water in tubes, heated air, &c., means should be applied to obtain ventilation entirely independent of the heating, and controlled by valves. If stoves are used, the chimney to carry off the products of combustion, and the tubes which supply the air necessary to maintain it, should have no communication with the chamber in which the stove is placed. Stoves of low combustion, like Arnott's stove, or the porcelain stoves used in the north of Europe, are the best: iron, heated to a high temperature, causes an offensive smell, and decomposes the air; besides, the air which comes in contact with it, in consequence of the temperature it acquires, rushes rapidly to the highest part of the room, and renders regulated ventilation impossible. The mild hot-water apparatus, when the pipes are suitably disposed, affords an agreeable warmth, and has this advantage — that the sources of heat not being confined to a particular part of the room, equable ventilation is rendered more easy. In rooms for public assemblies, where the air requires to be changed rapidly, greater difficulty is encountered: the best method undoubtedly is, to admit the pure air from a chamber in which it is previously heated (or cooled, as the case may require,) to the suitable temperature, and to carry off the respired and vitiated air by the shaft of a furnace.

Of late years the subject of ventilation, as connected with the public health, has engaged much attention; and a mass of useful information respecting it will be found in the recent *Parliamentary Reports*, particularly on the ventilating and acoustic arrangements of the present House of Commons, on education and manufactures, and the means of improving the health of large towns. (See *Tredgold's Principles of Warming and Ventilating Public Buildings, &c.; Arnott on Warming and Ventilation; the Monthly Chronicle*, vol. i. p. 220; *Dr. Reid's Chemistry of the Atmosphere; Encyc. Brit.* art. "Ventiation;" Peclet, *Traité de la Chaleur*.)

VENTILATOR. Any machine or contrivance for promoting or regulating ventilation. The commen ventilator placed in windows, which revolves in the same manner as a smoke-jack, in consequence of the impulsion of a current of air, serves only to retard in some degree the entrance of the current, to disperse it in different directions, and to prevent any sudden increase in the intensity of the draught. It has no power of acting so as to create a current, or keep up its intensity when it has been established.

VE'NTRICLE. (Lat. venter, *the belly*.) A term in Anatomy, applied to cavities of the brain and of the heart.

VE'NTRICOSE. In Zoology, a part is so termed when it bellies out as if filled with air.

VENTRI'LOQUIST. (Lat. venter, *the belly;* loquor, *I speak*.) One whose voice appears to come from his belly. Ventriloquists are generally supposed to have the power of making the voice appear to come from distant objects or quarters; but this is a deception, arising out of the manner in which the ventriloquist manages his voice. The art appears to consist in filling the lungs with air, and employing, during expiration, such organs of voice as can be used without the aid of the lips; or at least with as little movement of the lips, mouth, or cheeks, as is compatible with the pronunciation of certain words. By practice many individuals have acquired considerable dexterity in this art; and when certain words can be distinctly pronounced in different tones, in the way described, the imagination of the hearers easily leads them to suppose that they come from a person in a box, or up the chimney, or from inanimate objects, especially if adventitious means be resorted to to aid the illusion, as is generally the case in such exhibitions.

VENU'E. (Norm. Fr. visne; Lat. vicinetum, *neighbourhood*.) In Law. By the original institution of trial by jury, jurors were summoned from the immediate neighbourhood where a fact happened, to try it by their own knowledge. Hence, long after the institution had been altered in character, juries were still summoned in point of form from the parish, village, &c., until by 4 Ann. c. 16. they became summonable as they still are, from the body of the county. The venue, therefore, was the neighbourhood named in the venue facias, or writ summoning the jury; and the last relics of the old practice, in criminal proceedings, were abolished by 5 G. 4. c. 50. (*See* JURY.) The venue, therefore, is the county in which the action is to be tried, which is specified in all material allegations in the pleadings; and it need not be the county in which the fact took place except in what are called local actions. *See* PLEADING.

VE'NUS. In Astronomy, one of the principal planets, the second in the order of distance from the sun, and the most brilliant of all the planetary bodies. From her alternate appearance in the morning and evening, Venus was called by the Greeks *Hesperus* and *Phosphorus*, the *evening* and *morning star;* sometimes also she is called the shepherd's star.

The distance of Venus from the sun is ·7233316, that of the earth being unity; whence her true distance is about 68 millions of miles. Her sidereal revolution is performed in 224·7007869 mean solar days; and her synodical period, or the interval between her successive conjunctions with the sun, is 583·920 mean solar days. The inclination of the orbit to the ecliptic was 3° 23′ 28·6″ at the commencement of the present century, and is subject to a decrease of about 0·0455″ in a year. The eccentricity of the orbit is ·00686074, half the major axis being unity; and the longitude of the ascending node at the commencement of the present century was 74° 54′ 12·9″, having a motion westward, when referred to the fixed stars, amounting to 17·6″ in a year.

The mean apparent diameter of Venus, or her apparent diameter when at her mean distance, is 16·9″; but it is subject to great variations, being only 9·6″ at the time of her superior conjunction, and at the time of the inferior conjunction sometimes so much as 61·2″. Comparing this with her mean distance, her true diameter is ·975, that of the earth being unity; and is consequently about 7700 English miles. Her volume is therefore ·927 of that of the earth. Her mass, as compared with that of the sun, is ·0000024638.

Venus, being an inferior planet, is never seen in opposition to the sun. Her greatest elongation, or angular distance from the sun, varies from 45° to 47° 12′. According to her various positions relatively to the sun and earth, she changes her phases like the moon, appearing when she first emerges from the sun's rays and becomes visible in the morning as a fine luminous crescent, the horns of which are turned away from the sun. As the planet recedes from the sun, the breadth of the crescent increases: at the greatest elongation it becomes a semicircle; after this the breadth of the disk goes on increasing till the planet arrives at its superior conjunction, where it appears as a full orb, the illuminated side being turned towards the earth. These appearances, on account of the irradiation, are not appreciable by the naked eye, but they become visible in an ordinary telescope.

Venus is supposed to revolve about an axis; and the time of rotation is stated, from observations made by Schroeter, to be 23 h. 21 m. 7·2 sec., the axis of rotation being inclined to the ecliptic in an angle of about 75°. There is, however, considerable doubt as to the accuracy of these conclusions. On this subject Sir John Herschel remarks, that Venus, "although it attains occasionally the considerable apparent diameter of 61″, which is larger than that of any other planet, is yet the most difficult of them all to define with telescopes. The intense lustre of its illuminated part dazzles the sight, and exaggerates every imperfection of the telescope; yet we see clearly that its surface is not mottled over with permanent spots like the moon: we perceive in it neither mountains nor shadows, but a uniform brightness, in which we may, indeed, fancy obscurer portions, but can seldom or never rest fully satisfied of the fact. It is from some observations of this kind that both Venus and Mercury have been concluded to revolve on their axes in about the same time as the earth. The most natural conclusion, from the very rare appearance and want of permanence in the spots, is, that we do not see, as in the moon, the real surface of these planets, but only their atmospheres, much loaded with clouds, and which may serve to mitigate the otherwise intense glare of their sunshine." ("Astronomy," *Cabinet Cyclopædia*, p. 279.)

Venus is sometimes seen to pass over the disc of the sun, presenting a phenomenon analogous to that of a solar eclipse by the moon. This phenomenon, which is called a *transit of Venus*, can only happen when the planet is at its inferior conjunction, and, at the same time, very near one of its nodes. It is therefore of rare occurrence; but very important, inasmuch as it affords the best means astronomers possess of determining the sun's parallax, and consequently the dimensions of the planetary system. (*See* PLANET.) Delambre

has given a list of all the transits occurring in a period of 2000 years. The following contains all that have happened since 1631, and that will happen before the end of the 21st century:—

1631, Dec. 6.	1874, Dec. 8.
1639, Dec. 4.	1882, Dec. 6.
1761, June 5.	2004, June 7.
1769, June 3.	2012, June 5.

(See *Baily's Astronomical Tables and Formulæ.*)

The first transit ever seen was that of 1639, which was observed in this country by Horrox and Crabtree. The importance of the phenomenon for determining the sun's parallax was first pointed out by James Gregory in his *Optica Promota*, 1663.

VE'NUS. In Zoology, a name applied by Linnæus to a genus of *Vermes Testacea*, including those which have a bivalve shell with the frontal margin flattened, with incumbent lips; the hinge with three teeth, all of them approximate, and the lateral ones divergent at the top.

The Bivalves thus characterized enter into the Cardiacean family of the Testaceous Acephala of Cuvier, and are subdivided into the genera *Venus* proper, Lam.; *Astarte*, Sowerby; *Cytherea*, Lam.; *Capsa*, Brug.; *Petricola*, Lam.

VENUS. The Latin name of the Grecian Aphrodite ('Αφροδίτη). This goddess is generally supposed to have been of eastern origin, and to have been the same as the Phœnician Astarte. By the Grecian poets she was called the daughter of Jupiter and Dione; or, according to some accounts, arose from the foam of the sea. She was worshipped as the goddess of beauty and love, her principal seats being the islands of Cyprus and Cythera. The Romans regarded her as the progenitress of their nation, which was fabled to have sprung from Æneas, the offspring of her union with the Trojan Anchises. She was married to Vulcan; but was not remarkable for fidelity to her husband. Her amour with Adonis is particularly celebrated in ancient poetry. (See, as to her worship, *Mém. de l'Ac. des Inscr.* vol. xvi.; *Bryant's Mythology*, i. 392. iii. 157.)

VENUS URANIA, or HEAVENLY, was distinguished from Pandemos, or Popular, rather by philosophers than the multitude. The most celebrated ancient statues of Venus now existing are the Anadyomene and Medicean, both at Florence.

VERA'TRIA. An alkaline principle found in the root of the *Veratrum album*, or white hellebore; in the seeds of the *Veratrum sabadilla;* and in the bulb and seed of the *Colchicum autumnale*, or meadow saffron. It is acrid and poisonous; difficultly soluble in water, readily soluble in alcohol, and less so in ether. It excites violent sneezing, and is probably the principle upon which the efficacy of colchicum in the cure of gout depends.

VERB. (Lat. verbum, *a word.*) In Grammar, a part of speech which consists of an affirmation and a property or attribute affirmed. Verbs are distinguished into transitive, intransitive, and passive. Besides these, there is the verb substantive, which expresses simple affirmation abstracted from any particular property affirmed. *See* GRAMMAR.

VERBAL. In Grammar, a noun derived from a verb. In English verbals are commonly known by the terminations *icn, ive*, which are derived from the Latin.

VERD ANTIQUE. A beautiful mottled green marble; it is an aggregate of marble and serpentine.

VE'RDICT. In Law, the answer of a jury given to the court concerning the matter of fact in any cause committed to their trial. A special verdict is a verdict not delivered generally in behalf of either plaintiff or defendant, but stating the facts, and referring the law arising upon them to the judgment of the court. *See* JURY.

VE'RDIGRIS. A blue green pigment, originally prepared in the south of France by covering copper plates with the refuse of the grape after the expression of the juice for wine. It appears to be a mixture of the subacetates of copper, and is now largely manufactured in this country by alternating copper plates and pieces of coarse woollen cloth previously soaked in crude pyroligneous acid.

VE'RDITER. A blue pigment, generally prepared by decomposing solution of nitrate of copper by the addition of chalk. It is a hydrated percarbonate of copper.

VE'RDURER, or VERDEROR. An officer in the royal forests, whose peculiar charge was the care of the *vert: i.e.* in forest language, the trees and underwood of the forest, all vegetation sufficient to cover a deer being included in the term; which was divided, in old language, into *over vert* and *nether vert*. The verderor is sworn to keep the assizes of the forest; to view, receive, and enrol attachments and presentments, &c.

VERGE OF THE COURT. The compass of the king's court, within which is bounded the jurisdiction of the lord steward of the household. It is said to be so called from the verge, or rod of office, borne by the marshal. *See* STEWARD.

VE'RJUICE. The expressed juice of unripe or green grapes. The term is applied also to a kind of vinegar made of the juice of unripe apples.

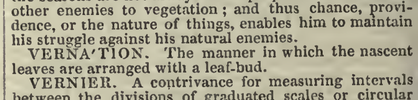
VER'MIFUGES. (Lat. vermis, *a worm*, and fugo, *I put to flight.*) Medicines used in effecting the expulsion of intestinal worms: these are sometimes merely purgatives, such as calomel, scammony, gamboge, jalap, &c. Some substances are supposed to have a specific action on the worm, such as male fern root; others act as mechanical irritants, such as the spiculæ of cowhage. The most effective vermifuge is a large dose of oil of turpentine. (*See* ANTHELMINTICS.)

VERMI'LION. Red sulphuret of mercury. *See* CINNABAR and MERCURY.

VE'RMIN. Quadrupeds, reptiles, worms, or insects, which are injurious to the cultivator. The number of these is great in every country, and calls into continual requisition the skill and vigilance of man to subdue them. In British agriculture the sheep and poultry are attacked by foxes, weasels, and other quadrupeds; the corn and other seeds and roots by rats and mice; and all plants, as well as seeds, by the weevil, the gnat, the turnip-fly, the Hessian-fly, the cockchafer, the wireworm, and numerous other insects. In gardening almost all plants are liable to the attacks of insects, seeds to those of rats and mice, and fruits to be eaten by birds. In general, the most efficient mode to subdue insects which attack plants is to invigorate their growth as much as possible by culture, because it is found that insects thrive best on plants which are in a state of incipient disease; and the next best mode to this, is the encouragement of such natural enemies to vermin as are not themselves more injurious than the creatures they prey upon. Thus birds of every kind, from the crow to the sparrow, are the natural enemies of insects; the crows seeking out and devouring the larva of the cockchafer, the beetle, and the wireworm, found at the roots of grasses; the blackbird and the thrush devouring snails, slugs, and worms; the turkey frogs, lizards, and small snakes; and the singing birds and sparrow destroying not only the larva of insects, but their eggs, and the insect in a winged state while flying through the atmosphere. Hedgehogs and weasels, while kept in outhouses and gardens, prey upon rats, mice, frogs, lizards, worms, snails, slugs, and beetles. There are some insects, such as the turnip-fly, the wheat or Hessian-fly, and the aphides or green fly, which propagate themselves very extensively, in consequence of the extensive propagation of the plants on which they feed; and these are the insects which are most injurious to the cultivator, because he cannot multiply their natural enemies in the same proportion as he multiplies the insects by cultivating on a large scale the plants on which they grow. The aphides he may destroy by the application of tobacco-water and other means; but he has little or no control over the turnip-fly or the wheat-fly. Happily for man the seasons are not always alike propitious to these and other enemies to vegetation; and thus chance, providence, or the nature of things, enables him to maintain his struggle against his natural enemies.

VERNA'TION. The manner in which the nascent leaves are arranged with a leaf-bud.

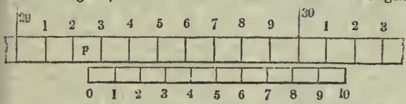
VERNIER. A contrivance for measuring intervals between the divisions of graduated scales or circular instruments. The name is given from that of the inventor, Peter Vernier, who published an account of the contrivance in a work printed at Brussels in 1631. It consists of a small moveable scale, which slides along the graduated scale; the divisions on the one scale being to those on the other in the proportion of two numbers which differ from each other by unity. The theory of the instrument, and the manner in which it is used, may be explained as follows:—Let A B $= a$ be a distance



on the scale containing n of its divisions. Let $v\,v$ be another scale equal in length to $n - 1$ of the divisions on A B; and let $v\,v$ be divided into n equal parts. Since the distance A B $= a$, and contains n equal parts, each division on the scale $= \frac{a}{n}$. Hence the length of the vernier $v\,v = a - \frac{a}{n}$; and, as it is divided into n equal parts, each division on the vernier $= \frac{1}{n}\left(a - \frac{a}{n}\right) = \frac{a}{n} - \frac{a}{n^2}$; and therefore the difference between a division on the scale and one on the vernier $= \frac{a}{n^2}$. Suppose the zero of the vernier to coincide with the division marked A

on the scale; then the first division on the vernier will not coincide with the first after A on the scale, but fall behind it by a quantity equal to their difference, or equal to $\frac{a}{n^2}$. In like manner, the next line on the vernier will fall behind the next on the scale by a quantity equal to twice the difference of the divisions, or equal to $\frac{2a}{n^2}$. The third on the vernier will fall behind the third on the scale by $\frac{3a}{n^2}$; and so on to the nth division on the vernier, which will fall behind the nth on the scale by $\frac{na}{n^2} = \frac{a}{n}$, that is, by a whole division; and therefore the nth on the vernier coincides with the division $n - 1$ on the scale. Conceive the scale to be a scale of inches, and suppose it divided into tenths; then $a = 1$ inch, $n = 10$, $\frac{a}{n} = \frac{1}{10}$th of an inch, and $\frac{a}{n^2}$ (the difference between a division on the scale and on the vernier) $= \frac{1}{100}$; so that the $\frac{1}{100}$th of an inch is exhibited on the scale, though its divisions are only to tenths.

The vernier is connected with the scale in such a way that it can be moved along it by means of a rack and pinion, or a tangent screw, or some similar contrivance, and its zero be brought to coincide with any point on the scale. If, when the vernier is thus adjusted, its zero coincides exactly with a division on the scale, the measure is read off at once; but if (as must generally happen) the zero falls between two of the divisions on the scale, then some one of the lines on the vernier will coincide, or very nearly coincide, with one of the divisions on the scale, and the distance of the zero beyond the last division on the scale, behind it is expressed in hundredths by the number of the division on the vernier which is coincident with a division on the scale. Suppose, for example, the position of the vernier with respect to the scale be as represented in the annexed figure, where the zero of the vernier is brought



to coincide with a certain point p on the scale. The point p is read on the scale 29 inches, 2-10ths, and a fraction which is to be measured by the vernier. Here the division 5 on the vernier coincides with that which is marked 7 on the scale; therefore the distance of the zero of the vernier from the last division (2) behind it on the scale is 5-100ths of an inch; for as 5 on the vernier coincides with 7 on the scale, the distance of 4 from 6 is 1-100th; of 3 from 5, 2-100ths; of 2 from 4, 3-100ths; of 1 from 3, 4-100ths; and of 0 from 2, 5-100ths. In like manner, if the vernier were pushed along till the division 8 coincided with 30 inches on the scale, then the reading of the zero point would be 29 inches 2-10ths and 8-100ths. If, when the zero is brought to coincide with p, none of the divisons on the vernier coincide exactly with a division on the scale,—for example, if the 5 on the vernier should be a little past the 7 on the scale, and the 6 not up to the 8,—the reading would be between 5-100ths and 6-100ths; but its precise amount could only be stated by estimation. If the line 5 appeared nearer 7 than 6 to 8, the distance measured would be greater than 5-100ths, or 10-200ths, but less than 11-200ths; and if the line 6 appeared nearer to 8 than 5 to 7, the distance would be greater than 11-200ths, but less than 12-200ths or 6-100ths. Thus in any case the limits of the uncertainty must be confined within a distance = 1-200th of an inch. In order that the coincidences may be observed with greater certainty, the divisions are usually read with a lens.

The vernier is equally applicable to circular scales as astronomical circles; it is then circular also, and must move concentric with the limb of the circle. Suppose the limb divided into intervals of $10'$; and let $n = 10$. We have then 10 divisions on the limb $= 100' = a$; and the length of the vernier $\left(= a - \frac{a}{n}\right) = 100' - 10' = 90'$; which, divided into 10 equal parts, gives $9'$ for the length of a division on the vernier, and consequently the difference of the length of a division on the scale and on the vernier $= 1'$. The arc, therefore, can be read to minutes. But the reading may be carried to much more minute quantities by increasing the length and the number of divisions on the vernier. Instead of embracing 9 intervals of $10'$ on the scale, let the vernier embrace 59 such intervals, and be divided into 60 equal parts. We have then $a = 10' \times 60 = 600'$, $n = 60$, $n^2 = 3600$; therefore, $\frac{a}{n^2} = \frac{600'}{3600} = \frac{1'}{6} = 10''$; that is to say, the arc may be read to $10''$.

In barometers, where a considerable degree of accuracy is required, the inch is divided into 20 equal parts; the vernier is made equal in length to 24 of these, and divided into 25 equal parts. In this case we have $a = \frac{25}{20} = 1{\cdot}25$ inch, $n = 25$; therefore $\frac{a}{n^2} = \frac{1{\cdot}25}{625} = 0{\cdot}002$; so that the vernier gives the reading to 1-500th of an inch.

Instead of making the vernier equal to $n - 1$ divisions of the scale, it is sometimes made equal to $n + 1$ divisions, and the object will still be accomplished in precisely the same manner. For in this case the length of a division on the scale being as before, $\frac{a}{n}$, and that of a division on the vernier $\frac{1}{n}\left(a + \frac{a}{n}\right) = \frac{a}{n} + \frac{a}{n^2}$, the difference is still $\frac{a}{n^2}$. The principle is the same in both cases.

The vernier is often called a *nonius*, but improperly, the contrivance invented by Nonius or Nunnez being on a quite different principle. See NONIUS.

VERRUCO'SE. (Lat. verruca, *a wart.*) In Zoology, when a surface presents several wart-like prominences.

VERSED SINE OF AN ARC, in Trigonometry, is the difference between the radius and the cosine.

VERT. (Fr. vert, *green.*) In Heraldry, one of the colours or tinctures employed in blazonry. It is equivalent to emerald among precious stones, to Venus among planets. In engraving it is represented by diagonal lines from the dexter to the sinister sides of the escutcheon.

VE'RTEBRÆ. The bones of the spine. They are divided into *true* and *false;* the former constituting the upper, and the latter the lower portion of the spinal column. The true vertebræ are further divided into those of the neck, back, and loins; or the *cervical, dorsal,* and *lumbar* vertebræ. There are seven cervical vertebræ; the first of which supports the head, and is called the *atlas;* the second is the *dentata:* it has a tooth-like process, forming a kind of pivot upon which the head rotates. The dorsal vertebræ are twelve in number, and the lumbar vertebræ five. In the neck the spine projects forwards; it is then curved backwards in the thorax, and in the loins again projects forwards. There is an elastic substance between the vertebræ, admitting of a certain degree of motion; small between the individual bones, but considerable as affects the whole column. The vertebræ, and their projections or processes, afford attachments for a number of muscles and ligaments; and the spinal marrow is lodged in the bony canal which their several perforations form.

VE'RTEBRATES, *Vertebrata.* (Lat. vertebra, *a bone of the spine.*) The name of a primary division of the animal kingdom, including those which have a cerebro-spinal nervous axis, protected by a bony cylinder composed of a succession of vertebræ, which are expanded into a cranium, where they inclose the enlarged anterior or upper portion of the nervous axis, called the brain. See ZOOLOGY.

VE'RTEX (Lat. *the top*), in Astronomy, is the point of the sphere directly over head, more frequently called the zenith. The vertex of an angle or a cone is the angular point, or that in which the sides of the angle or of the cone intersect. The vertex of a curve is the point in which the diameter meets the curve.

VE'RTICAL. Relating to vertex. *Vertical angles,* in Geometry, are the opposite angles formed by two straight lines which intersect each other. Euclid demonstrates that vertical or opposite angles are equal.

Vertical Circle, in Astronomy, a great circle of the sphere passing through the zenith and nadir. The meridian, and all azimuth circles, are vertical circles. The *prime vertical* is that particular vertical circle or azimuth which is perpendicular to the meridian, or which passes through the eastern and western points of the horizon.

Vertical Line, in Dialling, is a line perpendicular to the horizon; in the Conic Sections it signifies any line on a vertical plane which passes through the vertex of the cone.

Vertical Plane, in Conics, denotes a plane passing through the vertex, and parallel to the plane of the section.

VERTICE'LLUS, is a ring for organs of any kind placed round a stem upon the same plane. If the arrangement is not precisely so, and cannot be described by a line drawn horizontally round a stem, but consists of parts either above the line or below it, the verticellus is said to be broken. It is in English called *whorl.*

VERTI'GO. (Lat. verto, *I turn.*) Giddiness. This affection is a common symptom of fulness of the vessels of the head, and of nervous and general debility. In some it is produced by an overloaded stomach, and in others by emptiness of that organ. It is frequently symptomatic of fevers, inflammations, and other disorders, and requires peculiar treatment accordingly.

VERTIGO. In Zoology, a genus of marsh or land snails;

so named from the abrupt twist of the volutions of the shell. Several species of this genus are British; as *Vertigo secale*, *turton*, &c.

VERTU'MNUS. An Italian deity of rather obscure character. Some make him preside over merchandise, others over spring or the seasons in general.

VESA'NIÆ. (Lat. vesanus, *insane.*) A class of diseases in which the judgment is impaired without stupor or fever; it includes the various forms of insanity.

VE'SICANTS. (Lat. vesica, *a bladder.*) Substances which raise blisters upon the skin.

VE'SICLE. A small blister, or bladder-like tumour, formed by an elevation of the cuticle, and containing a serous fluid.

VESICULO'SANS, *Vesiculosa*. The name of a tribe of Tanystome Dipterous insects, comprehending those which have the abdomen in the form of a bladder.

VESPER, or HESPERUS. The evening star. A name given to the planet Venus when it is to the east of the sun, and consequently appears after sunset.

VESPERTILIO'NIDÆ. (Lat. vespertilio, *a bat.*) The name of a family of Cheiropterous Mammals, of which the genus *Vespertilio* is the type. It includes the insectivorous and bloodsucking species of the order.

VESPI'DÆ. (Lat. vespa, *a wasp.*) A family of aculeated hymenopterous insects characterized by their geniculate antennæ, composed in the males of thirteen joints, and sometimes, in this sex, hooked at the extremity. Mandibles strong and dentated; clypens large; ligula plumose or bilobed. The sting of the females and neuters long, powerful, and highly venomous. The larvæ of the wasp tribe are vermiform and without feet: those of the solitary species are inclosed separately in a cell, in which the mother deposits, with singular apparent foresight, at the same time with the egg, the bodies of insects, killed for the purpose, and upon which the larva feeds. The true wasps form large societies, composed of males, females, and neuters. A colony is commenced by a solitary female, which lays eggs that produce neuters or labourers. These proceed to enlarge the nest by detaching particles of old wood or bark, moistening and reducing them into a pultaceous mass resembling that of pasteboard, and constructing of this material a conical or subspherical comb, usually suspended by a stalk, and having on the under side ranges of vertical hexagonal cells. These are appropriated exclusively to the use of the larvæ, a cell to each, which the neuters enlarge in proportion to the growth of the occupant. The nest is generally surrounded by an envelope, pierced with a common central opening. The larvæ are nourished with the juices or pulp of fruit provided for them by the neuters; they are shut up, and spin for themselves a cocoon, when about to become nymphs.

VESTA. One of the four ultra-zodiacal planets which circulate between the orbits of Mars and Jupiter. Vesta was discovered by Dr. Olbers of Bremen, on the 29th of March, 1807. Its mean distance from the sun is 2·36787, the mean distance of the sun from the earth being unity; and its sidereal revolution is performed in 1325·7431 mean solar days. The orbit is inclined to the ecliptic in an angle of 7° 8′ 9″, and the eccentricity of its orbit is 0·08913. Vesta is supposed to be the smallest of all the celestial bodies with which we are acquainted, its volume being estimated to be only about a fifteen thousandth part of that of the earth, and its surface not to exceed that of the kingdom of Spain. On account of its smallness it is, however, difficult to determine its apparent diameter with any degree of certainty. It is distinguished from the other small planets by the vivacity of its light.

VESTA, the Hestia (Ἑστία) of the Greeks, in Classical Mythology, was a goddess about whom hangs considerable obscurity. She is called the daughter of Saturn and Rhea, and was worshipped as the patroness of the domestic and public hearth. At Rome she was attended by six virgins, called vestals, whose duty it was to preserve the sacred fire in her temple unextinguished; as the safety of the city was held to be connected with its preservation. (See *Mém. de l'Ac. des Inscr.* vol. xxvii. xxix.) According to Ovid (*Fast.* vi.),

> Vesta eadem est quæ Terra; subest vigil ignis utrique:
> Stat vi Terra suâ: vi stando Vesta vocatur.

(See Bryant, *Anc. Myth.* i. 77. 281.) The beautiful building popularly called the Temple of Vesta, at Rome, is not known to have been such.

VESTAL VIRGINS. This name was given to the six virgin priestesses of the goddess Vesta, who had charge of her temple at Rome, and the superintendence of the sacred fire, which was never to be suffered to go out. They had several privileges granted them; but the loss of their virginity was punished by burying the offender alive. Their institution is ascribed to Numa. Their abolition was one of the last victories of Christianity. (See Beugnot, *Destruction du Paganisme en Occident*, i. 164.)

VE'STIBULE. (Lat. vestibulum.) In Architecture, an area before the entrance of the Roman houses; said by some to have been so called because an altar to Vesta was placed therein. It was surrounded by a wall, and was the place in which the master of the house received his clients. It is used in modern architecture to signify an ante-hall, lobby, or porch.

VESTIBULE OF THE EAR. A small bony cavity of the internal ear, the opening of which into the cavity of the tympanum is closed by the small bone called the *stapes:* it is also connected with the cochlea and semicircular canals.

VE'STMENTS or VESTURES, ECCLESIASTICAL. Articles of dress or ornament worn by ministers in the celebration of divine service. The following were and are the principal known to the Western church, and many of them to the Eastern also:—1. The vestment properly so called, or chasuble, called in the Western churches *casula*, *planeta*, *pænula*, *amphibolum*, &c., and in the Eastern *φαινόλιον*, *phenolium*, was a garment extending from the neck nearly to the feet, closed all the way round, with only one aperture, through which the head passed. When the offices were performed, it was lifted up at the sides, while the front and back remained pendent. The Greeks retain this primitive form; the Latins have divided it at the sides. It admitted of various materials and colours. It is of very great antiquity, mentioned by Gregory of Tours, and appearing in a mosaic of A.D. 1540. 2. The cope (cappa, pallium, pluviale, &c.) similar in form to the vestment, but longer, and with a short division in the lower part of the front; and a cowl, which in modern times has given place to a sort of triangular ornament of the same shape, hanging over the shoulders. It is also of the highest antiquity in the Western church. 3. The tunicle, or dalmatica (in the East sticharion, used by deacons), received the addition of wide sleeves as early as the 4th century. 4. The alb (camisia, alba, linea; in the East poderis, from reaching the feet), a garment made of white linen. 5. The scarf, or stole, is worn by bishops with the rochet, and generally by dignitaries and prebendaries in cathedrals, and by chaplains. Its origin is obscure. It is called oradium by the Greeks. The pall (pallium, which see), generally worn by Western metropolitans, appears to have been a kind of stole, called ωμοφοριον in the East. 6. The rochet, a linen garment worn by bishops, much resembling the surplice; but in modern times, and in our church, with very wide sleeves. 7. The chimere, zimarra, cimar (probably from *χιμαρος*, *kid*), a sort of cape worn under the rochet by bishops; in modern England of black silk. 8. The pastoral staff (baculus pastoralis) was spoken of in the 4th council of Toledo, in the 7th century, as used by bishops. The form of the shepherd's crook is rather later. 9. The surplice (see that article), which only differs from the alb in having wider sleeves. 10. The hood was generally fastened to the back of the cape; called an "amice," "almatium" when lined with fur or wool. The square cap is thought to have been originally part of the amice.

Most of these vestments are noticed in the Act of Uniformity, passed in the 2d year of Ed. VI., which regulates the habits of the English church. But many of the directions are alternative; *e. g.* that a vestment or a cope, an alb or a surplice, may be used in particular instances. (See *Palmer's Origines Liturgicæ*, vol. ii. Appendix, from which this article is chiefly taken; and *Archæologia*, vol. xi.)

The extreme hostility conceived by the Calvinist and Zuinglian reformers, and the Puritan party in England, to vestments, and especially the surplice, is well known. The argument against them, as stated by Beza (*Tract. Theol.* iii. 29.), refers chiefly to the danger of wounding weak consciences, by retaining apparent relics of popery, &c. The defence by Hooker is in book v. ch. 29.

VE'STRY. (Lat. vestiarium.) The robing room attached to a church; and from hence applied to designate a meeting of parishioners for parochial purposes, the bishop and priests having in former times used these rooms when they met to consult together on similar affairs.

A *general vestry* is one to which every parishioner or outdweller assessed to or paying the church rates, or scot and lot, is admissible of common right. The minister, whether rector, vicar, or perpetual curate, is ex officio chairman of the meeting. The powers of the vestry extend to investigate and restrain the expenditure of parish funds; to determine on repairs, enlargements, ornaments, &c. of the church; and to elect certain parish officers.

Select vestries existed by custom in many large and populous parishes, especially in and round the metropolis. Originally these consisted of a number of householders annually elected by the rate-payers. But, by usage of long standing, these bodies were in many instances self-elected; *i. e.* the members of the vestry filled up by their own choice any vacancy occasioned by death or resignation.

Power has been given to parishes in which select vestries did not exist by custom to appoint such vestries

by the stat. 59 G. 3. c. 12.; and in many parishes the election of vestrymen, &c. has been regulated by local acts.

But in the first and second years of the last reign, an act was passed (1 & 2 W. 4. c. 60.) "for the better regulation of vestries, and for the appointment of auditors of accounts, in certain parishes of England and Wales." Every parish not already under a local act is empowered to decide, by a majority of the votes of its rate-payers, whether it will adopt the provisions of this statute. If adopted, a certain number of vestrymen, limited by the act according to the amount of the population, and five auditors, are to be annually elected by the rate-payers; the rector, district rectors, vicar, perpetual curate, and churchwardens, being always vestrymen ex officio. Vestrymen to be elected under this act must, in in any parish out of London and the metropolitan police district, be rated to the poor on a rental of 10*l.* a year within that district or city; if the resident householders amount to more than 3000, on a rental of not less than 40*l.* per annum. This act does not extend to parishes in which there are not more than 800 rate-payers, except in cities or towns.

VESU'VIAN. The volcanic garnet. The idocrase of Haüy.

VETCH. (Lat. vicia.) The name given to leguminous plants with herbaceous stems, often supporting themselves on surrounding objects by means of the tendrils with which their leaves are terminated. The common vetch or tare is extensively cultivated in Europe, and is considered a very valuable agricultural plant, being an excellent fodder for milch cows and working stock, &c.

VE'TERAN. (Lat. vetus, *old*.) Among the Romans, a soldier who had passed the legal age of military service, which extended from seventeen to forty-six, was termed veteranus; or, in the later times of the republic, one who had served a requisite number of campaigns, generally twenty-five.

VE'TO. (Lat. *I forbid*.) In Politics, the power enjoyed by a branch of the legislature, which cannot of itself originate or modify a law, to reject the propositions of the other branch or branches. In the Polish diet, every noble who was an independent member could prevent any resolution from passing by his simple dissent (expressed in the words "Nie pozwalam," *I do not permit*). The privilege of thus arresting the deliberations of the diet was termed the "liberum veto," and proved the fertile source of the disorders and anarchy of that country. In most constitutional monarchies the king has an absolute veto (as in France and England); in some it is only suspensive. Thus, in Norway, if three successive storthings (assemblies) repeat the same resolution, it becomes law against the will of the king. The president of the United States may return a bill, with his reasons for dissenting from it, to the house in which it originated; but if both houses pass it afterwards by a majority of two thirds in each, it is not in his power again to reject it.

VETO. An act passed by the General Assembly of the Church of Scotland, known by the name of the Veto Act. Lay-patronage, or the presentation by a lay-patron of a minister to a living in the church, has never been cordially recognised on the part of the people of Scotland. On the final establishment of Presbytery as the national church, in 1690, patronage was vested in the elders and heritors (landowners) of a parish. In 1711 (10 Anne, c. 12. s. 4.) that law was annulled, and patronage was transferred as a civil right to individuals as an accessory of land, or as a separate estate; and those patronages which had of old belonged to the pope, or to monasteries, or to archbishops, bishops, and chapters, were vested in the crown. The act of Queen Anne was never universally acceptable in Scotland. Two dissenting denominations (the United Associate Synod, and the Relief) owed their origin to the indiscreet exercise of lay-patronage; and though patrons were generally disposed, particularly within the last twenty years, to show due deference to the feelings of the people, yet hostility to this mode of nominating clergymen having gained greater force, the general assembly, in 1834, passed the Veto Act, whereby, if a majority of the male heads of families, in full communion with the church, appear before the presbytery and dissent, or lodge dissents at the meeting for "moderating in a call," the presentee was to be rejected. No specific objections were required to be made by the act, the dissentients being only required to declare, if asked, that they were actuated by no factious or malicious motive, but solely by a conscientious regard for the spiritual interests of themselves and the congregation; and if such declaration was made, their dissent was sustained; if not, it was rejected. Those entitled to dissent are ascertained from a roll annually made up. The Veto Act was first passed as an interim act; but, being referred to presbyteries, and having received the sanction of a majority of presbyteries, it was enacted into a standing law of the church by the General Assembly of 1835. (*Hill's Practice of the Judicatories of the Church*, p. 83.)

Against the provisions of this act, the minority of the assembly entered, and had recorded, both in 1834 and 1835, their solemn protest, on the ground that these provisions were not merely wrong in themselves, but also *ultra vires* on the part of the assembly, in violation of the statutes conferring on the church the privileges of an establishment, and calculated, therefore, on the first occasion on which a patron or presentee should determine to enforce his rights, to lead to a collision between the ecclesiastical and civil courts. Nor was this opinion without foundation. Immediately after the rising of the assembly of 1835, the Earl of Kinnoull, as patron of the church and parish of Auchterarder, and the Rev. Robert Young, whom his lordship had presented to that living, and whom the presbytery of Auchterarder had rejected in terms of the Veto Act, raised an action in the court of session to have it found and declared that the said presbytery had acted illegally, and to the hurt and prejudice of the pursuers, in having rejected Mr. Young; there being no other ground of such rejection, as admitted in the record of presbytery, than that a majority of the male heads of families, communicants, in the parish of Auchterarder, had dissented, without any reason assigned, from his admission as minister. In giving judgment in this action, the court of session (8th March, 1838) repelled the objections started against the jurisdiction of the civil court in the matter, and to the competency of the action, and found that the presbytery had acted illegally and to the hurt and prejudice of the pursuers, and in violation of their duty, and in particular contrary to the provisions of the statute of 10 Anne.

This decision of the court of session was appealed from by the defenders to the House of Lords; and this supreme court affirmed the judgment in question (3d May, 1839) without the alteration of a single word. Subsequently to this affirmation, when the case had been remitted to the court of session to apply the sentence, the latter tribunal pronounced in regard to it a further judgment, to the effect that the presbytery and the individual members thereof "are bound and astricted to make trial of the qualifications of the pursuer, the said Rev. Robert Young, as presentee to the church and parish of Auchterarder; and if, in their judgment, after trial and examination in common form, he is found qualified, to receive and admit him minister of the said church and parish, according to law."

The dominant party of the church had, meanwhile, come to the resolution not to obey or recognise the judgment of the court of session, though confirmed by the highest judicatory in the empire, to which themselves had made the appeal, but to declare the ecclesiastical law as supreme. Accordingly, the assembly of 1839 resolved, by a majority of forty-nine, to adhere to the Veto Act, notwithstanding the decision of the House of Lords. They maintained that the ecclesiastical and civil courts were endowed with co-ordinate powers; that their provinces were sufficiently distinct, each being supreme in its own department; and that the church courts were the sole and only judges of what was spiritual and what was civil. In short, they refused to induct Mr. Young as minister of the church and parish of Auchterarder. They regarded the parish as still vacant, and nominated a clergyman of their own sentiments to the parochial charge, *quoad spiritualia*, leaving the temporalities untouched. Thus the case still stands: but Mr. Young has raised an action of damages against the members of the presbytery of Auchterarder, both as a body and as individuals, for illegally and contumaciously depriving him of both his ecclesiastical and civil rights and privileges.

But the case of the parish of Marnoch, in the presbytery of Strathbogie, affords a still more striking illustration of the fruits of the collision that has taken place between the civil and ecclesiastical courts. The Rev. Mr. Edwards having been legally presented to that parish, and having been rejected by means of the Veto Act, a majority of the members of the said presbytery (seven in number) were disposed, in consequence of the decision in the Auchterarder case, and of the veto having been declared by the highest civil judicatory of the land as *ultra vires* of the church, to show due respect to the civil law, and to proceed with the settlement of Mr. Edwards, as if such a statute as the Veto had never existed. The majority, however, feeling the delicacy of the circumstances in which, both as clergymen, and as loyal subjects bound to obey the civil law, they were placed, did not proceed hastily to take steps towards the induction of Mr. Edwards. They remained inactive till a special decree, on the application of the presentee, had been obtained from the court of session, finding that they were bound to take him on trial, in common form, and that, if they found him qualified, to receive and admit him according to law. On their adopting the preliminary steps for the purpose, the commission of the General Assembly, 1839, suspended the seven ministers from the function of their sacred office, both judicial and ministerial. Against this proceeding the seven ministers applied to the court of session for protection; which

leugth; but the young are of such microscopic minuteness that Mr. Bauer, the naturalist, by whom this parasite has been successfully investigated, has calculated that 50,000 of them might be contained in one grain of wheat. The disease thus occasioned is commonly termed ear-cockles. Scalding water has been mentioned as the most obvious remedy for these creatures.

VIBRI'SSA (Lat. vibrissa, *a whisker*), in Mammalogy, are the stiff long-pointed bristles which grow from the upper lip and other parts of the head. In Ornithology, the term is also applied to hairs which stand forward, like feelers; or which in some birds, as the fly-catcher, point both upwards and downwards from both the upper and under sides of the mouth; or which spread out on each side like a comb from the upper sides of the mouth only, as in the goatsucker, when they are termed *vibrissæ pectinatæ*.

VI'CAR. (Lat. vicarius.) An ecclesiastical personage who has the care of a parish in the place of (vice) a lay or collegiate rector. *See* TITHES.

VICARS OF THE EMPIRE. In the German constitution, princes who had the right of representing the emperor in case of absence or interregnum. The king of the Romans, whenever there was one, was perpetual vicar. If there were none, the office was divided into two: the elector of Saxony exercised the vicariate in the two Saxon circles; the electors palatine, and of Bavaria, alternately in the remainder of the empire. They administered revenues, presented to benefices, received feudal homage, &c.

VICE-CHAMBERLAIN. An officer of the king's household immediately under the lord chamberlain.

VICEGE'RENT. (Lat. vicem gerens, *holding the place of any one*.) Any officer acting as deputy or lieutenant of another. In France the bishops appointed formerly vicegerents to the official in every ecclesiastical officiality.

VI'CEROY, or VICE-KING. A title often applied in common usage to any officer representing the supreme authority in a dependency; *e.g.* the lord lieutenant of Ireland. But it has seldom been officially given, except to the governors of certain dependencies of the old Spanish monarchy; such as Naples, Peru, and Mexico, each of whom bore the pompous title of "Alter Ego" of the sovereign.

VICTIM. (Lat. victima, of uncertain etymology; said to be from vinco, *I bind*.) The creature immolated at a sacrifice was so called among the Romans. (*See* SACRIFICE.) The well-known ceremonies of leading the victim, unbound, to the altar; pouring wine, oil, &c. on its forehead; the ceremonies of killing and burning it,—are all amply described in ancient writers. The general object of sacrifice, in all ancient religions, was expiation; but to this must be added another, peculiar to the Romans,—that of deducing auguries from the appearance of the entrails of the victim. Victims of different kinds had many designations: *bidentes*, according to some, all kinds of sheep; according to others, lambs only: *eximiæ*, animals chosen beforehand out of a flock or herd, for their beauty or other fitness, to serve for sacrifice: *prodigæ*, according to Festus, those which were entirely consumed, instead of leaving, as in the ordinary case, various parts which were consumed or sold by the priests: *succidaneæ*, those immolated in a sacred sacrifice to repair some error committed in a former one: *probatæ*, after they had been examined by the priest to ascertain their fitness. Various auguries were deduced from the demeanour of the victim: its resistance, its unusual cries, above all its flight, were unlucky. Artificial victims, made of flour, spices, &c., were sometimes sacrificed. Pythagoras seems to have introduced this custom among his disciples.

VI'CTORY. In Classical Mythology, a goddess, called by Varro the daughter of Heaven and Earth. Her altar was preserved in the curia or senate house of Rome; and its destruction was the subject of one of the latest contests between Christians and Pagans. (See Beugnot, *Destr. du Paganisme en Occident*, l. 410. 430.; *Mém. de l'Ac. des Inscr.* vol. xviii. 21.)

VIDA'ME. In French Feudal Jurisprudence, originally an officer who represented the bishop, as the viscount did the count (vice-dominus). In process of time these dignitaries erected their offices into fiefs, and became feudal nobles, such as the vidame of Chartres, Rheims, &c.; continuing to take their titles from the seat of the bishop whom they represented, although the lands held by virtue of their fiefs might be situated elsewhere.

VIDE'LICET. (More properly *scilicet*.) In Law. In pleading, it is usual to state any allegation which forms part of the facts set out, but which it is not intended to prove with precision, with the word "scilicet" (in English, "to wit") preceding it. Thus, numbers and dates, for instance, are frequently laid under a videlicet: as where any thing is alleged to have taken place heretofore, "to wit," on such a day; or where, in trespass, the plaintiff charges the defendant with carrying away or injuring divers, "to wit," so many articles, &c. The general rule on this subject is, that where an allegation is in itself material, so that the issue cannot be established without it, there the putting a videlicet before it will not dispense with the proof; but where an allegation is in itself immaterial, there (in general, but not always) the omission of a videlicet before it will render it material and make it necessary for the party so alleging it to prove it as stated. But the distinctions on this subject run, as may be supposed, into extreme minuteness.

VI'GIL. (Lat. vigilium, *watch*.) An ecclesaistical usage, the evening before a feast day, is so termed. The observation of vigils is said by some to be nearly the oldest of Christian ceremonies. According to Lactantius, Jerome, and other ancient authorities, the second advent of our Saviour was expected to take place on the vigil of Easter. They were originally celebrated by meeting together at night (as they are still on some occasions in the Eastern churches), and are said thus to preserve the memory of the nocturnal assemblies of Christians in times of persecution.

VIGNE'TTE. (Fr.) A small ornamental engraving used in printing for the illustration or decoration of a page of any work.

VIGORO'SO. (It. *vigorous*.) In Music, a term which, prefixed to a movement, denotes that it is to be performed with strength and firmness.

VI'LLA. In Roman Antiquities, originally any country dwelling, farm-house, &c., but in architectural language, the country residences of individuals of the wealthier classes were so called. Many descriptions of ancient villas are here and there scattered in the pages of classical writers; but the two most complete, undoubtedly (besides those contained in the work of Vitruvius,) are the accounts given by Pliny the younger of his Laurentine and Tuscan residences (Epist. ii. 17. and v. 6.): the first being the complete picture of a marine, and the second of an inland villa. The remains of the first are thought to have been discovered not far from Ostia, in the beginning of the last century. To these may be added the pleasing, though over ornamented poetical delineation of Statius, (*Silvæ*, lib. 3. entitled "Surrentinum Pollii," describing a magnificent residence overlooking the Bay of Naples. The most important parts of an ordinary villa were the porticoes, one or more, along the front or sides of the mansion; the triclinium or dining room: the wings forming suits of living apartments, commonly called, in the time of Pliny, diætæ; the baths, with their appurtenances, the hypocausta or vaulted heating rooms, apodyteria or dressing rooms, rooms for exercise (sphæristeria), &c. Adjacent to the main portico are generally the xystus (which see). There is a work by A. Castle on the villas of the ancients, with illustrative engravings. (fol. 1728.) The remains of several have been discovered in England. (See *Archæol.*vol. 8.; *Pictorial History of England*, i. 564.)

VI'LLAGE, or VILL. (Lat. villa, properly a *country house*.) In English Legal phraseology, a subdivision of a parish; sometimes a whole parish, and sometimes a manor. Most commonly it means the out part of a parish, consisting of a few houses separate from the rest. (See *Fleta*, l. 6.; and 1 *Inst.*) In countries where there are peasants attached to the glebe, or possessing distinct rights and obligations from other subjects, a village is properly a place inhabited by peasants only. From the Latin villa was derived the French ville, *city*, originally signifying any residence; and thence a collection of houses which gradually grew around a principal residence. Thus, especially in Normandy, ville is a common termination to the names of places, like *ton* or *by* in England; and consequently, also, of family names. The English "town" furnishes a parallel instance of the alteration of the meaning of a word produced by an increase of population, our original "towns" having been single residences or hamlets; and in Scotland, at this day, a house with its appurtenances in rural districts is sometimes called "the town."

VILLEIN, *Villenage*. In Anglo-Norman Feudal Jurisprudence, the villeins are thought to have been those who, under the Saxons, had held by the tenure known to the Saxons as "folk-land." Villeins were either "regardant," *i.e.* annexed to the manor, or "in gross," transferable from one owner to another. On the Continent, the rank of "villeins," "vilains," seems to have been from the beginning superior to that of serfs. (See Guizot, *Civilisation en France; Archæologia*, vol. ii.; The word villein is derived from the Latin villa; whence villani, *country people*. Besides the actual servile population of the Roman empire, there appears to have been a class of cultivators of the soil, who probably became greatly multiplied in the later period of the western division of that empire, known under the name of *coloni*, who were wholly or in part attached to the soil, and liable to certain fixed services to the proprietors of it, but not destitute of property or civil rights. Out of this class, augmented in process of time by the addition of numbers whom the vicissitudes of conquest, during the revolutions of the dark ages, subjected, with or without their consent, to the protection and control of masters, arose

the villein population of Europe in the middle ages. Among the causes which increased their numbers, Mr. Hallam also enumerates the fines and compositions so generally imposed in the barbarian codes of law, by default in payment of which many were reduced into this state; and the prevalent superstitions, which induced many to surrender their persons as well as their property to the control of churches and monasteries. The villeins are designated in these early codes under the general name of *lidi*, *leudcs*, &c. (leute, *people*); a name which, however, is also applied to the free vassals, or liegemen: some, who were attached to the soil of royal or church demesnes, are termed *fiscalini*, or *ecclesiastici;* and the condition of various classes appears to have been extremely different. (See Meyer, *Institutions Judiciaires*, liv. i. c. 7.) The general obligation common to all villeins was that of remaining on the lord's estate, and passing along with it by subinfeudation and alienation. The lord had also every where jurisdiction over the persons of his villeins. But in other respects there were several degrees of servitude. In England, at least from the reign of Henry II., only the inferior sort of villeins, or absolute serfs, seem to have existed. They were not only bound to the soil (*villeins regardant*), but they might also be severed from the soil and conveyed apart from it by the lord; and then became, in legal phraseology, *villeins in gross*. They were incapable of acquiring a full right to property, their *peculium* (as the Romans termed the possessions of a slave) being liable to be seized at any moment by the lord. Their tenure bound them to what were termed villein or ignoble services, indeterminate in degree. It must, however, be observed, that these villein tenures were rather attributes of the land than of the individual holding it, insomuch that lands held in villenage were frequently in the occupation of freemen; and thus, in process of time, our English copyhold tenures have been derived from those which prevailed in these lands of a villein equality. In France and Germany, where serfs of this description likewise existed, there were at the same time other classes whose servitude was of a less severe character, being bound only to fixed duties and payments in respect of their lands.

The abolition of villenage, in the greater part of Western Europe, was brought about by various causes. Among others, 1. Manumissions, which during some centuries were extremely common from religious principles, being strongly inculcated by the church; although that body is accused of not having added the force of example to its precepts, the villeins on church lands having been, in most parts, among the last emancipated. Redemption by the villein himself was also a common mode of acquiring freedom. 2. The influence of the towns, within which, when enfranchised, serfs by a certain period of residence frequently obtained their freedom. But, perhaps more generally, the process was gradual; the severest attributes of personal servitude being the first to disappear, while predial servitude, *i. e.* a liability to servile duties and payments in respect of land, existed down to a comparatively late period in most countries of Western Europe, and still exists, though much modified, in parts of Germany. In the 15th century there were, according to Machiavel, no villeins left in Italy. Predial servitude, in some rare instances, existed in England, it is believed, as late as the reign of Charles I. In France, it was not wholly abolished until the Revolution. In the greater part of the Prussian territories, the condition of the peasantry was still in some respects marked with the attributes of villenage until the reforms of Stein in the present reign. In those eastern parts of Europe in which the feudal system never prevailed (Russia and Poland), the condition of the great mass of the people is still servile, and, in some respects, lower perhaps than that of most feudal villeins. The Russian peasants are divided into those belonging to the crown, and those belonging to individuals; the former being rather more than half as many as the latter throughout the empire. The late emperor Alexander introduced some ameliorations in the condition of the crown peasants, with a view to their ultimate enfranchisement. He also planned measures for the prevention of the sale of serfs apart from the estates on which they reside. Under his superintendence, the nobility in the German provinces of Courland and Livonia abolished villenage altogether; but hitherto without much advantage in improving the state of the peasantry.

VILLO'SE. (Lat. villus, *wool*.) In Zoology, when a part is covered with soft flexible hairs thickly set.

VILLOUS. In Anatomy, this term is applied to vascular surfaces which, when minutely examined, look like the pile of velvet; as in the *villous* or internal coat of the intestinal canal.

VINA'LIA. According to Varro and Ovid (from vinum, *wine*), a festival in ancient Rome. There were two Vinalia: the first in April, sacred to Venus; the second in August, to Jupiter. The latter was considered as the beginning of the vintage season, before which new wine was not permitted to be conveyed into Rome. (See Ovid, *Fast.* l. iv.)

VI'NCULUM. (Lat. *a bond or tie.*) In Algebra, a mark or character which connects several letters or quantities, and indicates that they are to be treated as a single quantity. Vieta first used the bar or line over the quantities for a vinculum, thus, $a \times \overline{b + c}$; meaning that the quantity a is to be multiplied by the sum of the quantities b and c. This manner of connecting quantities was generally used by the early English writers on algebra; but it is now more common to make use of the parenthesis, which is a much more convenient mode of notation, especially when the expression is somewhat long. Thus, instead of writing $a \times \overline{b + c}$, or $\sqrt{x^2 + 2xy + y^2}$, it is more usual to write $a(b + c)$, $\sqrt{(x^2 + 2xy + y^2)}$. The parenthesis, which has generally been used by the foreign mathematicians, is said by Hutton to have been first used as a vinculum by Albert Girard.

VINE, in Horticulture, (*Vitis vinifera*, L.) the grape vine, is a ligneous climber, found wild in Syria and in various parts of Asia and in Greece, the fruit of which is in universal demand for the desert, either fresh, or dried as raisins, and its fermented juice forms wine, the noblest liquor that ever gladdened the heart of man. The best grapes for the table are grown under glass; but grapes are also grown of very good quality against walls and on cottages south of London, and on walls heated artificially as far north as Glasgow. Formerly the grape vine was grown in England without any protection, for the purpose of wine making; and Mr. Hoare in his interesting work on the *Cultivation of the Vine*, maintains, that with proper care, this might be done in some districts even at the present day. *See* VINEYARD.

VINE is often employed in a general sense to designate any stem which trails along the ground without rooting, or entangles itself with other plants, to which it adheres by means of its tendrils or by twining; as the cucumber and the hop.

VI'NEGAR. This term is applied to various modifications of the acetic acid. The simplest mode of obtaining vinegar is to excite a second or acetous fermentation in wine: in this case oxygen is absorbed, a variable proportion of carbonic acid is generally evolved, and the alcohol of the wine passes into acetic acid. Very good vinegar is also made from strong beer, or from a wort or infusion of malt prepared for the purpose, or from a decoction of common raisins, or from a mixture of about 1 part of brandy with 8 of water and some sugar and yeast.

When vinegar is distilled, various impurities which it contains remain in the still, and the liquid which passes over is the acetic acid, nearly pure, but largely diluted with water. In this state it is usually called *distilled vinegar*, and is used chiefly in pharmacy. But though a considerable quantity of vinegar is made in wine countries by the first-mentioned process, and here and elsewhere by the second, in which malt is employed; yet for all the purposes of the arts and manufactures, as well as for domestic consumption, the market is chiefly supplied from another source, which is the destructive distillation of wood. It has long been known that when certain kinds of dry wood, especially beech and such woods as are not resinous, instead of being burned in the open air, are converted into charcoal in close vessels, so as, in fact, to be submitted to distillation, that the vapours which pass off yield, when condensed, a large quantity of tar, and of very acid water. The latter is, in fact, an impure vinegar; that is, it owes its acidity to acetic acid, which is formed during the process out of the carbon, hydrogen, and oxygen of the wood, which elements are also those of acetic acid, and, what is remarkable, not in very different proportions. When this impure acetic acid is freed from the tar and empyreumatic oils with which it is mixed, it is called *crude pyroligneous acid*. To convert it into pure acetic acid, that is, to separate from it the empyreumatic products with which it is intimately combined, is a somewhat circuitous process, of which the following is an outline: — It is first distilled, by which *pyroxilic spirit* and *oil of tar* first pass over, and these are followed by a quantity of impure or rough acetic acid. This rough acid, which is used by dyers and calico-printers, and by makers of sugar of lead, is saturated with powdered slaked lime, and being filtered, yields a solution of impure acetate of lime, which is evaporated to dryness, and which, distilled with dilute sulphuric acid, yields a purer acetic acid than the former, but which still has a burned and disagreeable flavour; it is therefore again saturated by lime, and this liquid acetate of lime is mixed with a solution of sulphate of soda, which acting by double decomposition, yields a precipitate of sulphate of lime, and acetate of soda remains in solution. The latter salt is procured by evaporation, and purified by torrefaction and crystallization. The vinegar-makers, who purchase it, decompose it in retorts or proper stills, by means of sulphuric acid, by which a very pure and strong acetic acid passes over, sulphate of

soda remaining in the retort. The acetic acid thus obtained, which is in its most concentrated state, is extremely acrid, sour, and pungent, and is often called *radical vinegar*, or, when perfumed, *aromatic vinegar;* it is also occasionally termed *glacial* acetic acid, from its property of congealing at a low temperature, and remaining frozen at temperatures below 50°. In this state it is a compound of 1 atom of real acetic acid = 51, and 1 of water = 9; the real or anhydrous acid, as it exists in the dry acetates, being composed of—

	Atoms.	Equiv.	Per Cent.
Carbon - - -	4	24	47·06
Hydrogen - -	3	3	5·88
Oxygen - - -	3	24	47·06
	1	51	100·00

proportions which are equivalent to 4 atoms of carbon and 3 of water. When this strong acetic acid is diluted with water and slightly coloured, it forms a very pure and excellent substitute for common vinegar, and is cheaper than acid of the same strength prepared in any other way.

The combinations of acetic acid with various bases are called *acetates;* and of these salts some are importantly useful in the arts: such especially are the acetates of lead, copper, iron, and alumina, which are chiefly employed in dyeing and calico printing; the acetates of ammonia and of potash, which, as well as acetate of lead, are used in medicine; and the acetates of lime and of soda, which have been mentioned as steps in the preparation of strong acetic acid. The acetates are recognized by their solubility in water, and by the fumes of acetic acid which they evolve when acted upon by sulphuric acid. The specific gravity of the strongest liquid acetic acid is 10629; that of good malt vinegar is 10200; and that of distilled vinegar about 10023. The strength or value of vinegar, and of acetic acid, can only be learned by its saturating power.

A duty of 2*d*. per gallon is imposed upon vinegar; and the manufacture is consequently placed under the control of the excise. Previously to 1826 the duty was 4*d*. per gallon. The manufacture is chiefly confined to England, the quantity produced in Scotland and Ireland not amounting on the annual average to more than 100,000 gallons. The quantity of vinegar manufactured in England is nearly 2,700,000 gallons annually.

VINEYARD. A plantation of grape vines cultivated for the purpose of making wine. Though vineyards at present are chiefly confined to the warmer parts of the Continent, yet it appears that formerly they were occasionally to be met with in Britain, more particularly in the neighbourhood of religious establishments. Among the last vineyards which we have any account of, are one at Haffield, near Ledbury, which belonged to the celebrated Jacob Tonson; one in the Isle of Wight; another at Pain's Hill, in Surrey. The ground chosen in all these cases was a sloping surface of dry gravelly soil, with a southern aspect; and the vines were planted in rows at four feet apart every way, and trained to short stakes about four feet high. Every year the shoots were cut down to within a foot of the ground, and not more than three shoots were allowed to be matured by each plant. Each shoot produced two or three bunches of grapes, and the shoots were shortened in the course of the summer so as never to reach higher than the stakes, to which they were tied with rushes previously cut and dried for the purpose, or with twigs of willow. The kinds of grapes grown were chiefly the Burgundy or large black cluster, and the small black cluster or miller grape, so called from the white mealy appearance of the leaves. In fine seasons a tolerably good wine was produced. On the Continent, the vineyards which produce the best wine are invariably found on dry soils, more or less calcareous; and the most celebrated are on the dry sunny sides of granitic or calcareous hills, with the surface formed into terraces, like the steps of stairs on a large scale; each step or terrace being supported on the lower side by a stone wall, to which the vines planted at the base of the wall are sometimes attached, not by nails, as wall trees are in Britain, but by hooked sticks driven into the interstices between the stones, such walls being for the most part built without mortar. In France and the south of Germany, vines are seldom allowed to grow higher than four feet; and they are cut down every year, after the crop has been gathered and the leaves dropped, to within one or two feet of the ground. In the neighbourhood of Stuttgard, and between that city and Heidelberg, where the sides of the hills are covered with vineyards, the shoots are not cut down before winter; but those of each stool or plant are bent down to the ground, where they are tied together with a straw band, and retained in that position by laying a stone on the bundle. This is for the purpose of preserving the vines from the extreme cold of winter; the shoots, when so laid prostrate, being soon covered with snow. In spring, the shoots are raised up again, pruned, and tied to stakes. In the north of Italy, and chiefly in the plains of Lombardy, the vineyards are managed much in the same manner as they are in France; but in Tuscany, the Papal States, and Naples, the vineyards are interspersed with mulberry trees, which are kept pollarded; and to these the vines are attached, partly by ties of willow and partly by their tendrils, and they produce bunches of grapes to the height of six or eight feet from the ground. Sometimes the shoots are trained to elms, mulberry trees, or poplars, in which case they produce grapes to a much greater height. The only plantation of vines in the manner of a vineyard, which we know of in England at present, is a small one at White Knights, near Reading; where, however, the plants for several years past have been in a state of utter neglect, the leaves and young shoots being injured or totally destroyed by rabbits. The ground which was occupied by the vineyard at Pain's Hill is now covered with a plantation of pine trees, among which some of the vines still continue to spring up. The vineyard in the Isle of Wight has long since been laid down in pasture. In the early part of the last century there were several small vineyards in the neighbourhood of London: the situation of one at Hammersmith still bears the name of the Vineyard, and is now occupied as a nursery. But the most celebrated of the London vineyards appears to have been one cultivated by Richard Warner, at Rotherhithe, who is supposed to have introduced the Hamburg grape. There was a vineyard in the neighbourhood of Gloucester cathedral; one at St. Alban's; and one at Canterbury, the ground occupied by which is now cultivated as a nursery, by Mr. Masters of that city.

VIOL, or VOYOL. In Naval language, a purchase used occasionally in weighing the anchor.

VIOLA. (It.) In Music, a musical instrument of the same form and with the same number of strings as a violin, and, like it, played with a bow. The English call it the tenor violin.

VIOLA'CEÆ (*Viola*), are Polypetalous Exogens, well represented by the sweet violet of our woods, and distinguished by having five membranous anthers adhering to each other round a superior ovary, with parietal placentæ. The heartsease or pansy is a kind of violet, and there is a large number of other species in different parts of the world. An emetic property resides in their roots, and renders some of them useful medicinal agents as substitutes for ipecacuanha.

VIOLI'NO. (It.) In Music, a musical instrument, vulgarly called a fiddle, mounted with four strings, and played with a bow. It consists of three parts, — the neck, the table, and the sounding board; at the side are two apertures in the shape of *S s*. On it is a bridge, which bears the strings up from the belly, over which they pass from one extremity, called the tail-piece, to the other near the head, where they are received by turning pins, which tighten or loosen them at pleasure.

VIOLONCE'LLO. (It.) In Music, a bass violin with four strings, whose principles of construction are the same as those of that instrument.

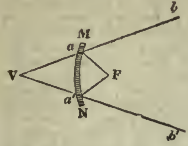
VIOLO'NE. (It.) In Music, a large bass violin, commonly called a *double bass;* seldom played with more than three strings, which lie an octave below the violoncello.

VI'PER. (Lat. a contraction of Vivipar; from vivus, *alive*, and paro, *I bring forth.*) The common name of a genus of venomous serpents which produce living young, and have a head broader than the neck, and no pits behind the nostrils. The true vipers (*Vipera*) are distinguished by the head being covered with scales, like those on the back, and by the nostrils being very large. The horned viper of North Africa and the puff adder of South Africa belong to this group. The adders (*Berus*) have the head covered with granular scales, with larger ones intermixed in some species, and have the nostrils of moderate size. The black adder and the common adder (*Berus chersea*), which are the only indigenous venomous reptiles of Great Britain, are examples of this group.

VIRGI'LIAN HUSBANDRY. That kind of agriculture which was practised by the Romans, and which is described in the *Georgics* of Virgil; or, in other words, the old mode of managing arable land throughout Europe. By this system two or three corn crops were taken in succession, and the land afterwards allowed to lie fallow for several years, when it was broken up again; being sometimes prepared by paring and burning. The Virgilian and Roman practice is fully described in *Dickson's Agriculture of the Ancients*. The first departure from this kind of husbandry in Britain was made by Jethro Tull in the middle of the last century, whose plan it was to keep arable land continually under crops cultivated in rows, and alternately growing corn and pulse, or plants cultivated for their leaves or roots.

VIRGO (the Virgin). In Astronomy, one of the twelve zodiacal constellations, or signs, being the sixth in order, beginning with Aries. Virgo is usually represented with an ear of corn in her hand, and is hence called *Signum Cereris*. The sun enters this sign about the 22d of August. The constellation Virgo contains one bright star of the first magnitude, called *Spica Virginis*.

VIRTUAL FOCUS, in Optics, is the point from which rays, having been rendered divergent by reflection or refraction, appear to issue. Thus, let M N be a metallic speculum, F a radiating point, F a, F a' rays falling on the speculum at a and a', and reflected into the directions $a\,b$ and $a'\,b'$; then the point V, in the concourse of the straight lines $a\,b$ and $a'\,b'$, is called the *virtual focus* of the reflected rays. *See* REFLEXION.

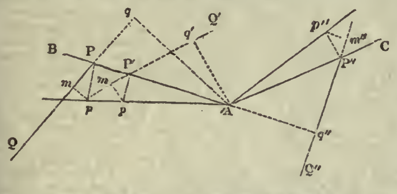


VIRTUAL VELOCITY, in Mechanics, is the velocity which a body in equilibrium would actually acquire during the first instant of its motion in case of the equilibrium being disturbed.

The general principles on which the laws of equilibrium in machines are established may be reduced to three; namely, the principle of the *lever*, the principle of the *composition of forces*, and the principle of *virtual velocities*. The last consists in this, that forces are in equilibrium when they are in the inverse ratio of the virtual velocities of the points to which they are applied, estimated in the direction in which they respectively act. Thus, let F and F' be two forces applied to the points p and p' of a body which is in equilibrium between their joint actions, and let s and s' be the spaces which the points p and p' would describe in the first instant of time, in case of the equilibrium being disturbed; then $F : F' :: s' : s$, or $Fs = F's'$. The principle is thus enunciated generally by Lagrange (*Mec. Analytique*, p. 22.): —

"If any system of bodies or material points, urged each by any forces whatever, be in equilibrium, and there be given to the system any small motion, by virtue of which each point describes an infinitely small space, which space will represent the virtual velocity of the point; then the sum of the forces, multiplied each by the space which the point to which it is applied describes in the direction of that force, will be always equal to zero or nothing, regarding as positive the small spaces described in the direction of the forces, and as negative those described in the opposite direction."

In order to illustrate this principle, we may take as an example the case of the bent lever. Let P, P′, P″ be



the points of application of the three forces F, F′, F″, acting on the lever B A C, in the directions P Q, P′ Q′, P″ Q″, which are all supposed to be comprised in the same plane. Suppose the lever to describe an infinitely small angle about the fulcrum A, so that the points P, P′, P″ come into the positions p, p', p''. According to the definition given above, the infinitely small arcs Pp, $P'p'$, $P''p''$, which may be considered as straight lines, will be the virtual velocities of the points of application P, P′, P″, of the three forces F, F′, F″. From the points p, p', p'', let there be drawn pm, $p'm'$, $p''m''$ respectively perpendicular to the lines P Q, P′ Q′, P″ Q″; then P m will be the virtual velocity of the point P reduced to the direction P Q of the force F, and P′ m', P″ m'' will in like manner represent the virtual velocities of the points P′ and P″ reduced to the directions in which the forces F′ and F″ respectively act. Let $Pm = s$, $P'm' = s'$, and $P''m'' = s''$; and as the force F acting in the direction P Q tends to turn the lever in the direction in which the motion has been supposed to take place, while F′ and F″ tend to turn it in the contrary direction, the space s must be regarded as positive, and s' and s'' as negative.

Now, according to the principle of virtual velocities, the sum of the given forces, each multiplied by the velocity of its point of application reduced to the direction of that force, is zero in the case of equilibrium; and, reciprocally, when this sum is zero the system is in equilibrium; hence the equation of the equilibrium of the lever is

$$Fs + F's' + F''s'' = 0.$$

It is easy to verify this equation by showing that it may be derived from the equation of equilibrium deduced from the principle of the lever. From A let A q, A q', A q'', be drawn respectively perpendicular to the directions P Q, P′ Q′, P″ Q″, and let the angle $PAp = \theta$; then, since the angle A P p may be regarded as a right angle, $m\,Pp = PA\,q$; whence the two triangles m P p q A P are similar, and $mP : Aq :: Pp : PA ::$ tan. $\theta : 1$; therefore $m\ P = A\,q$ tan. θ, that is, $s = A\,q$ tan. θ. In like manner we have $s' = A\,q'$ tan. θ, $s'' = A\,q''$ tan. θ; whence, by substituting in the above equation, and leaving out the common multiplier tan. θ, we find

$$F \cdot Aq + F' \cdot Aq' + F'' \cdot Aq'' = 0,$$

which is the well-known equation of equilibrium. *See* STATICS.

The equation $Fs + F's' + F''s'' = 0$ may be extended to a solid body of any form, or to any machine whatever. Let dm be an element of the body, F an accelerating force applied to dm, v the velocity of that element, z the angle comprised between the direction of the force F and that in which the element dm moves; then the moving force of the element will be $F\,dm$, and v cos. z its velocity estimated in the direction of this force; and consequently, by the principle of virtual velocities, the equation of equilibrium will be $\int F\,v \text{ cos. } z\,dm = 0$.

The principle of virtual velocities is easily verified by experiment with respect to all the simple machines; namely, the lever, the pulley, the wheel and axle, the inclined plane, and the screw. Its importance as a fundamental principle in rational mechanics was first recognized by John Bernoulli (see the *Nouvelle Mécanique* of Varignon, tom. ii.); and Lagrange has derived from it the whole theories of statics and dynamics in his celebrated work, the *Mécanique Analytique*. Fourier (*Journal de l'Ecole Polytechnique*, cahier v.) has demonstrated the principle from the property of the lever.

VIRTUE, in Moral Philosophy, is employed both in an abstract and comprehensive sense, to signify the law or laws in which right conduct consists, and also concretely for that quality of actions and persons which arises from their agreement with the rules of morality. By theories of virtue are understood the different explanations which have been given, both of that which distinguishes right from wrong, and of the nature of the feelings with which virtue and vice are contemplated by mankind. The distinction of these two questions, so frequently confounded by ethical writers, is due to Adam Smith, but has since been strongly insisted upon by Mackintosh and Hampden. The former question Mackintosh entitles "The Inquiry into the Criterion of Morality in Action," and the latter, "The Theory of Moral Sentiments;" whereas Smith and Hampden designate the former as "the Inquiry into the Nature of Virtue," and apply the term *criterion of virtue* to the principle of approbation. In the use of the phrase "Theory of Moral Sentiments," the last two writers again are at issue: Smith understands by it moral philosophy in general, while Hampden limits it to a division only of ethical inquiry. According to the latter, it comprises the two investigations already specified: that into the nature, and that into the criterion, of virtue. It constitutes the *subjective* branch of ethics, and arises from a consideration of man in himself as the *subject* of moral action, while the objective branch results from a regard to the end or object to which the moral nature of man has reference. This speculation into the final cause of man's capacity for virtue and happiness, Hampden considers to be the complement of ethics, and entitles it *the theory of natural religion*. Lastly, he defines ethics thus understood to be the science of *what ought to be*, as distinct from the science of *what is;* or of moral facts, as they are exhibited in life, or as they may be gleaned from the philosophy of history, and the study of the intellectual arts, which are based upon an appeal to the actual moral nature of man. These two together make up the whole domain of moral philosophy. (*Hampden's Lectures on Moral Philosophy.*)

The several theories of virtue are conveniently divided into ancient and modern. The distinction, however, is not founded on any essential difference of theory, but rather on the opposite points of view from which they respectively viewed the moral facts. While modern theories are permanently subjective, the objective question is the characteristic feature of ancient ethics. The leading speculation of the former is: what is the origin and nature of moral obligation? The first problem of the latter was to determine the object or end to which the moral constitution of man has reference, and this ultimate end of human activity they usually denominated the end or sovereign good (τελος, *finis bonorum, summum bonum*). And although the consideration of this question might tend in a few, as in Socrates and Plato, to carry the mind forward to some higher and ulterior existence, in which should be realised that entire satisfaction after which man aspires, still, as these promptings of natural religion were but vague and unauthoritative, the ethical writers of antiquity confined their views to this life alone, and the sovereign good which they proposed as the final cause of moral action was limited to the greatest good attainable in the present state of existence.

With Socrates, the first object of speculation was to

acquire a knowledge of man's true and proper nature; but this self-knowledge he held to be impossible so long as man continues ignorant of the universal principle. Now the nature of God can only be learned from his works, and these bespeak him to be good and intelligent. Moreover the consciousness of man attests his participation in the divine essence; consequently the ultimate destination of man is reason and goodness, and his moral end is the cognition and practice of good. Virtue, therefore, is the intelligent performance of duties, whose notions man may arrive at by a study both of his own nature and of the laws of an all-wise Creator discoverable in the system of the universe. In this pursuit happiness is inseparable from virtue. But if Socrates thus founded morality on a disinterested principle, he reconciled it with interest rightly understood; and on the other hand raised political science above the mere calculation of utility, by identifying it with justice as founded not on convention (*δογμα πολεως*), but on natural right, or the invention of what is (*του οντος εξευρεσις*).

Socrates having thus referred the laws of morality to the Deity as their author and upholder, Plato proceeded by a definition of the divine nature to guard against the objection of their arbitrary position by the will of God. He made the Deity to be the perfection of intelligence as resulting from an union of the good, the beautiful, and the true, which are in their nature eternal, necessary, and immutable. This perfection is also the term to which man spontaneously tends. For reason is the true principle of his nature, although in the present existence there is mingled with it a foreign element — *matter*, which, by obstructing its development, becomes the cause of his falling short of perfection. All, then, that is now possible for man is an approach to the divine excellence. This is virtue, and is effected by the harmony of the *rational*, *irascible*, and *concupiscible* parts of the soul. Although the two latter belong to the foreign element in man's nature, they are yet indispensable to the moral act: for the third affords a motive to action, inasmuch as beauty, being identical with the good and true, gives rise to desire or love (*ερως*), and thereby impels to virtuous action; while the second, disapproving what is base, and ugly, and false, furnishes the fortitude requisite for attaining to what is approved under every difficulty and every discouragement. To each of the three parts of the soul Plato assigns a special virtue, in a lower sense, and names them, respectively, *prudence*, *fortitude*, and *temperance* (*φρονησις, ανδρεια, σωφροσυνη*), while in a proper sense he declares virtue to be eminently one and the same with justice (*δικαιοσυνη*). These four are the so-called cardinal virtues. From the notion of justice he draws the connection of ethics and politics: the latter is but an application of the former to society. At the close of the republic he teaches that as an individual cannot be at peace with himself except by the harmonious adjustment of all his faculties, wherein each is allowed its due weight, so in the whole world happiness is proportionate to justice, and each individual derives the greater benefit from the community the more complete the harmony is in which he lives with all his fellow citizens.

Essentially agreeing, the ethical systems of Plato and Aristotle are chiefly distinguished by the relative value which they respectively ascribe to happiness; the former considering it as the natural fruit of virtue, while the latter rather viewed virtue as the means of attaining to happiness. Plato taught, that although the just man regulates his conduct by no reference to his own enjoyment, yet pleasure invariably attends him, since justice is good not only in itself, but also in its effects, and renders all things fitting and friendly to man. In Aristotle's opinion, the end of morality is to render individuals as useful as possible to society; the objects of whose institution is to procure in its members the highest moral perfection, as necessary to the attainment of the greatest possible felicity by the whole. Man, he teaches, is a free and rational agent, and therefore acts spontaneously and deliberately, invariably proposing to himself some end as the motive to action. All human arts and pursuits, then, have their appropriate ends; but among these there is a certain subordination, which implies a supreme end towards which they all converge; it being desirable not for its own sake, but the cause for which all else is sought. This supreme good is perfection: virtue is the approximation thereto, and consists in the habit of mediocrity according to right reason; in other words, it is self-control, which triumphs alike over the impetuosity of the passions and the weakness of the will, and thereby accomplishes a just mean. Every special virtue, in like manner, lies in a kind of middle between the two opposite vices of too much and too little: courage, for instance, being a mean between cowardice and rashness, of which the former offends by an excessive, the latter by a defective, regard to the proper objects of fear.

According to the Stoics, the supreme good which is the final cause of every special good is to act conformably to nature; *i. e.* in obedience to the immutable laws which reason discovers in the universe. This eternal and universal order, which they called *fate*, is an infinite enchainment of causes and effects, in virtue of which whatever happens is what ought to be: it embraces all living things, and man therefore has a principle within him which obliges him to seek that state of his nature which is the best and most perfect that it is capable of. This is reason. Wisdom, therefore, is man's chief good, and the pursuit of it is philosophy. Perfect wisdom, however, as modelled in the sage of the Stoics, they did not believe to be conceded to mortals, to whom nothing more is granted than to be in *the way to* perfection. Now, as they made reason to be the supreme arbiter in moral determinations, they naturally held vice to be but an error: yet this error, they taught, is the only evil; and, on the other hand, nothing is good but what is such in all times and all circumstances: all else is morally indifferent. But even indifferent things are, in a lower sense, agreeable to nature, and objects more or less of choice or aversion. That perfect rectitude of conduct, therefore, which constitutes the essence of virtue, consists in a just and accurate discernment of good, and in assigning to every object its due importance according to the place it holds in the natural scale of things. Lastly, although their first object was to emancipate the moral man from all dependence on external conditions and from the slavery of his passion, — and although, therefore, they removed all sensuous pleasures and pains from the catalogue of good and evil, — nevertheless the apathy which they taught was not, as commonly understood, an absolute insensibility, but rather the undisturbed supremacy of reason over the passions.

All the preceding theories agree in making reason the end of human activity, and are thereby distinguished from the Epicurean, which gave the first place to the sensuous element of humanity, and reduced science to the rank of a mean. According to Epicurus, pleasure alone is sought for its own sake, and philosophy and all else is but the pursuit of it. If, sometimes, it seems to be foregone, it is only with a view to some higher gratification, as pain also may occasionally be endured in the acquisition of a pleasure whose intensity will fully compensate for the intermediate suffering. The pleasures and pains that are primarily the objects of desire and aversion are corporeal, and from these the pleasures of the mind are ultimately derived, and consist merely in the anticipation of future and in the recollection of past states. This, however, constitutes the superiority of the secondary pleasures of the mind over their corporeal originals, for the latter do not extend beyond the present sensation. *Virtue*, therefore, is an enlightened pursuit of pleasure, which, although it is selfish in its principle, still allows free course to the social and benevolent affections, as being a part of man's nature and an additional source of gratification beyond the calculations of personal interest. For though they may expose a man to the chance of pain, as in the case of the death of a friend, still this is a less evil than apathy, and the deprivation of a natural enjoyment. Justice, lastly, has no other object than the general good; and right, properly understood, is but the sign of utility.

Modern ethics having taken their rise from a system greatly resembling the Epicurean, the inquiry into the nature of virtue became the first question that was proposed for solution. Accordingly this fact furnishes a general classification of the later theories of morals into selfish or disinterested, according as they found virtue on a selfish or on a benevolent principle.

The selfish theory has found its ablest advocates in Hobbes, Helvetius, Paley, and Bentham. Of these the first and last deserve a particular notice: Hobbes as the originator of the controversy into the nature of morality; Bentham as furnishing the most complete and elaborate exposition of the utilitarian scheme. According to Hobbes (born 1588, died 1679), the only motive that can induce men to any act is the pleasure which will follow from its execution. A preconception of pleasure is the necessary condition of every moral determination. Good and evil are simple tendencies to pleasure and pain, without which every object is indifferent. Self-love is the exclusive passion of man's nature. Other passions differ from it outwardly only, *i. e.* in the objects which excite them: pity, for example, is but the imagination of misfortunes which may happen to ourselves, suggested by the contemplation of another's sufferings; love, the conception of advantages to be derived from its object; and benevolence, nothing more than the consciousness of power sufficient to secure not only one's own happiness, but that of others also. The first law of nature is self-preservation: whatever tends, therefore, to this end is lawful and good, and all men have a natural right to appropriate by every means in their power whatever may contribute to their personal happiness. As this is the imprescriptible right of all, there are as many forms of natural right as there are separate and independent wills; and actions of the most opposite kinds are equally virtuous and legitimate. Now, as all possess an equal right to all things, and as there is no reason why one

should yield to another the objects which both may desire, the state of nature must be one of war; but as, in such a condition of things, the safety of every one is constantly endangered by the conflicting interests of all others, peace, at any price, becomes preferable to it. Peace, however, is the result of society alone; *i. e.* as defined by Hobbes, of the existence within a community of a sufficient force to control all individual wills and forces. But this is only practicable in two ways: either all are seized with a desire to terminate the state of hostility, and enter into a mutual compact, by which they engage to do no violence, nor to suffer it to be done to each other; or a single person succeeds by stratagem or force in establishing his own authority over the rest. The latter form of society is as legitimate as the former; and indeed, as the end of the institution is the suppression of warfare among its members, and as the more unlimited the power is the better calculated it must be to effect this object, an absolute monarchy is the very best polity that can be devised. Against the government in such a society, it is evident that subjects cannot consistently possess any rights; for these would impede its effectiveness: they have but one simple duty, and that is — implicit obedience. (*On Human Nature; Leviathan, &c.*)

Bentham (born 1748, died 1832), sets out from Hobbes' principle, that every object would be perfectly indifferent but for its fitness to produce pleasure or pain, which, he declares, are the sole motives of human determinations. This proposition he does not attempt to prove, but, asserting that it is one of those primary and self-evident truths which are the foundation of all reasoning, he proceeds to draw from it certain practical conclusions in the form of definitions. Thus he defines utility to be the fitness of actions and things to augment the happiness, or to diminish the misery, of individuals and communities; and maintains that this is the only true and intelligible interpretation of what is usually called the lawfulness, goodness, justice, and morality of an action. The principle of utility is next defined to be that which exclusively derives the quality of actions from their twofold property of augmenting the happiness or misery of one or many. This, he asserts, is the only valid principle of moral appreciation; and he reduces all opposing theories to two classes, which he designates by the principle of asceticism, and the principle of sympathy and antipathy. Under the latter head, Bentham comprises every theory of morals which draws the distinction of good and evil from any other principle than a consideration of consequences; whereas he explains the ascetical principle as agreeing with the utilitarian in drawing its qualification of objects from their tendency to produce pleasure or pain, but as differing from it in that it proceeds in an inverse manner, and calls pain good, but pleasure an evil. To forego the least pleasure, simply as pleasure, is to act on a principle of asceticism; but the true disciple of utility holds every pleasure to be in itself good. Even the abominable pleasure which the wretched criminal enjoys in gloating over his crime is good, so far as it is a pleasure; it is only evil so far forth as it entails the ill consequences of fear and punishment, which far transcend its guilty enjoyment. The practical conclusion, therefore, of the theory of utility is, that an action is only really good when it will give rise to more of pleasure than of pain; and evil, when its painful exceed its pleasurable consequences. It becomes, consequently, of the first importance to possess an accurate standard by which the amount of pleasure and pain likely to result from certain actions, and the relative value of the two quantities, may be measured. This desideratum Bentham has attempted to supply in a manner that constitutes the most original and characteristic feature of his theory and system. The first item of this moral arithmetic is what is intended for an exhaustive enumeration of all the pleasures and pains of which human nature is susceptible: in the next, he proceeds to furnish a method of determining their comparative value. For this purpose it is necessary to take into the account the following considerations: — I. What are the intrinsic circumstances of the pleasure itself which can augment or diminish its value: and these are, 1. intensity; 2. duration; 3. certainty; 4. proximity, or remoteness; 5. fecundity, or the probability of its immediate pleasures engendering others more remote; 6. purity, or whether its pleasures are mixed or not with more or less of pain. II. What circumstances are likely to affect the sensibility of the agents, and so to modify indirectly the result. These are of two kinds, individual and general: to the former belong temperament, constitution, habits, intellectual development, and other traits of personal character: those of the latter order are little more than generalizations of the first, and are — sex, age, education, profession, climate, national character, government, and religion. III. What are the consequences which, going beyond the immediate objects of the action, remotely affect others more or less numerous, and even the whole of society. By allowing their due weight to all these particulars, Bentham pretends that any ordinary capacity may form a correct estimate of the real tendency of actions, and thereby arrive at that general utility which it is the proper end of morality to secure. (*Treatise on Morals and Legislation.*)

The recognition of a principle of action independent of self-love will afford a general characteristic of the remaining theories. Some of these, however, place the origin of the disinterested determination in a perception of moral good and evil by the intellect or reason; while others explain the distinction by certain facts which take place within the sensibility or emotive part of man, so that the disinterested determinations which result proceed from an instinct or sentiment. These two classes may be conveniently designated the rational and the sentimental or instinctive. Of instinctive theories, however, while some are content with referring the moral principle to an original and admitted tendency of human nature, such as sympathy or benevolence, others have derived it from a new and peculiar faculty.

To begin with the former class. According to Smith (born 1723, died 1790), when we are in the company of another who is sensibly affected with any sentiment or passion, our nature spontaneously, and without the intervention of reason or will, tends to reproduce in ourselves the same sentiment or passion: and not only have we this disposition to sympathy, but we even feel a pleasure in finding ourselves to be brought thereby into harmony with those around us. Indeed, so strong and so instinctive is the desire for such union between our own minds and those of others, that when we are under any strong emotions in the presence of another who is unable to conceive any thing that approaches to the same degree of violence with our own, in such a case we involuntarily and unconsciously lower our passion to that pitch in which the spectator can go along with it. The spectator, on the other hand, seeing what we suffer, endeavours to enter into our sentiments, and rises by an instinctive complaisance to the level of them. In regard to those objects which have no peculiar relation either to ourselves or others, this sympathy is simple. In whatever degree, for instance, the love of truth may be felt, it will not directly affect the happiness of any one; it cannot excite any feeling but a simple emotion of sympathy. It may, therefore, be allowed to appear as it is felt, because there is no reason either of instinct or of reason to suppress it. There are, however, certain internal dispositions which excite a twofold or even a triple sympathy, which are all of the same kind; thus, when we see a man animated with sentiments of charity and love, pity and benevolence, towards his fellow men, we are affected by a twofold sympathy, *directly* with the benevolent disposition, and *indirectly* with the gratitude which is due from its objects. As, then, the two mutually strengthen each other, the benevolent dispositions evidently awaken the highest degrees of sympathy, and consequently they contribute most of all to effect that perfect harmony of sentiments and affections to which all men instinctively aspire. But, on the other hand, there is a divided sympathy. Suppose the case of merited anger; on the one hand we sympathise with the passion of anger, and on the other with the object of it, and with the sufferings which it may bring upon him. These are the elements of moral approbation and disapprobation. We approve those sentiments of others in which we ourselves are able to participate; and when this sympathy is pure our approbation is unqualified, but mixed with disapprobation when our sympathy is divided. But further, when we witness, for instance, an act of benevolence, we sympathise not only with the feelings of the actor, but also with the emotion of the party benefited. Now this emotion is gratitude; but what else is gratitude but an instinctive desire to do good to the benefactor? Consequently, as we participate in the feelings of the obliged party, we wish to do good to the author of the obligation; we feel that he *merits* it in reward for the good which he has done. As to the judgment which we pass on our own sentiments and actions, Smith asserts that if it were possible for a human creature to grow up to manhood in some solitary place without communication with his species, he could no more think of his own character, of the propriety or demerit of his own actions, of the beauty or deformity of his own mind, than of the beauty or deformity of his own face. Since society is essential to sympathy, which is the rule of qualification of all our acts, the solitary cannot arrive to a consciousness of that rule, and by it appreciate the morality or immorality of his acts. Our moral criticisms are first exercised upon the character and conduct of others, but we soon learn that others are exercising their judgment upon our own: we become anxious to know how far we deserve their censure and applause; and, in order to examine in this respect our own passions and conduct, we have the faculty of supposing ourselves spectators of our own dispositions and behaviour, and so experience in some degree the same sensations as would be excited in our minds by the sight of similar actions

acquire a knowledge of man's true and proper nature; but this self-knowledge he held to be impossible so long as man continues ignorant of the universal principle. Now the nature of God can only be learned from his works, and these bespeak him to be good and intelligent. Moreover the consciousness of man attests his participation in the divine essence; consequently the ultimate destination of man is reason and goodness, and his moral end is the cognition and practice of good. Virtue, therefore, is the intelligent performance of duties, whose notions man may arrive at by a study both of his own nature and of the laws of an all-wise Creator discoverable in the system of the universe. In this pursuit happiness is inseparable from virtue. But if Socrates thus founded morality on a disinterested principle, he reconciled it with interest rightly understood; and on the other hand raised political science above the mere calculation of utility, by identifying it with justice as founded not on convention (*δογμα πολεως*), but on natural right, or the invention of what is (*του οντος εξευρεσις*).

Socrates having thus referred the laws of morality to the Deity as their author and upholder, Plato proceeded by a definition of the divine nature to guard against the objection of their arbitrary position by the will of God. He made the Deity to be the perfection of intelligence as resulting from an union of the good, the beautiful, and the true, which are in their nature eternal, necessary, and immutable. This perfection is also the term to which man spontaneously tends. For reason is the true principle of his nature, although in the present existence there is mingled with it a foreign element — *matter*, which, by obstructing its development, becomes the cause of his falling short of perfection. All, then, that is now possible for man is an approach to the divine excellence. This is virtue, and is effected by the harmony of the *rational*, *irascible*, and *concupiscible* parts of the soul. Although the two latter belong to the foreign element in man's nature, they are yet indispensable to the moral act: for the third affords a motive to action, inasmuch as beauty, being identical with the good and true, gives rise to desire or love (*ερως*), and thereby impels to virtuous action; while the second, disapproving what is base, and ugly, and false, furnishes the fortitude requisite for attaining to what is approved under every difficulty and every discouragement. To each of the three parts of the soul Plato assigns a special virtue, in a lower sense, and names them, respectively, *prudence*, *fortitude*, and *temperance* (*φρονησις*, *ανδρεια*, *σωφροσυνη*), while in a proper sense he declares virtue to be eminently one and the same with justice (*δικαιοσυνη*). These four are the so-called cardinal virtues. From the notion of justice he draws the connection of ethics and politics: the latter is but an application of the former to society. At the close of the republic he teaches that as an individual cannot be at peace with himself except by the harmonious adjustment of all his faculties, wherein each is allowed its due weight, so in the whole world happiness is proportionate to justice, and each individual derives the greater benefit from the community the more complete the harmony is in which he lives with all his fellow citizens.

Essentially agreeing, the ethical systems of Plato and Aristotle are chiefly distinguished by the relative value which they respectively ascribe to happiness; the former considering it as the natural fruit of virtue, while the latter rather viewed virtue as the means of attaining to happiness. Plato taught, that although the just man regulates his conduct by no reference to his own enjoyment, yet pleasure invariably attends him, since justice is good not only in itself, but also in its effects, and renders all things fitting and friendly to man. In Aristotle's opinion, the end of morality is to render individuals as useful as possible to society; the objects of whose institution is to procure in its members the highest moral perfection, as necessary to the attainment of the greatest possible felicity by the whole. Man, he teaches, is a free and rational agent, and therefore acts spontaneously and deliberately, invariably proposing to himself some end as the motive to action. All human arts and pursuits, then, have their appropriate ends; but among these there is a certain subordination, which implies a supreme end towards which they all converge; it being desirable not for its own sake, but the cause for which all else is sought. This supreme good is perfection: virtue is the approximation thereto, and consists in the habit of mediocrity according to right reason; in other words, it is self-control, which triumphs alike over the impetuosity of the passions and the weakness of the will, and thereby accomplishes a just mean. Every special virtue, in like manner, lies in a kind of middle between the two opposite vices of too much and too little: courage, for instance, being a mean between cowardice and rashness, of which the former offends by an excessive, the latter by a defective, regard to the proper objects of fear.

According to the Stoics, the supreme good which is the final cause of every special good is to act conformably to nature; *i. e.* in obedience to the immutable laws which reason discovers in the universe. This eternal and universal order, which they called *fate*, is an infinite enchainment of causes and effects, in virtue of which whatever happens is what ought to be: it embraces all living things, and man therefore has a principle within him which obliges him to seek that state of his nature which is the best and most perfect that it is capable of. This is reason. Wisdom, therefore, is man's chief good, and the pursuit of it is philosophy. Perfect wisdom, however, as modelled in the sage of the Stoics, they did not believe to be conceded to mortals, to whom nothing more is granted than to be in *the way to* perfection. Now, as they made reason to be the supreme arbiter in moral determinations, they naturally held vice to be but an error: yet this error, they taught, is the only evil; and, on the other hand, nothing is good but what is such in all times and all circumstances: all else is morally indifferent. But even indifferent things are, in a lower sense, agreeable to nature, and objects more or less of choice or aversion. That perfect rectitude of conduct, therefore, which constitutes the essence of virtue, consists in a just and accurate discernment of good, and in assigning to every object its due importance according to the place it holds in the natural scale of things. Lastly, although their first object was to emancipate the moral man from all dependence on external conditions and from the slavery of his passion, — and although, therefore, they removed all sensuous pleasures and pains from the catalogue of good and evil, — nevertheless the apathy which they taught was not, as commonly understood, an absolute insensibility, but rather the undisturbed supremacy of reason over the passions.

All the preceding theories agree in making reason the end of human activity, and are thereby distinguished from the Epicurean, which gave the first place to the sensuous element of humanity, and reduced science to the rank of a mean. According to Epicurus, pleasure alone is sought for its own sake, and philosophy and all else is but the pursuit of it. If, sometimes, it seems to be foregone, it is only with a view to some higher gratification, as pain also may occasionally be endured in the acquisition of a pleasure whose intensity will fully compensate for the intermediate suffering. The pleasures and pains that are primarily the objects of desire and aversion are corporeal, and from these the pleasures of the mind are ultimately derived, and consist merely in the anticipation of future and in the recollection of past states. This, however, constitutes the superiority of the secondary pleasures of the mind over their corporeal originals, for the latter do not extend beyond the present sensation. *Virtue*, therefore, is an enlightened pursuit of pleasure, which, although it is selfish in its principle, still allows free course to the social and benevolent affections, as being a part of man's nature and an additional source of gratification beyond the calculations of personal interest. For though they may expose a man to the chance of pain, as in the case of the death of a friend, still this is a less evil than apathy, and the deprivation of a natural enjoyment. Justice, lastly, has no other object than the general good; and right, properly understood, is but the sign of utility.

Modern ethics having taken their rise from a system greatly resembling the Epicurean, the inquiry into the nature of virtue became the first question that was proposed for solution. Accordingly this fact furnishes a general classification of the later theories of morals into selfish or disinterested, according as they found virtue on a selfish or on a benevolent principle.

The selfish theory has found its ablest advocates in Hobbes, Helvetius, Paley, and Bentham. Of these the first and last deserve a particular notice: Hobbes as the originator of the controversy into the nature of morality; Bentham as furnishing the most complete and elaborate exposition of the utilitarian scheme. According to Hobbes (born 1588, died 1679), the only motive that can induce men to any act is the pleasure which will follow from its execution. A preconception of pleasure is the necessary condition of every moral determination. Good and evil are simple tendencies to pleasure and pain, without which every object is indifferent. Self-love is the exclusive passion of man's nature. Other passions differ from it outwardly only, *i. e.* in the objects which excite them: pity, for example, is but the imagination of misfortunes which may happen to ourselves, suggested by the contemplation of another's sufferings; love, the conception of advantages to be derived from its object; and benevolence, nothing more than the consciousness of power sufficient to secure not only one's own happiness, but that of others also. The first law of nature is self-preservation: whatever tends, therefore, to this end is lawful and good, and all men have a natural right to appropriate by every means in their power whatever may contribute to their personal happiness. As this is the imprescriptible right of all, there are as many forms of natural right as there are separate and independent wills; and actions of the most opposite kinds are equally virtuous and legitimate. Now, as all possess an equal right to all things, and as there is no reason why one

should yield to another the objects which both may desire, the state of nature must be one of war; but as, in such a condition of things, the safety of every one is constantly endangered by the conflicting interests of all others, peace, at any price, becomes preferable to it. Peace, however, is the result of society alone; *i. e.* as defined by Hobbes, of the existence within a community of a sufficient force to control all individual wills and forces. But this is only practicable in two ways: either all are seized with a desire to terminate the state of hostility, and enter into a mutual compact, by which they engage to do no violence, nor to suffer it to be done to each other; or a single person succeeds by stratagem or force in establishing his own authority over the rest. The latter form of society is as legitimate as the former; and indeed, as the end of the institution is the suppression of warfare among its members, and as the more unlimited the power is the better calculated it must be to effect this object, an absolute monarchy is the very best polity that can be devised. Against the government in such a society, it is evident that subjects cannot consistently possess any rights; for these would impede its effectiveness: they have but one simple duty, and that is — implicit obedience. (*On Human Nature; Leviathan, &c.*)

Bentham (born 1748, died 1832), sets out from Hobbes' principle, that every object would be perfectly indifferent but for its fitness to produce pleasure or pain, which, he declares, are the sole motives of human determinations. This proposition he does not attempt to prove, but, asserting that it is one of those primary and self-evident truths which are the foundation of all reasoning, he proceeds to draw from it certain practical conclusions in the form of definitions. Thus he defines utility to be the fitness of actions and things to augment the happiness, or to diminish the misery, of individuals and communities; and maintains that this is the only true and intelligible interpretation of what is usually called the lawfulness, goodness, justice, and morality of an action. The principle of utility is next defined to be that which exclusively derives the quality of actions from their twofold property of augmenting the nappiness or misery of one or many. This, he asserts, is the only valid principle of moral appreciation; and he reduces all opposing theories to two classes, which he designates by the principle of asceticism, and the principle of sympathy and antipathy. Under the latter head, Bentham comprises every theory of morals which draws the distinction of good and evil from any other principle than a consideration of consequences; whereas he explains the ascetical principle as agreeing with the utilitarian in drawing its qualification of objects from their tendency to produce pleasure or pain, but as differing from it in that it proceeds in an inverse manner, and calls pain good, but pleasure an evil. To forego the least pleasure, simply as pleasure, is to act on a principle of asceticism; but the true disciple of utility holds every pleasure to be in itself good. Even the abominable pleasure which the wretched criminal enjoys in gloating over his crime is good, so far as it is a pleasure; it is only evil so far forth as it entails the ill consequences of fear and punishment, which far transcend its guilty enjoyment. The practical conclusion, therefore, of the theory of utility is, that an action is only really good when it will give rise to more of pleasure than of pain; and evil, when its painful exceed its pleasurable consequences. It becomes, consequently, of the first importance to possess an accurate standard by which the amount of pleasure and pain likely to result from certain actions, and the relative value of the two quantities, may be measured. This desideratum Bentham has attempted to supply in a manner that constitutes the most original and characteristic feature of his theory and system. The first item of this moral arithmetic is what is intended for an exhaustive enumeration of all the pleasures and pains of which human nature is susceptible: in the next, he proceeds to furnish a method of determining their comparative value. For this purpose it is necessary to take into the account the following considerations: — I. What are the intrinsic circumstances of the pleasure itself which can augment or diminish its value: and these are, 1. intensity; 2. duration; 3. certainty; 4. proximity, or remoteness; 5. fecundity, or the probability of its immediate pleasures engendering others more remote; 6. purity, or whether its pleasures are mixed or not with more or less of pain. II. What circumstances are likely to affect the sensibility of the agents, and so to modify indirectly the result. These are of two kinds, individual and general: to the former belong temperament, constitution, habits, intellectual development, and other traits of personal character: those of the latter order are little more than generalizations of the first, and are — sex, age, education, profession, climate, national character, government, and religion. III. What are the consequences which, going beyond the immediate objects of the action, remotely affect others more or less numerous, and even the whole of society. By allowing their due weight to all these particulars, Bentham pretends that any ordinary capacity may form a correct estimate of the real tendency of actions, and thereby arrive at that general utility which it is the proper end of morality to secure. (*Treatise on Morals and Legislation.*)

The recognition of a principle of action independent of self-love will afford a general characteristic of the remaining theories. Some of these, however, place the origin of the disinterested determination in a perception of moral good and evil by the intellect or reason; while others explain the distinction by certain facts which take place within the sensibility or emotive part of man, so that the disinterested determinations which result proceed from an instinct or sentiment. These two classes may be conveniently designated the rational and the sentimental or instinctive. Of instinctive theories, however, while some are content with referring the moral principle to an original and admitted tendency of human nature, such as sympathy or benevolence, others have derived it from a new and peculiar faculty.

To begin with the former class. According to Smith (born 1723, died 1790), when we are in the company of another who is sensibly affected with any sentiment or passion, our nature spontaneously, and without the intervention of reason or will, tends to reproduce in ourselves the same sentiment or passion: and not only have we this disposition to sympathy, but we even feel a pleasure in finding ourselves to be brought thereby into harmony with those around us. Indeed, so strong and so instinctive is the desire for such union between our own minds and those of others, that when we are under any strong emotions in the presence of another who is unable to conceive any thing that approaches to the same degree of violence with our own, in such a case we involuntarily and unconsciously lower our passion to that pitch in which the spectator can go along with it. The spectator, on the other hand, seeing what we suffer, endeavours to enter into our sentiments, and rises by an instinctive complaisance to the level of them. In regard to those objects which have no peculiar relation either to ourselves or others, this sympathy is simple. In whatever degree, for instance, the love of truth may be felt, it will not directly affect the happiness of any one; it cannot excite any feeling but a simple emotion of sympathy. It may, therefore, be allowed to appear as it is felt, because there is no reason either of instinct or of reason to suppress it. There are, however, certain internal dispositions which excite a twofold or even a triple sympathy, which are all of the same kind; thus, when we see a man animated with sentiments of charity and love, pity and benevolence, towards his fellow men, we are affected by a twofold sympathy, *directly* with the benevolent disposition, and *indirectly* with the gratitude which is due from its objects. As, then, the two mutually strengthen each other, the benevolent dispositions evidently awaken the highest degrees of sympathy, and consequently they contribute most of all to effect that perfect harmony of sentiments and affections to which all men instinctively aspire. But, on the other hand, there is a divided sympathy. Suppose the case of merited anger; on the one hand we sympathise with the passion of anger, and on the other with the object of it, and with the sufferings which it may bring upon him. These are the elements of moral approbation and disapprobation. We approve those sentiments of others in which we ourselves are able to participate; and when this sympathy is pure our approbation is unqualified, but mixed with disapprobation when our sympathy is divided. But further, when we witness, for instance, an act of benevolence, we sympathise not only with the feelings of the actor, but also with the emotion of the party benefited. Now this emotion is gratitude; but what else is gratitude but an instinctive desire to do good to the benefactor? Consequently, as we participate in the feelings of the obliged party, we wish to do good to the author of the obligation; we feel that he *merits* it in reward for the good which he has done. As to the judgment which we pass on our own sentiments and actions, Smith asserts that if it were possible for a human creature to grow up to manhood in some solitary place without communication with his species, he could no more think of his own character, of the propriety or demerit of his own actions, of the beauty or deformity of his own mind, than of the beauty or deformity of his own face. Since society is essential to sympathy, which is the rule of qualification of all our acts, the solitary cannot arrive to a consciousness of that rule, and by it appreciate the morality or immorality of his acts. Our moral criticisms are first exercised upon the character and conduct of others, but we soon learn that others are exercising their judgment upon our own: we become anxious to know how far we deserve their censure and applause; and, in order to examine in this respect our own passions and conduct, we have the faculty of supposing ourselves spectators of our own dispositions and behaviour, and so experience in some degree the same sensations as would be excited in our minds by the sight of similar actions

and feelings in another. By virtue of this faculty we feel as it were a sympathy with ourselves when we have acted well, and are led to suppose that all other spectators would be similarly affected. This consciousness of unison between our own conduct and the sentiments of our fellows constitutes the pleasure of rectitude. And further, by aid of the same principle by which we judge of the actions of others, we feel that we have a right to pronounce our own also to be good. This is a source of inward tranquillity and satisfaction, while the least suspicion of the contrary gives rise to the pains of remorse. In manhood, indeed, when experience has drawn a system of general rules from the occasional judgments of sympathy, and established them in the mind, a new source of pleasure arises. We have now an intellectual perception also of the conformity of the act with the law of morality; and, independently of the instinctive approbation, the reason also awards to it its sanction. This rational perception is wanting in the infantine and uncultivated mind; but it is invariably found wherever education or experience has stored the mind with the general maxims of morality which are primarily founded on the instinctive emotions. The act of reason in approbation is simply a perception of the agreeableness of the act with the moral laws, and therefore implies them. Lastly, the act itself appears by its very nature to be part of a system of conduct fitted to establish a perfect agreement of sentiments among mankind; and this universal harmony being eminently beautiful in itself, we judge, in virtue of this perception, the act in question to be not only good but even beautiful. This is the principle of moral beauty, which is the origin of every other species of the beautiful. (*Theory of Moral Sentiments.*)

The doctrine of a moral sense owes its origin to Lord Shaftesbury (born 1671, died 1713). According to this writer, the human dispositions are of two kinds, — the social or benevolent, and the personal or selfish. The former lead us to desire the welfare of others simply for its own sake and without regard to our own interests. In the developments of these affections the soul takes part, and some are naturally agreeable and others disagreeable to it; of the former it approves, but disapproves the latter. As, then, these dispositions are a source of pleasure to the soul, there must be in it some faculty distinct from the dispositions themselves, by virtue of which they become agreeable or otherwise, and which performs the same office in their case as they do with respect to their immediate objects. This faculty Shaftesbury calls a sense which he characterises from its mode of operation as *reflex*, and from its object-matter as *moral*. The dispositions which this reflex sense approves or disapproves are morally good or evil: virtue consists in yielding to the former, but resisting the latter. Between goodness and virtue there is agreement, but not identity; the former being merely a constitutional predominance of the benevolent affections in the character and conduct, the latter being the same state produced by the operation of the conscience or moral sense, which, when the personal affections are of equal force with the social ones, interposes its authority, and inclines the balance in favour of the latter.

Butler (born 1692, died 1752), in the same manner divides the principles of action into those which lead directly to private good, and those which promote immediately the good of the community; but of both he shows with great originality that they are alike disinterested. The objects of both classes of passions are outward things, which are sought as ends in themselves and without any regard to their tendency to promote happiness, which is the proper end of self-love. This, again, is distinguished by Butler from selfishness, which consists in the weakness of the public affections and the undue strength of personal desires. Self-love, or an enlightened regard to our general happiness, is not a vice; whereas selfishness is utterly at variance with the happiness of him who harbours it, since without the gratification of the benevolent feelings it is impossible to attain to the greatest satisfaction of our nature, of which they are a part. But, besides these personal and social instincts and self-love, Butler discovers in man another faculty, which by its very nature is supreme over all others, and authoritatively approves or disapproves both the affections of our minds and the actions of our lives. This principle is conscience. Its perceptions are immediate, and its very idea implies that supremacy and authority are essential to it. (*Sermons at the Rolls Chapel.*)

The first object of Hutcheson (born 1694, died 1747,) is to show that the very frame of our nature which determines us to pursue happiness for ourselves, also determines us both to esteem and to benevolence on their proper occasions. But besides these original desires, he shows that there arise, in consequence of them, *secondary* desires of every thing useful to gratify the primary ones. But there is also in man an idea of moral good which can be explained by neither of the former. By a careful analysis, Hutcheson shows that by moral good we understand neither what gives pleasure by satisfying our benevolence, nor what is simply good to others; nor is it what is useful to others or agreeable to the spectators; nor, lastly, is it a conformity to the will of God, or to law, or truth, or order: it is simply what the word itself expresses, which is simple and original and inexplicable by any other. From this originality and simplicity of the term, Hutcheson argues that it must be perceived by a sense, because the senses alone are percipient of simple qualities; and by a special sense, since the quality apprehended by it differs from all other objects of sensation. Further he observes that this perception is attended with pleasure, which is the property of all sensuous perceptions; and that as moral good is an end and motive of action, it must be apprehended by a sense, since the understanding can neither propose the ends of human activity nor exercise any influence on the will. Again, the pleasure which accompanies the perception of good, being a consequence of the discovered quality, necessarily presupposes it; therefore it is impossible to resolve moral good, or the approbation which we award to it, into that pleasure; this would be to resolve the cause into the effect, and the consequence into the principle. As the qualities which it is the province of the moral sense to discover belong to the internal affections and emotions, it is internal, and not external, although, like the outward senses, it is capable of improvement by education and habit. This sense is designed to govern all the others, and we have an immediate consciousness of its authority. Reason is the servant of this sense, its only office being to discover and to combine the means necessary to the attainment of the objects which the moral sense approves of. The object of this approbation is benevolence alone: every action or measure which has in view our own advantage is, simply on that account, morally wrong; it may be innocent — it cannot be virtuous. (*Inquiry into Beauty and Virtue.*)

According to Hume, (born 1711, died 1776,) all the mental qualities and actions which are generally approved of by mankind agree in the circumstance of being useful to society. The fact that the different degrees of moral approbation correspond to the degrees of utility, affords an explanation of the greater merit ascribed to the benevolent passions: for these tend to the happiness of many, and indeed of all; whereas the personal affections tend to that of the agent alone. Yet even the latter are in a degree meritorious, inasmuch as they are useful to one, and they are only to be blamed when they are entertained at the sacrifice of the social feelings. The pursuit of self-interest is in the latter case culpable, although in itself it is not only innocent, but praiseworthy: for we admire in any character certain qualities, such as prudence, for instance, merely because they appear fitted to promote his personal welfare. In short, whatever is useful is morally good, and is only to be disapproved when it is preferred to what is more useful. That which judges of utility and the contrary is reason; but if we approve of one and disapprove of the other, and call the former good, but the latter evil, this is in virtue of a primary sentiment of our nature, which leads us to prefer the useful to the hurtful, as we prefer what is sweet to what is bitter. This instinct, however, is distinct from and frequently opposed to self-love; for this would lead us to love what is useful to ourselves, and not what is useful in itself absolutely and independently of any reference to our own advantage. This instinct is commonly called conscience, or the moral faculty, but more frequently designated by Hume as benevolence or humanity, inasmuch as its object is the good of mankind generally. As to the idea of moral obligation, it is simply a conception of the understanding. What is honoured by this name is, he says, nothing more than the undoubtedly correct view, that there is more happiness in obeying the impulses of the moral sense than in following the dictates of self-love. The reason is incapable of exercising any influence on the will. What determines us when we resolve to act rightly is merely the charm which utility exercises on the mind, and the force of certain dispositions which propel us to seek the good of ourselves and others, and are invariably seconding the promptings of conscience. (*Inquiry concerning the Principles of Morals.*)

Mackintosh (born 1765, died 1832,) agrees with all the writers of the instinctive school in denying conscience to be either a state or act of the understanding: but he differs from one form of the sentimental theory by denying that man has any special organization for moral perception, while he equally dissents from the other view, which would refer these perceptions to some one of the original and admitted sentiments of our nature. Butler and Stewart had shown that self-love is a secondary principle; and Hartley had exhibited the important part which association plays in the formation of our passions and affections, and even of our sentiments of virtue and duty. This view was further developed by Mackintosh, who declared conscience itself to be a similar derivative.

In the same manner he says that in the formation of self-love the desire which originally attaches to external objects is transferred to the pleasure which results from their attainment; so in the case of conscience the agreeable and disagreeable sensations which belong naturally to certain actions is transferred to the volitions which determine conduct, so that the latter become at last the immediate objects of love and repugnance. In this manner there is formed by association a number of secondary desires and aversions, whose proper object is volition, and which collectively form that interior principle called conscience, which judges, without regard to consequences, unerringly and authoritatively. As to the action of conscience on the will, this is composed both of the peculiar energy of the primary dispositions, which it causes to triumph, and of the pleasures naturally attached to them, as well as those which are produced by the gratification of the secondary affections. Accordingly, Mackintosh strongly insists upon the distinction between perception and emotion, and declares that the phrase *association* of ideas, as overlooking this distinction, conveys but a partial and incomplete view of the truth. He therefore proposes to substitute for it association of thoughts with emotions and with each other, but at the same time declares that the term "association" very inadequately indicates that perfect combination and fusion which occurs in these operations of the mind. For the moral faculty is properly and intelligibly spoken of as one. Now it is as common in mind as in matter for a compound to have properties not to be found in any of its constituent parts: the originally separate feelings are so completely blended together that they can no longer be disjoined from each other. Thus the sentiment of moral approbation, formed by association out of antecedent affections, may become so perfectly independent of them that we are no longer conscious of the process by which they were formed. It is in this mature and sound state of nature that our emotions at sight of right and wrong are ascribed to conscience. And although this supreme arbiter and judge of human conduct does not supersede the ordinary motives of virtuous feelings and habits, which are the ordinary motives to good actions, it yet exercises a lawful authority over them. Whatsoever actions and dispositions are approved by conscience acquire the names of virtues and duties; they are thereby pronounced to deserve commendation, and we are justly considered as under a moral *obligation* to practise the actions and cultivate the dispositions. The peculiar character of the moral sentiments is their exclusive reference to *states of the will*, and this is a character both of the private desires and social affections, and, indeed, among the many dissimilar elements that enter into the formation of conscience, this is the only common property that the mind can discover. Hence, however, the facility with which general terms, at first limited to relations between ourselves and others, are gradually applied to any voluntary acts and dispositions: it is thus that prudence and temperance, for instance, become objects of moral approbation. On the other hand, as the will is the sole means of gratifying any passion, the power of conscience is coextensive with the whole man. It is a universal principle, because will is the universal means. And as, when the mind is in a healthy state, nothing is interposed between it and the will, the dictate of conscience is immediately followed by a determination of will; conscience is thus at once universal, independent, and commanding. Lastly, as Mackintosh held that utility, as tending to promote the greatest happiness of the species, is the criterium of morality, he naturally felt himself called upon to explain the fact, that, while the moral approbation involves no perception of a beneficent tendency, there is nevertheless a striking coincidence between that principle and the moral sentiments. He replies that it is true that conscience itself rarely contemplates so distant an object as the welfare of all sentient beings, but that all its elements are invariably tending to this end. The social affections promote happiness, so far as their foresight and power extend; the rules of justice are conducive, if not necessary, to the well-being of society; even the angry passions, so far as they are ministers of morality, are employed in removing hindrances to the welfare of ourselves and others; and if the private passions terminate in the happiness of the individual, this is yet a part of the general happiness. And although this beneficent tendency be not one of the natural objects of conscience, because our voluntary acts are not felt to affect it, yet little is left to reason to perform; which is, to discover merely the truth, that the acts of those who labour to promote separate portions of happiness must increase the amount of the whole. (*Dissertation on the Progress of Ethical Philosophy.*)

The distinctive characteristic of the rational theory of morality is, that it considers the idea of good to be an *à priori* conception of reason, in which the idea of obligation is necessarily and essentially implied. As to the nature of the idea itself, two opinions have been held. While some moralists of this school pronounce it to be simple and immediate, others resolve it into some higher notion of the intellect, from which it derives at once its explanation and authority.

The most distinguished representatives of the latter opinion are Clarke and Wollaston; while the former has found able advocates in Cudworth, Price, and Stewart.

According to Clarke (born 1675, died 1729), the universe is an assemblage of objects held together by certain mutual relations which result from their respective natures; but as the nature or essence of things is immutable and real, and the essence is the principle of the relations, the latter must be equally real and immutable; and as they must have been always present to the Eternal Mind, they are also eternal. Now, as soon as reason conceives these relations as constituting the laws of individual things, and the order of the universe, they immediately appear to command the respect of every free and rational agent. Hence the obligation on every creature capable of thought to act conformably to those relations; and every act agreeable to them is judged to be good, and evil if opposed to them. Now, moral good being the conformity to the relations of objects, these, while they constitute, serve also to explain, all duties. Thus, the true nature of God and man, and their reciprocal relations, being known, the duties of man towards God are at once discoverable. In the same way the duties of man to his fellows similarly suggest themselves from a consideration of their relations as equally free and independent beings; and as the latter relation is one of equality, whereas that between God and man is one of inequality, the difference between the two classes of duties which those relations respectively engender is at once conceivable. In confirmation of this view of the moral principle, Clarke appeals to the historical fact of the gradual development of moral ideas among mankind: for the knowledge of the nature of things, and their consequent relations, is neither natural nor immediate to the mind, but is gradually unfolded by observation and science, which are more or less complete according to the degrees of its culture. The evolution of moral science, although subsequent to that of nature, nevertheless, being once awakened, is promoted by its progress, and keeps pace with the advancement of civilization. (*Being and Attributes of God; Evidence of Natural and Revealed Religion.*)

Wollaston (born 1659, died 1724,) makes morality to be conformity to truth. In support of this view he asserts that actions, equally with words, are but signs, and that consequently every true proposition, *i. e.* one which expresses things as they are, may be contradicted by deeds as well as by words. To violate a compact, for instance, is simply to deny by that act that there is any such compact subsisting. He then asserts that no act, whether word or deed, of any free and rational agent to whom moral good and evil are imputable, which interferes with any true proposition, or denies anything to be as it is, can be right. For, 1., if a false proposition be wrong, the act which implies, or is founded on it, cannot be right. 2. Whatever interferes with a true proposition, which expresses the relation between the subject and attribute as it is in nature, must, therefore, interfere with nature, and is consequently unnatural, or wrong in nature. 3. An act which contradicts a true proposition contradicts what is, and is, therefore, a revolt against God, the author of whatever is. 4. To deny things to be as they are, is a transgression of the great law of our nature — the law of reason. What is said of acts inconsistent with truth may be said of omissions to act, since by these, also, true propositions may be denied to be true. For instance, whoever having engaged to do some certain act, nevertheless voluntarily omits to do it, behaves himself as if there had been no such promise or engagement. Having thus established his theory, he proceeds, like Clarke, to show that it is agreeable to facts, and especially with that of the progressive development of morality. For morality being simply the truth expressed in action, it implies the knowledge of truth; and consequently the improvement of the moral perceptions must be proportional to the progress of science. It also affords an explanation of erroneous views in morality, and of the difference so universally drawn by the common sense of mankind between error and vice. If it is possible to err in morals, this is because the mind is liable to err in science, and not to see things as they actually are. To err in morals is but to affirm practically a false position: hence the act may be evil, but the agent is not culpable, since his error is involuntary. Lastly, Wollaston maintains that his theory, far from being inconsistent with the acknowledged characteristics of the idea of moral good, affords the only just explanation of them. The truth is immutable, because it expresses the unchangeable nature of things, and therefore the ideas of moral good are immutable. Hence, too, the same eternal distinction between moral good and evil as between truth and falsehood. Whatever, in short, may be predicated of truth, is applicable to the moral principle; and its foundations are as valid and

imperishable as those of science itself. (*The Religion of Nature.*)

The other form of the rational theory, which explains the idea of good to be an immediate conception of the intuitive reason, intelligible in itself, and incapable of definition, now remains for elucidation. According to Cudworth (born 1617, died 1688), certain universal and absolute ideas exist from all eternity in the Divine mind, from which the human intellect emanates; and, therefore, by its nature possesses these ideas antecedently to experience. They remain dormant, it is true, until outward objects call them forth; but when once awakened, they immediately apply themselves to things, and give them a significant character, which in themselves they do not possess. Cudworth's chief object in advancing this theory of intellection, was to exempt the ideas of right and wrong from the arbitrary and relative character with which the sensuous doctrines of Hobbes had invested them. Accordingly, he shows that no relation of human will or pleasure can constitute these ideas. Positive laws, he urges, do not oblige by their mere enactment, but by virtue of the natural ideas of justice and obligation which they imply. Neither is this idea the mere creature of man's reason, for this does but conceive it, and, by applying its unchangeable standard to actions and characters, appreciates and judges them. Lastly, this idea is simple and indefinable, and inseparably combined with that of obligation. Hence every virtue assumes the character of a duty, and is as unalterable as good itself. (*Eternal and Immutable Morality.*)

Price (born 1723, died 1791,) ascribes all simple ideas to two faculties — sense and understanding. The latter sees things as they are; the former perceives the effects only that they produce on the sensuous organization. The ideas of the understanding consequently express realities which are independent of man, whereas those of the latter are sensations which would be different if man's sensuous organs were changed. Now the question of the objective reality and immutability of the ideas of right and wrong reduces itself to the inquiry into their origin. According to Price, they belong to the understanding as a faculty of intuition or immediate power of perception, distinct from the understanding as a reasoning or deductive faculty. The doctrine which would assign them to sensation as their origin has its source in the fact that the moral perceptions are invariably attended with agreeable or disagreeable emotions, and the exclusive consideration of this circumstance. But when men declare gratitude to be a virtue, and ingratitude a vice, they intend to signify not merely that they produce emotions in their own minds, but that they are naturally virtuous and vicious in themselves. If by virtue and vice nothing more be meant than certain mental affections, then, in that case, our moral judgments would be infallible, and the same act might with equal truth be the subject of the most conflicting estimates, and all things would be indifferent in their own nature, since the understanding, which alone apprehends things as they are, could see in them neither good nor evil. Moreover, in this case, they would be without authority; for what obligation can there be to do what is pleasing, or to forbear what is displeasing? But these ideas are both immutable and imperative: they are immutable, since they are real qualities of actions, and every real quality is a part of the nature of things, which is immutable. God may destroy the things themselves, but he cannot cause them to be what they are not. After establishing the rational origin and immutable character of the moral perceptions, Price proceeds to explain the manner in which they are apprehended by the intuitive reason. As the sight of an event suggests the idea that it must have taken place in time, and thereby we arrive at the idea of duration, in the same way certain actions of free and rational agents are immediately apprehended to be good or evil, and the ideas of right and wrong arise in the consciousness. As to the notions of moral beauty and deformity, these we ascribe to good and evil actions in virtue of the pleasure and pain which accompany, but yet are distinct from the perception of right and wrong. In contemplating the actions and affections of moral agents, we have both a *perception of the understanding* and a *feeling of the heart;* the latter are the effects of the former, and partly depend on the positive constitution of our nature, and partly on the essential congruity of object and faculty. The former are wholly inexplicable, and the only account we can give of them is — such is our frame; so God has seen fit to make us. But there are some objects and ideas which have a natural fitness and unfitness to please our mind, and such is the nature of certain actions that when perceived by a rational being, there must result in him certain emotions and affections. These are at first of a purely intellectual kind; but, as such, they are too weak to govern and actuate mankind, and they are therefore combined with a stronger excitement, and we are endowed with certain special instincts which impel us to goodness, and by means of these we are effectually moved towards their proper objects. As to duty or obligation: this idea is so intimately allied to that of good, that one cannot appear without the other. Obligation to action and rightness to action are plainly coincident and identical. It is not plainer that figure implies something figured, than that rightness implies oughtness. Rewards and punishments suppose in their very idea moral obligation, and are founded upon it. They do not make it, but enforce it, or furnish additional motives to comply with it. They are the *sanctions* of virtue, but not its *efficients.* The ideas of good and ill desert are equally immediate; for they are really nothing less than a species of the ideas of right and wrong; although there is this difference in them, that while the latter are properly ascribed to actions, merit and demerit are applicable to agents or persons only. We have an immediate approbation of making the virtuous happy, and discouraging the vicious, apart from all consequences. The conception of virtue is totally distinct from the fact that virtue is a source of pleasure; for it is one thing to find by experience that the tendency of virtue is to the happiness of the world, and vice to its misery, and another to conceive that virtue is by a necessary truth deserving of happiness. Neither does it result from the view that virtue is of public utility; for, even though this consideration may incline us to wish good to the virtuous, yet are we antecedently moved to the same wish by the more immediate and more simple consideration that he is virtuous, and as such, without any other consideration, we pronounce him deserving of honour. Lastly, Price makes liberty and intelligence to be essentially necessary to the morality of the agent, and rightly distinguishes absolute virtue, which is to act voluntarily and consciously in conformity with the moral laws, from practical virtue, or acting on a belief of good in supposed conformity to good. (*View of Principal Questions and Difficulties in Morals.*)

Stewart (born 1753, died 1828,) distinguishes two questions in the fundamental problem of ethics — that of the nature of good, and that of the faculty which discerns and judges of it. With respect to the first, he teaches that upon observation of certain actions the idea of good arises in the mind. This idea represents a certain quality of the actions themselves, and inherent in them, like the primary qualities of bodies, and therefore independent of the sensuous percipient, and not, like the secondary qualities, mere relations between us and the actions. As to the nature of these qualities, they are, like the ideas which we have of them, perfectly original, simple, and irreducible, and consequently indefinable. He further shows, after Price, that it is impossible to explain the terms good and evil except by synonyms, or by substituting for the ideas which they represent some of the circumstances which accompany the perception of them. As to the second question, Stewart argues that good being a simple and real quality in actions, it is impossible to refer the idea of it to any faculty which is not a source of original ideas, and which does not apprehend the real and inherent qualities of objects. It is, therefore, impossible to refer it to a sense,—such as that of taste or smell, which do not reveal the real nature of objects, but only the effect which they produce in the perceiving subject; nor to reason, — if by this term we understand nothing more than the faculty which seizes the relations and deductions of ideas previously established, because the idea of good is simple and original, and not one of relation and consequence; but if by sense we understand a faculty analogous to that which perceives the primary qualities of bodies and their existence,—or if by reason we mean the intuitive understanding which furnishes the simple, primary, and original ideas of time, space, and causation,—then the ideas of good and evil may be referred to either. If Stewart inclines, nevertheless, to favour the claims of reason, he yet declares the question to be unimportant when once it has been admitted that good and evil are simple and indefinable. (*Philosophy of the Active and Moral Powers.*)

In this exposition, the first object has been to give a correct and impartial view of the several theories which have been proposed of the nature of virtue and of the moral perceptions. Their comparative merits have been left to the reader's judgment, unbiassed and undisturbed by any critical estimate by the writer himself, except so far as his arrangement of the subject-matter necessarily implies his own opinion. (Cf. Ritter, *History of Ancient Philosophy;* Mackintosh, *Dissertation on Ethical Philosophy;* Schleiermacher, *Kritik der Ethik;* Jouffroy, *Droit Naturel;* Cousin, *Cours de Philosophie Morale;* and the articles ETHICS and SCHELLING in this work.)

VIS (Lat. *force* or *power*), in Mechanics, is synonymous with *force.* The term is chiefly used by the older writers, and is applied by them to divers kinds of forces or powers. Thus, *vis acceleratrix*, accelerating force; *vis inertiæ*, resistance; *vis motrix*, moving force, &c. *Vis mortua*, and *vis viva*, are terms which were used by Leibnitz and his followers; the former signifying a pressure, and the latter the force of a body in motion estimated by the distance the body goes to.

About the beginning of the last century, a keen dispute arose among mathematicians with respect to the manner in which the forces indicated by those terms ought to be estimated. It began with a prize essay by John Bernoulli on the "Investigation of the Laws of the Communication of Motion," and was carried on for many years with great asperity. The question was, whether the force of a moving body is proportional to the square of the velocity, or to the simple power only of the velocity. No controversy, says Playfair, was ever carried on by more illustrious disputants: Maclaurin, Stirling, Desaguliers, Jurin, Clarke, Mairan, were all engaged on the one side; and on the opposite were Bernoulli, Herman, Poleni, S'Gravesande, Muschenbroek. The dispute was taken up as a point of national honour. Germany, Holland, and Italy declared for the *vis viva;* England stood firm for the old doctrine; and France was divided between the two opinions. (*Dissertation on the Progress of Math. and Phys. Science, Ency. Brit.*) The difference in this case, as in most other disputes of a similar kind, arose from the parties not understanding each other. When the effect of a body in motion is measured by the distance to which it goes, the effect is proportional to the square of the velocity; if measured by the time that elapses before the motion is destroyed by a resistance of uniform intensity, it is as the velocity simply. Both measures may be considered as correct, and they are not inconsistent when rightly understood. (*Playfair's Nat. Phil.* vol. i. p. 56.) The *vis viva*, considered as a power residing in a moving body, is otherwise called *impetus*. *See* FORCE.

VI'SCOUNT. A title of honour; in its original signification, the delegate of a count (vice-comes), and applied to governors of towns and districts under the authority of that officer. In England, the appellation of vice-comes, or viscounte, in Norman French, was long used to designate the sheriff of a county (the vicegerent of the earl) before it became a title of peerage. It is the most modern of English honours in the latter sense; and was first conferred by letters patent on John Lord Beaumont, and the heirs male of his body, by Henry VI. in 1440. For the rank of the viscount, see PRECEDENCY.

VISHNU. One of the three principal deities of the Hindoo mythology, the other two being Brahma and Siva. He is commonly called the Preserver, the other two being respectively the Creator and the Destroyer. The great objects of his providence are brought about by his successive incarnations or avatars, in which he appears and acts on earth. Nine of these have taken place. The last is said to have been the appearance of Buddha, which is supposed by some learned orientalists to have taken place about A. D. 1014; and hence the Buddhists reject the Vedas, which were compiled before that event. (*See* VEDAS.) The tenth avatar of Vishnu is yet to take place, when he will appear on a white horse, with a blazing scimitar, for the everlasting punishment of the wicked. One of the incarnations of Vishnu is the celebrated Juggernaut, whose temple and worship hold such a prominent place in Indian superstition. On the great annual festival in his honour, all distinctions of castes and classes are forgotten, and even on that occasion the Brahminical Hindoos and the followers of Buddha cease their religious hostilities. The word Juggernaut signifies literally *Lord of the Universe;* and it is said that on the day he expired, Buddha assumed this appellation, exclaiming, "*O Universe, I am thy Lord.*"

VI'SIBLE. Capable of being seen. Objects are visible or otherwise, according as they emit or reflect a sufficient quantity of light to make a sensible impression on the retina of the eye. According to Newton, colour is the proper object of sight; the visibility of an object must therefore depend on its transmitting to the eye rays of a different colour from those which proceed from the surrounding objects.

VI'SION. In Optics, the faculty of seeing. Philosophers have disputed much respecting the means of vision, and its seat in the eye. The Platonists and Stoics held vision to be effected by the emission of rays out of the eyes. The Epicureans supposed vision to be performed by the emanation of images or corporeal species from objects to the eye; and the Peripatetics differed in opinion from the Epicureans by supposing the species received by the eye to be incorporeal. Modern philosophers agree in referring the cause of vision to the impressions of light on the eye; but whether this impression is made by material particles emanating from a self-luminous body, and reflected from visible objects, or by the medium of a fluid of great elasticity exciting the eye by the vibrations communicated to it by the luminous body, is a question which is still undetermined. (*See* LIGHT.) In what manner the eye, or the particular part of it affected by the light, conveys to the brain the impressions it receives from the luminous rays, is a question which philosophy has not yet solved, and will probably never be able to solve.

Seat of Vision. — The retina of the eye, on which an inverted image of external objects is formed, has usually been regarded as the seat of vision; but this opinion was long ago brought into doubt by the accidental discovery of Mariotte, that the base of the optic nerve is insensible to the rays of light, and consequently incapable of conveying to the brain the impression of vision. But the retina, being only the extension or contraction of the optic nerve, Mariotte inferred that if the former were the true seat of vision, that part of it at the entrance of the nerve, and where it exists in the greatest quantity, and where precisely vision is wanted, ought to be at least as sensible to the rays of light as the other parts. Mariotte, therefore, concluded that the choroid coat which lies immediately below the retina, and lines the whole bottom of the eye excepting the place at which the optic nerve is inserted, is the real seat and cause of vision. (*Priestley on Vision, Light, and Colours*, p. 722.; or *Hutton's Dictionary*.) The opacity of the choroid coat, and the transparency of the retina, which render it an unfit ground for the reception of images, furnish arguments in support of this view; and an interesting fact was observed by Sir D. Brewster which points to the same conclusion. He observed that in young persons the choroid coat, which is generally supposed to be black, and to grow fainter by age, reflects a brilliant crimson colour, like that of dogs and other animals. Hence, if the retina is affected by rays which pass through it, this crimson light, which must necessarily be transmitted by it, ought to excite the sensation of crimson, which he found not to be the case. ("Optics," *Cab. Cycl.* p. 291.)

M. Lehot, a French writer, has recently attempted to prove that the seat of vision is in the vitreous humour; and that instead of seeing a flat picture of objects, we actually see an image of three dimensions. To produce this effect, he supposes that the retina sends out a number of small nervous filaments, which extend into the vitreous humour, and convey to the brain the impressions of all parts of the image. (Id. p. 292. For further information on this subject, see *Jurin's Essay on Distinct and Indistinct Vision*, in *Smith's Optics; Robins' Tracts*, vol. ii.; a paper *On Vision* by Dr. T. Young, *Phil. Trans.* 1793; *Horn on the Seat of Vision*, 8vo. 1813.) *See* OPTICS.

VISION, BEATI'FIC. In Theology. The doctors of the church distinguish three manners of seeing or knowing God: which they call, 1. *Abstractive vision;* i.e. through the consideration of his attributes. 2. *Beatific* or *intuitive vision;* that which the faithful enjoy in heaven. (1 Cor. xiii. 12.) The belief termed Catholic by the Romanists is, that this vision is accorded to the just, who die without leaving a sin unexpiated, immediately on their departure. The Greek church holds that they do not enjoy it until after the general resurrection. This is one of the opinions condemned by the Council of Florence in 1439; and its decision is confirmed by that of Trent. 3. The third kind of vision, or *comprehension*, is that which belongs to God, who alone can know Himself as He is. Prophetic vision is only the knowledge of future or distant events, given by inspiration.

VISITA'TION. In Ecclesiastical Law, the inspection by the bishop of the several parishes in his diocese; or by an archbishop of the dioceses in his province. By the ancient canon law visitations were to be held once a year, and by the personal repairing of the ordinary to each parish; but the modern practice, which appears to have come gradually into use, owing to the extent of dioceses, is to summon the clergy from several parts to one convenient place. The times of episcopal visitations are now usually fixed in this country about Easter and Michaelmas. By Can. 60. of the English Church, such visitations for the purpose of confirmation must be triennial at least. The care of the ancient parochial institutions has by degrees devolved on the archdeacons. They are bound to see that the offices of the church are duly administered; to keep account of the ornaments, vestments, &c. appertaining to the churches; to examine into the state of repair of parsonages, churchyards, &c.; and to receive presentments of excesses committed by ecclesiastical persons. Ecclesiastical corporations, such as conventual bodies, had usually their special visitors appointed by the founder; as is the case at present with colleges in our universities, hospitals, &c.

VISITATION. A festival of the Western Church, in honour of the visit of the Virgin Mary to Elizabeth; said to have been first instituted among the Franciscans by Saint Bonaventure, general of that order. It is celebrated on the 2d July. A female religious order was founded in Savoy in 1610 by St. Francis de Salis, in honour of the visitation.

VISUAL ANGLE, in Optics, is the angle under which an object is seen, or the angle formed at the eye by the rays of light coming from the extremities of the object. *Visual rays* are the lines of light coming from an object to the eye.

VI'TAL VESSELS. A name given by Schultz to certain vessels ramifying in all directions in plants, especially near the surface, and conveying latex, which that

physiologist calls a vital fluid. The milk-vessels of spurges are vital vessels.

VITE'LLUS. In Botany, a name given to the fleshy sac that is sometimes present in seeds; interposed between the albumen and the embryo, and enveloping the latter. It is the enlarged sac of the amnios.

VITILI'GO. (Lat. vitulus, *a calf.*) A disease of the skin, giving it a white appearance somewhat resembling that of calves.

VI'TIS (Celt. gwid, *a tree*), the grape vine, is doubtless a native of Asia Minor, although its universal cultivation renders it no longer possible to distinguish the wild from the domesticated kinds. It is the type of the Vitaceous order, which consists of plants climbing by tendrils, and producing small green flowers, succeeded by succulent fruit. None of the species are, however, to be compared with the true grape, *Vitis vinifera*, for quality; the best of the American species being disagreeable to the taste, and some of the order even acrid. The reputed varieties of grape are innumerable, if we are to believe the writers on the subject; 1400 being cultivated in the garden of the Luxembourg alone. There is no doubt, however, that many of these are repetitions of each other. When the pulp is fleshy and sweet, and the skin thick, raisins are prepared from the fruit; and when it is watery and less sweet, with a thin skin, grapes are best suited for wine. The currants of the grocers are the dried berries of a small variety of the grape cultivated at Zante.

VITREOUS HUMOUR, so called from its glassy appearance, is the third or interior humour of the eye, filling a large portion of the eyeball, and greatly exceeding in quantity the aqueous and crystalline humours together. According to Sir D. Brewster, the refractive power of the vitreous humour is 1·3394. *See* Optics.

VI'TRIFIED WALLS or FORTIFICATIONS. Ancient remains discovered in Scotland, constructed of stones piled rudely upon one another, and firmly cemented together by some matter which has been vitrified by means of fire. They generally surround the top of some steep conical hill. They have been discovered chiefly in the Highlands, but also in Galloway. The vitrification is mostly external, the interior of the walls being a mere heap of loose stones. Daines Barrington considered the vitrification to be accidental, but his explanation of how it took place is not very intelligible. (*Archæologia*, vol. vi.) It seems more reasonable to suppose that the art was derived from observation of the ease with which some kinds of earth containing much iron ore are vitrified by fire, and that the process was rendered easy by the quantities of wood which in early days covered the Highlands.

VITRI'NA. (Lat. vitrea, *glass.*) A genus of freshwater Gastropods; so called from the extreme thinness and fragility of the shell, and its watery green appearance. *Vitrina pellucida* and *Vitr. elongata* are natives of Great Britain.

VI'TRIOL. (Lat. vitrum, *glass;* from the glassy character of its crystals.) This term is applied by the old writers to crystallized sulphate of iron, or *green vitriol:* sulphate of copper and sulphate of zinc were afterwards called *blue vitriol* and *white vitriol. See* Iron, Copper, Zinc.

VITRIOL, OIL OF. The old name of sulphuric acid, which was originally obtained by distilling green vitriol. *See* Sulphur.

VIVA'CE. (It. *lively.*) In Music, a term which, affixed to a movement, denotes that it is to be executed by the performer in a lively manner. It is a mean between *largo* and *allegro;* but, if any thing, rather nearer the latter than the former.

VIVE'RRIDÆ. (Lat. viverra, *a ferret.*) Civet tribe. The name of a tribe of Carnivorous Mammals, of which the genus *Viverra* is the type. The characters are three premolars above, and four below; two tolerably large tuberculate molars above, one tuberculate and one sectorial molar below; the tongue beset with firm papillæ; claws more or less retracted; a large anal scent-gland and pouch.

VIVI'PAROUS, *Vivipara.* (Lat. vivus, *alive*, and pario, *I bring forth.*) Those animals are so called which bring forth their young developed and alive, and commonly extricated from the egg coverings; as all the Mammalia, which were hence called Zootoka by Aristotle; many reptiles, as the viper or "viviper;" some fishes, and numerous invertebrate animals. In its restricted sense, the term signifies that mode of generation in which the chorion, or external tunic of the ovum, contracts a vascular adhesion with the uterus; and hence only the Placental Mammalia are truly viviparous, the rest being termed ovi-viviparous.

VIZIR. (In Arabic *a porter;* and, by a singular metaphor, the title in various oriental countries of a minister and councillor of state.) The grand khalifs had their vizirs, who attained to the highest rank and consideration in their states, and were often more powerful than their masters; but after the creation of the new dignity of Emir-ul-omrah (commander of commanders), by Khalif Radhi, the older title lost much of its consideration. In Turkey, the councillors of state who sit in the divan, generally eight in number, are styled vizirs; and the chief among them vizir azem, rendered by us by grand vizir, which is the highest temporal dignity in the empire.

VOCA'TION. (Lat. voco, *I call.*) In Divinity, the grace vouchsafed by God to any man in calling him from death unto life, and putting him into the way of salvation. It is also used for the call of the Holy Spirit, by which persons are supposed to be initiated into the clerical order.

VOICE. The sound produced by the vibration of air emitted from the lungs of animals, which vibration is caused by an organ developed in the wind-pipe, called the "larynx." Mammals, birds, and reptiles, are the only animals, which, according to the above definition, possess a voice; but many species of other classes produce peculiar sounds, by which the individuals are attracted to each other, or express their wants and feelings. A true organ of voice includes the lungs, bronchi, trachea, larynx, and mouth. The most essential parts are two vibratile chords bounding a slit-shaped aperture, called the "glottis," and this may be situated at different parts of the air-tube in different animals; the portion of the tube between the glottis and the oral outlet being the true sonorous instrument. In mammals and reptiles the glottis is situated at the end of the wind-pipe, which communicates with the bronchial tubes, and consequently the whole trachea becomes, in this class, part of the vocal instrument. The organ of voice in reptiles consists of a simple larynx, without an epiglottis, and in which the glottis is merely membranous, not provided with fibrous vocal chords. Since neither fleshy moveable lips nor soft palate exist in this class, the voice cannot undergo any farther modification after its formation by the simple larynx. It consequently rarely rises beyond a hiss; and in the frog tribe, where the bones or gristles of the larynx are largest and most complicated, and the vibratile membrane of the glottis is best developed, the voice is only a more or less noisy croak.

In mammals, the air driven by the muscles of expiration from the lungs through the trachea strikes against the two vibratile "vocal chords," which bound the sides of the glottis; and a voice is produced, varying in different animals, according to the power of regulating the degree of tensions of the chords, and according to the size and shape, and various complications of the laryngeal sacculi of the pharynx, of the tongue, and of the mouth and lips.

The superior organization and mobility of the tongue and lips enables man to modify his vocal sounds so as to render them articulate, and adapted to express the ideas which it is his peculiar privilege to form. Although some quadrupeds possess the imitative faculty, and can be taught to do certain tricks, it would seem that the physical condition of their vocal organs is an insuperable impediment to their imitation of the human speech.

The sacculi or membranous pouches which communicate with the larynx in the chimpanzee, orang, and most other quadrumanous animals, together with their thicker and more confined tongues and less flexible lips, are assumed to constitute the impediments to speech in them; but it may be doubted whether they have the imitative faculty for sounds possessed by the parrot or starling; and in respect of their voluntary application of their vocal organs to speech, the absence of any such application is accounted for by presuming that they have nothing to say.

In birds, which possess the most diversified and complicated organ of voice, combined in some species with a high degree of imitativeness, instances are not uncommon, especially in the parrot and crow tribe, of an acquired power of forming articulate sounds superadded to the ordinary voice.

VOIRE DIRE. (Norm. Fr. a corruption of vrai dire, *to speak the truth.*) In Law, according to ancient practice, an objection to the competency of a witness, in a trial at common law, could only be taken on a preliminary examination, in which the witness was sworn *to speak the truth*, and then examined touching his interest in the subject matter. The same practice is still followed occasionally, although the objection may now be taken when it arises on the examination in chief.

VOLATILE ALKALI. *See* Ammonia.

VOLCA'NO. *See* Geology.

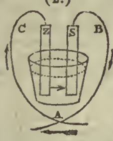
VOLTA-ELE'CTRIC INDUCTION. The term *induction*, as applied to common electricity (of tension), has been explained under the word Electricity. By volta-electric induction, we mean the electricity that is induced by a proximate electric *current*. The phenomena thus produced were discovered by Mr. Faraday in 1831 (*Philos. Trans.*), and were briefly as follows: — A long copper wire was wound in the form of a spiral round a cylinder of wood; a similar, but perfectly separate spiral, was then wound upon the same rod, the coils of each

being interposed and close to each other, but nowhere in contact; the extremes of one of the wires were then connected with the galvanometer, and those of the other with a voltaic battery. At the moment of making the contact with the battery, as well as of breaking it, the deflection of the galvanometer indicated a current of induced electricity in the proximate spiral; but in the interval, that is, whilst the current of electricity was continuing quietly to traverse, no deflection took place: the induced current was found to be in one direction upon making the contact, and in an opposite direction upon breaking it.

VOLTAIC ELECTRICITY. The phenomena resulting from the evolution of electricity by chemical action, as manifested by that important instrument of electro-chemical research called the *Voltaic Battery*, are usually included under the above term. Whenever substances act chemically upon each other, their electrical states are disturbed; but the electricity thus evolved is, in ordinary cases, so lost and dissipated as to escape observation. It may, however, be rendered manifest by the following simple arrangements:—When a plate of pure zinc (or of common zinc rubbed over or amalgamated with mercury) is dipped into a glass of very dilute sulphuric acid, little or no action is observed; nor does any thing happen when a similar plate of silver is placed in the same cup of acid, provided the metals be kept apart from each other. But if, as in the annexed figure, the zinc and silver be brought into contact, at their extremities out of the liquid, the water is decomposed; its oxygen combines with the zinc to form oxide of zinc, which is dissolved by the acid; and its hydrogen passes over to the surface of the silver, where it collects, and ultimately escapes in gaseous globules. These phenomena are further connected with the production of a continuous current of electricity passing *from* the zinc across the water *to* the silver, and again from the silver, by metallic contact, to the zinc, in the direction represented by the darts. It is not necessary that the metals should be connected exactly as represented in the above diagram; but it *is* necessary to the establishment of the continuous electric current that they should be somewhere in contact, or at least connected by what is usually termed a perfect conductor. By modifying (as represented in the margin by fig. 2) the preceding arrangement, so that the metallic contact between the plates be made *out* of the vessel, namely, at the point A, the electric current takes the same direction, travelling through the liquid *from* the zinc or generating plate Z *to* the conducting plate S, and through the wires B and C back again to Z, as shown by the darts. Here again Z is oxidized and dissolved, and hydrogen is liberated upon S; but the moment that the circuit is broken, by parting the wires at A, these actions cease, because the electric current ceases to flow. It is evident that various substances may be interposed between the wires at A, or they may be immersed into different liquids; and provided these are capable of transmitting electricity, the current will still pass, and its phenomena under a variety of circumstances may be studied. In this arrangement the end of the wire B is the *emitting*, and of C the *receiving* point or pole; hence these have been termed, in reference to the common electrical machine, the *positive* and *negative poles*. Mr. Faraday, with a view of avoiding certain misapprehensions to which these terms give rise, calls them the *electrodes;* the positive electrode he further terms the *anelectrode*, and the negative the *catelectrode*. See ANODE.

(1.)

(2.)



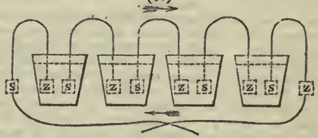
In the preceding paragraph it has been assumed that the generating metal is *zinc*, the conducting or conveying metal *silver*, and that the intermediate liquid is *dilute sulphuric acid*. A number of other metals may be substituted for the above; namely, for the zinc, cadmium for instance, or iron; and for the silver, platinum, gold, or copper. Many liquids may also be substituted for the dilute sulphuric acid; the requisite condition being that one of the metals shall be chemically acted on, whilst the other is indifferent, or at least not acted on by the liquid to the same extent. And the current is always in the direction above represented; that is to say, passes *from* the metal most attacked *to* that least attacked, whenever the communication is perfect or the circle closed. In the above cases also certain forms of charcoal, which are excellent conductors of electricity, may be substituted for the conveying metal, or passive element of the arrangement. Another requisite condition to the phenomena properly called *Voltaic* is, that the interposed fluid shall conduct; and further, that it shall be capable of that form of decomposition which Faraday has designated *electrolysis*, that is, resolvable into its elements by the electric current. See ELECTROLYTE.

Such, then, are the conditions requisite for this evolution of electricity. The existence of the electric current, and its direction, may be rendered manifest in various ways: the most striking is perhaps afforded by its magnetic effects, as exhibited by the galvanometer. See GALVANOMETER and ELECTRO-MAGNETISM.

The *quantity* of electricity generated in the above instances depends chiefly upon the superficial extent of the metals concerned, and upon the activity of the liquid acting upon the generating metal; and that it is considerable, even where small surfaces and weak acids are used, is manifest by the violence with which the magnetic needle of the galvanometer is deflected. But in the above described arrangements, the *intensity* of the electricity is very feeble; and in order to attain this, and to give the current that apparent impetus which it requires to traverse bad conductors, and easily to effect electro-chemical decompositions, it becomes necessary to repeat the metallic alternations; or, in other words, to employ a properly arranged succession of generating, conducting, and electrolytic substances. This leads to the grand discovery of Volta; namely, the construction of the *Voltaic Pile* or *Battery*.

In this arrangement, which, like the simple circles, admits of infinite varieties, the metals generally used are zinc on the one hand, and copper or silver or platinum on the other. The alternations originally adopted by Volta, and which are quite effectual, were zinc, silver, and flannel or pasteboard soaked in acid; and these were repeated according to the effects that were to be obtained. The inconvenience of arrangement led him, however, to various modifications of it; and, among them, to that represented in the following diagram (fig. 3.), which he called the *crown of cups* (couronne

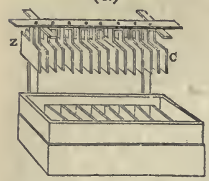
(3.)



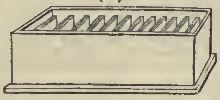
des tasses), and which, slightly modified, has since been very generally adopted. The flannel is rejected, and in its place a cup of dilute acid, or other proper electrolyte, is substituted; so that each silver and zinc plate are in metallic communication, though in separate vessels: the arrangement being zinc, acid, silver; zinc, acid, silver, &c. Here the direction of the electric current is the same as in the simple circle, namely, from the zinc through the liquid to the silver; but in this form of the apparatus, for the mere convenience of carrying on the series, the conducting wire connected with the first zinc plate has a supernumerary silver one attached to it, and that with the last silver plate a supernumerary zinc plate; so that much confusion has arisen in regard to the direction of the current in these cases, in consequence of calling what is here the silver extreme the *negative pole*, and the zinc extreme the *positive pole;* whereas it is in fact the reverse, and the circulation of the current goes on through the electrodes precisely as in the simple circle. But though the *direction* of the current is the same, and the absolute *quantity* of travelling or circulating electricity not increased, the case as regards *intensity* is very different; and with numerous series arranged as above we obtain, on removing the electrodes (which in this experiment ought to consist of pointed pieces of well-burned boxwood charcoal) a little from each other, a most brilliant and continuous current of fire, luminous, so that the eye can scarcely endure it, and capable of overcoming obstacles and traversing conductors and electrolytes in a way essentially different from that of the simple circuit. Yet even with all these energetic phenomena, and with a quantity of circulating electricity far beyond any thing which the most powerful frictional machines can afford, the intensity is still insufficient to penetrate a thin layer of card or paper, or to make its way through non-conducting obstacles, as it does in the case of the discharge of the Leyden jar or battery. And now, if the hands be well moistened with salt and water, so as to overcome the non-conducting tendency of the cuticle, and the body be made part of the circuit, an extraordinary and unendurable sensation is perceived, which is in fact a *continuous shock*. By the same means wires may be ignited, metals burned, combustibles exploded, magnets made, and galvanometers affected, at any distance from the pile, provided the conducting communication is perfect. Thus it is that this power has been used to blast rocks, to explode gunpowder under water, and to communicate telegraphic signs, as in the arrangement of Professor Wheatstone.

The modification of Volta's couronne des tasses, and the form of voltaic apparatus in most general use, is the annexed (fig. 4.), in which the plates are attached, in proper order and connection, to a piece of dry wood, so that they may at once be plunged into the cells of the porcelain trough over which they are suspended. Sometimes also plates of zinc and copper soldered together are cemented into a wooden trough with intervening cells, which, when required for action, are filled with proper acid or saline solutions, as shown in fig. 5.

(4.)

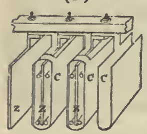


(5.)



An important modification, as regards the arrangement of the plates of fig. 4., introduced by Dr. Wollaston, is represented in fig. 6.; in which the copper plate, instead of being single, is doubled over the zinc plate, actual contact being prevented by wooden cylinders placed between them. In this way much of the electricity lost in the preceding arrangements is brought into circulation.

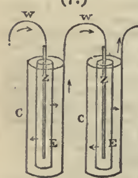
(6.)



But the most important modification of this instrument is that suggested by Mr. Daniell, and which he terms "a constant battery." In all the preceding arrangements the electrical power is liable to fluctuation; and after a time various causes induce such a falling off of its evolution as to render them inconvenient, or even useless, where continuous or regular action is required. In Wollaston's battery, for instance, which is the best of them, several circumstances combine to render it inconstant in its action: the adhesion of hydrogen to the copper plate, and the precipitation of zinc upon it, the saturation of the acid by oxide of zinc, and the ocal action which common zinc induces, are perhaps the principal sources of the above-mentioned irregularity and inconstancy. In Mr. Daniell's arrangement those inconveniences are to a great extent obviated; and although it is more complicated than the preceding, its constant and regular action, when it is properly constructed, amply repays the additional trouble and expense: there are, indeed, many investigations which can scarcely be carried on without it.

The annexed diagram, fig. 7., which is intended to represent two cells of the constant battery, may perhaps serve to illustrate the arrangement.

(7.)



C C are cylindrical vessels of copper; E E smaller cylinders or tubes of porous earthenware; Z Z are rods of amalgamated zinc, which are connected by the wires W W with the next copper cylinder, and so on in succession. The porous tubes are filled with dilute sulphuric acid (about 1 part of acid to 8 of water); and the copper cylinders are filled with a strong solution of sulphate of copper, also acidulated by sulphuric acid: so that the acid in the generating cells is separated from the solution of sulphate of copper; but the porosity of the tubes allows of their becoming so far imbued with the acid liquid as to admit of the passage of electricity, the current being in the direction of the darts. At the same time the sulphate of zinc is prevented mixing with the sulphate of copper, and thus all precipitation of zinc upon the copper prevented; while at the same time the hydrogen evolved in the copper cells or cylinders tends to reduce the oxide of copper, and continuously to throw down a film of metallic copper, with which they ultimately become lined. In proportion as the sulphate of copper is decomposed fresh portions of that salt are added, and the acid in the generating cells requires occasional renewal: for the former purpose there is a perforated receptacle or colander in the upper part of the copper cell, which is kept filled with crystals of sulphate of copper. (See *Daniell's Introduction to Chemical Philosophy*, p. 438.)

It has already been stated that, in all the ordinary forms of the voltaic battery, two metals and an acid dissolved in water are the essential elements. But it is by no means necessary that two metals should be employed to obtain an electric current; for if only one metal be used, different parts of which are differently acted on by an acid or other fluid, electricity will be evolved, according to the same law, the portion of the metal most acted on becoming the *generating* element. Thus, a current is established when a plate of clean zinc and one of oxidized or corroded zinc are used; or even when one of the plates is of cast and the other of rolled zinc. So also when a stick of copper, clean at one end and corroded at the other, is immersed in dilute nitric acid, an electric current is produced. In all these cases the surface most open to chemical action corresponds to the zinc, and that least so to the silver of the above described simple circles.

An electric current is also manifested when a single plate of metal of uniform surface is acted on by two fluids exerting distinct chemical actions upon it. If, for instance, a vessel be half filled with a strong solution of sulphate of copper, and then carefully filled up with dilute sulphuric acid, so that the latter may lie upon but not mix with it, a plate of iron immersed will be so acted on as to produce an electric current; the upper part becoming the equivalent of the zinc, and the lower that of the copper in the simple circle. A plate of copper immersed in the same way will produce a similar effect, and metallic copper will be deposited upon its lower end. (See *Faraday's Researches, Philosophical Transactions*, 1840.)

The chemical powers of the electric currents produced by and circulating under the circumstances above detailed are, to a certain extent, manifest by the phenomena of the pile itself; but they are more especially illustrated by interposing different substances between the electrodes in proper vessels, so that the changes which they suffer in the axis of the electric current may be more conveniently and distinctly observed. Under these circumstances, we find that all electrolytes must, to a certain extent, be conductors; and that the same body in different states may either be or not be an electrolyte, according as it has or has not a power of conduction. Thus *water* is a conductor and an electrolyte; but *ice* is a non-conductor, and therefore unsusceptible of electrolysis. So also nitre, chloride, iodide, and bromide of silver, and many other salts, require to be *fused* in order to become susceptible of electrolytic action. It would moreover appear probable, from Faraday's researches, that all bodies susceptible of true or primary electrolytic action (electric decomposition) must be compounds of single atoms, or equivalents of their components (*proto-compounds*): thus protochloride and protoiodide of tin are decomposed, but the bichloride and biniodide are not. Of this phenomenon the ultimate cause requires further investigation. The principal apparent exceptions to it have beeen ranked by Faraday among cases of *secondary decomposition*. Thus when common sulphuric acid, or oil of vitriol (which is a compound of 1 atom of sulphur, 3 of oxygen, and 1 of water, or the ultimate elements of which are 1 atom of sulphur, 1 of hydrogen, and 4 of oxygen), is subjected to the electric current, sulphur and hydrogen appear at the cathode (or negative electrode), and oxygen at the anode (or positive electrode). But in this case the sulphur is the result of the action of the hydrogen upon the acid; for in all cases of true or primary electrical decomposition of the sulphurets, the sulphur is evolved at the anode.

Not only, however, are the ultimate elements of binary compounds thus evolved in obedience to certain uniform laws, but *proximate* elements are also similarly separated. Thus when sulphate of soda, nitrate of potassa, and other neutral salts, are subjected in aqueous solution to the action of the current, the respective acids travel with the oxygen to the anode, and the alkalies, oxides, or bases, with the hydrogen to the cathode. Faraday terms substances susceptible of these transferences *ions*, and those which go to the anode *anions;* those to the cathode *cations:* thus doing away with the less definite terms of *electro-negative* and *electro-positive* bodies. And he has drawn up the following table of simple and compound anions.

Anions.

Oxygen.	Sulphuric acid.
Chlorine.	Phosphoric acid.
Iodine.	Carbonic acid.
Bromine.	Nitric acid.
Fluorine.	Selenic acid.
Sulphur.	Chloric acid.
Selenium.	Boracic acid.
Cyanogen.	Acetic acid.
Sulpho-cyanogen.	Tartaric acid.
	Citric acid.
	Oxalic acid.

Cations.

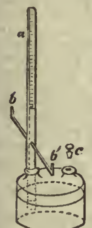
Hydrogen.	Nickel.
Potassium.	Antimony.
Sodium.	Bismuth.

Lithium.	Mercury.
Barium.	Silver.
Strontium.	Platinum.
Calcium.	Gold.
Magnesium.	Ammonia.
Manganese.	Potassa.
Zinc.	Soda.
Tin.	Lithia.
Lead.	Baryta.
Iron.	Strontia.
Copper.	Magnesia.
Cadmium.	Alumina.
Cerium.	Protoxides generally.
Cobalt.	Vegeto-alkalies generally.

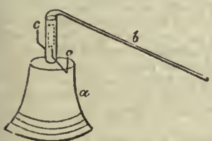
Analogy leads us to assume that all elementary bodies are *ions;* but this has not been experimentally proved in regard to carbon, phosphorus, nitrogen, silicon, boron, and aluminum.

VOLTA'METER. (Ital. volta, and Gr. μετρον, *a measure.*) An instrument contrived by Mr. Faraday for measuring the voltaic electricity passing through it, and which, being interposed in the course of the current used in any particular experiment, serves as a *comparative standard* of effect, or as a *positive measurer* of the electricity.

The indicating body used in this instrument is water acidulated by sulphuric acid. The electrodes are plates of platinum; and the quantity of electricity which has passed is indicated by the quantity of the mixed gases (oxygen and hydrogen, resulting from the decomposition of the water) evolved, or, in other words, by the weight of water decomposed. When the quantity of evolved gases is small, the voltameter represented in the margin is a good form: *a* is a graduated straight tube closed at the upper end, and including two platinum electrodes, connected with the external wires *b b*. This tube is fitted by grinding into one mouth of the double-necked bottle containing the acidulated water, and is filled by inclining it; so that when an electric current is passed through it the gases evolved collect in the upper part of the tube and displace the dilute acid, the stopper *c* being left open. When the graduated part of the tube is filled with the mixed gases the electric current may be broken by removing the wires connected with *b b*, the stopper *c* replaced, and the meter-tube refilled by inclining the instrument; a second measure of the gases is then collected on re-establishing the circuit, and so on.



When large quantities of the mixed gases are to be measured, as in cases where the current is left continuous for several hours or days, a voltameter in the form of a small retort may be used, set up in the block or foot *a*, and the evolved gases will then pass by the tube *b* into the common pneumatic trough, where they may be received into a graduated jar and measured: *c c* are the projecting wires by which communication is made with the platinum electrodes.



In using these and similar forms of apparatus for the electro-chemical decomposition of water, great care must be taken that the electrodes are kept continually covered by the water, and that their ends are never exposed to the mixed gases in the tube; for in that case they would be apt to become heated, and even incandescent, in consequence of the peculiar action of clean platinum on a mixture of hydrogen and oxygen, and in such a case an explosion might ensue. In these voltameters the contact of the electrodes is prevented by inserting between them a small piece of glass tube.

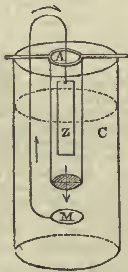
VO'LTATYPE, or ELECTROTYPE. It has been stated under the article on VOLTAIC ELECTRICITY, that when metallic solutions are subjected to the transmission of the electric current, the metallic oxides which they hold are in certain cases decomposed; so that the metal in its pure state is deposited upon the cathode, or upon what is usually termed the negative electrode. In these cases the metallic deposition is usually a secondary effect, arising out of the action of the hydrogen evolved at the cathode upon the oxide of the metal. A good illustrative experiment of this metallic precipitation consists in plunging two pieces of clean platinum into a solution of sulphate of copper: nothing happens. But if the electric current be transmitted through the solution, so that these platinum plates may form the electrodes, copper is immediately precipitated upon the catelectrode or negative surface, the positive surface or anelectrode remaining clean. If the current be now reversed, the copper will be removed from the platinum plate upon which it had just been deposited, and will be transmitted to the clean plate; and thus by reversing the direction of the electric current, the copper may be sent backwards and forwards, it always being deposited upon the negative pole, or, in other words, upon that surface by which the electric current leaves the electrolyte. A solution of sulphate of copper is particularly well adapted to this experiment, especially if it be slightly acidulated by sulphuric acid, inasmuch as it deposits the copper in a clean metallic state; and by a continuance of the electric current, and keeping up the strength of the solution by the occasional addition of fresh portions of the salt of copper, the metallic film upon the cathode may be obtained of any required thickness, and may afterwards be peeled off the platinum surface. The texture of the deposited copper varies with the power employed and with the temperature and strength of the solution; so that it may be obtained hard, brittle, and crystalline, or malleable and tough, or even pulverulent, according to the management of the operator. A low electric power, or rather a current of low intensity, a moderately strong acidulated solution of sulphate of copper, and a temperature not below 60° or 70°, are the circumstances under which the best deposit of copper is usually obtained for the purposes to which this process is commonly applied.

When the negative pole or cathode, instead of being, as above represented, a plane surface of platinum, is irregular, or worked into a pattern, or a medal or coin for instance, an exact impression of the irregularities of surface, or of the device upon the medal or coin, may be taken off on the precipitated copper; and to copies or plates of this kind the term *voltatype*, or *electrotype*, has been more particularly applied. Gold, silver, and other metals may, by proper management, be substituted for copper, and thus a variety of voltatypes may be obtained; or, if the precipitated metal be left upon the surface on which it is thrown down, gilding, silvering, and coppering may be extensively and beautifully effected. Thus it is that a new art of *plating* has arisen also out of these electro-chemical actions.

We shall now proceed briefly to point out the manipulation in a few of the principal applications of this new art, and to describe the apparatus commonly employed; illustrating the subject, in the first instance, by one of the simplest cases, in which we will suppose that an impression in copper is to be obtained from a copper medal, which, being in relief, will of course yield an impression in indent: the original being a cameo, the copy will be an intaglio.

The medal is first slung in a loop of annealed copper wire, so that it may be conveniently suspended and made electro-negative in the metallic solution; the following simple voltaic arrangements may then be used.

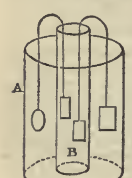
A is a glass cylinder (a common lamp-glass answers the purpose), closed at bottom with a piece of bladder, or with a plug of plaster of Paris, and filled with dilute sulphuric acid (1 of acid to 8 of water by measure); Z is a piece of zinc immersed in the acid, and connected by a copper wire with the medal M; C is a jar nearly filled with a strong solution of sulphate of copper, acidulated by the addition of about a tenth part of sulphuric acid. In this arrangement, the acid in the generating cell is prevented mixing with the solution in the jar by the diaphragm of bladder or plaster; which, however, when thoroughly wetted, suffers the electric current to pass from the zinc to the medal (or negative pole), and so through the wire, in the direction of the darts, back to the zinc. In this way a film of metallic copper is gradually thrown down upon M, which goes on increasing, and which, when it is sufficiently thick (perhaps in 24 or 30 hours), the wire with Z and M at its ends is lifted out; and by the point of a knife carefully applied, and aided, if necessary, by a file, the deposited copper is pulled off of M, of which it presents a faithful and minute copy or impression. To prevent the deposition of copper upon the edges, and upon the reverse of the medal, those parts should be covered with a varnish not acted upon by the solution; and the connecting wire should also be similarly varnished, to prevent its receiving an unnecessary incrustation of copper. In this way, by careful management, any number of impressions may be taken from either side of a medal without materially injuring the original; and for the medal any other metallic plate may be substituted, provided its dimensions and weight be not such as to render it inadmissible or inconvenient in this form of apparatus.



But it often happens that the article to be *voltatyped*,

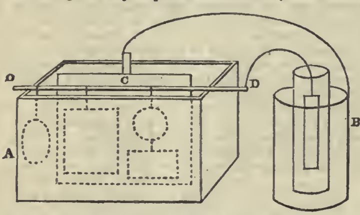
as this process is now called, is not a conductor of electricity; as, for instance, a seal, or sulphur or wax impression, or a plaster cast of a medal or coin. In these cases the surface is carefully covered by a film of the purest plumbago, or black lead, which is applied by a soft brush, and which, being a good conductor of electricity, renders the surface equivalent to that of a metal, care being at the same time taken that the conducting wire is in good contact with the plumbago, so that the electrical current may be nowhere intercepted by a non-conductor. Where the material of the cast is porous, or permeable to water, it must be imbued with melted wax or oil, or some kind of fatty matter; where plaster casts are used, melted spermaceti answers best: the surface to be voltatyped is then carefully blackleaded, and the process carried on as above. The use of black lead, so extremely convenient in these and a number of similar cases, was first suggested by Mr. Robert Murray, and communicated by him to the Society of Arts, who awarded a medal for the invention.

In the case of seals, coins, and other small articles, a number of them may be put in process at once by the following modification of the above described apparatus. A is a jar filled with a saturated and slightly acid solution of sulphate of copper; B is a porous earthenware cylinder, similar to those used in Daniell's constant battery, filled with dilute sulphuric acid. The articles to be coated with copper are prepared as above described, and attached to copper wires having a small piece of zinc at their other end; several of these may then so be suspended round the porous tube as that the zinc being in the acid, and the coin or seal in the cupreous solution, the process goes on until the voltatype is perfect.



When a number of articles of different sizes are to be voltatyped, the following is the preferable arrangement, and is that which is generally used where the process is employed upon a large scale; as in preparing voltatypes from wood-cuts, copper-plates, plaster casts, &c.

A is a trough of any required dimensions, made of slate



or wood, and filled with a proper solution of sulphate of copper; C is a copper-plate immersed in the trough, and forming the positive electrode of the constant battery B (of which one cell only is here represented, but of which two or more may be employed as required); D D is a copper rod forming the negative electrode, to which the articles to be coated with copper are suspended by copper wires. These several articles, previously properly prepared by the means above described, are retained in the circuit till adequately coated by copper. In this form of apparatus it is not necessary to provide against the impoverishment of the cupreous solution; for in proportion to the quantity of copper deposited upon the moulds is that which is taken up from the plate C, and when this plate is so far dissolved as no longer to form an effective electrode it must be replaced by another.

Where other metals are to be employed, proper solutions must be selected for the purpose, and the electric power modified accordingly: the weakest power, consistent with the precipitation of the metal and the non-evolution of hydrogen at the negative electrode, is that which is generally to be preferred. For gilding copper or silver, the solution which is generally employed is a double cyanide of gold and potassium: it is made by dissolving about 60 grains of sulphuret or of oxide of gold in a pint of a solution of cyanide of potassium containing 1 part of the cyanide to 10 of water. The sulphuret of gold is prepared by precipitating a solution of perchloride of gold by sulphuret of potassium, and washing the precipitate with hot water: the oxide of gold may be similarly prepared by precipitating the solution of the chloride by carbonate of potassa at a boiling heat. With this solution silver and copper may be effectively gilded, and the thickness of the coat of gold may be carried to any required extent. If it be desired to gild the inside of a silver vessel, the vessel may be filled with the gilding solution, and connected by its outside with the negative electrode, a plate of gold immersed into the centre of the solution in the vessel constituting the positive electrode.

For covering or plating articles with silver, a solution of 60 grains of chloride or of oxide of silver in a pint of the solution of cyanide of potassium of the strength above stated is to be used. In this case the article which is to receive the deposit is made the negative electrode, and a plate of silver may be used as the positive electrode. Here, as in the case of gold, the plating may be carried to any extent, and articles from which the silver has been abraded by wear may easily be replated.

In all cases where silver or gold is to be thus voltaically deposited so as to give a durable adhesive coating, the receiving surfaces must be perfectly clean; hence the necessity of dipping them in the first instance into warm aquafortis (or nitric acid diluted with three or four parts of water), and then washing them in a large quantity of pure water, previously to putting them into the solution: it is also generally right to make the connection with the battery, and immerse the positive pole, previous to putting the article into the depositing liquid. Messrs. Elkington of Birmingham, who have patented these operations, have produced a number of beautiful specimens both of gilding and silvering, and have largely applied them in numerous processes of the arts.

Mr. Palmer of London has made the most important applications of these precipitations to the purposes of the fine arts, in voltatyping the plates of engravings executed by the first artists. In these cases much care and dexterity are required in the manipulations, but the results are then beautifully perfect. The first impression of the etched or engraved plate is of course in relief, and serves as a *matrix*, from which any number of impressions in indent (or fac-similes of the original plate) may be obtained. Mr. Palmer has also invented various modifications of the process, full descriptions of which would be inconsistent with our present object, but which promise to render it much more extensively subservient to the purposes of the fine and useful arts. Messrs. De la Rue have also carried these processes to great perfection, and have extensively multiplied their applications to various purposes of ornamental printing. (See the article VOLTAIC ELECTRICITY in this Dictionary. Also Mr. Smee's *Elements of Electro-Metallurgy*, whose platinized silver battery is well adapted to most of the preceding operations.)

VO'LTI. (It. *turn*.) In Music, a term directing that the leaf is to be turned over.

VO'LUME. (Lat. volumen, from volvo, *I roll*.) A book. Thus a library is said to consist of so many thousand volumes, and a long work is divided for convenience into several volumes. Every single roll of paper or parchment, in an ancient library, was of course equivalent to a single book in one of our own; hence the name is derived. It should seem that the *books* (in the sense of divisions of the subject) of ancient works were originally actual volumes; so that the *History* of Herodotus or *Iliad* of Homer consisted of as many volumes, in ordinary writing, as books. The French word *tome* (signifying, properly, a single volume of a work containing more than one) is derived from the Greek *τεμνειν*, *to cut* or *divide*.

VOLU'TA. (Lat. voluta, *a wreath*.) A name applied by Linnæus to a genus of the *Vermes Testacea*, including those which have a univalve spiral shell, with an aperture without a beak, and somewhat effuse; and a columella twisted or plaited, generally without lips or perforation. The Mollusca thus characterized form a family in the Buccinoid tribe of the Pectinibranchiate Gastropods of Cuvier's system, and are distributed into the following subgenera:—*Oliva*, Brug.; *Volvaria*, Lam.; *Voluta* proper; *Cymbium*, Montf.; *Marginella*, Lam.; *Colombella*, Lam.; *Mitra*, Lam.; *Cancellaria*, Lam.

VO'LUTE. (Lat. volvo, *I roll*.) In Architecture, the spiral scroll appended on each side to the capital of the Ionic order. The Corinthian and Composite capitals are also decorated with volutes; but their character is different, their size smaller, and they are always diagonally placed. In the Corinthian order they are more numerous, and in the Composite they are larger than in the Corinthian.

VO'LVA, or WRAPPER. A term used in describing fungi to denote the involucrum-like base of the stipes of *Agaricus*. It was originally the bag enveloping the whole plant, but was left at the foot of the stipes when the plant elongated and burst through it.

VO'LVULUS. (Lat. volvere, *to roll up*, because it was supposed to arise from twisting of the intestines.) *See* ILIAC PASSION.

VO'MICA. (Lat. vomo, *I spit up*.) An abscess of the lungs.

VOMITO'RIA. (Lat. vomo.) In Architecture, the openings, gates, or doors, in the ancient theatres and amphitheatres, which gave ingress and egress to the public.

VO'RTEX. (Lat.) An eddy or whirlpool; a body of water running rapidly round and forming a cavity in the middle, into which floating bodies are drawn. The term is also applied to whirlwind. In the Cartesian philosophy, vortex signifies a collection of material particles, forming a fluid or ether, endowed with a rapid rotatory motion about an axis. By means of this hypothesis, and the received doctrine of centrifugal forces, a plausible explanation may be given of the motion of the planets, which move nearly in the same plane; but the motions of the comets which traverse the heavens in all directions are inexplicable, and in fact are inconsistent with the hypothesis. Descartes, nevertheless, had the merit of attempting to show how the universe might have assumed its present form and be preserved on mechanical principles. For an explanation of the system of vortices, see *Maclaurin's Account of Newton's Philosophical Discoveries.*

VO'RTICEL, *Vorticella.* (Lat. vortex, *a whirlpool.*) The generic name of certain pedicellate Wheel Animalcules, which are provided with vibratile organs at their anterior extremity, whose apparently rotatory actions produce little whirlpools in their vicinity, and thus attract the particles of food.

VO'TIVE. (Lat. votum, *vow.*) In Numismatics, votive medals are such as were struck in grateful commemoration of any auspicious event, such as the recovery from sickness of a prince, &c.; especially those of the Roman emperors, struck every five, ten, or twenty years, on which the public vows on their behalf are recorded. The custom is said to have originated in the repeated continuance of Augustus in his high offices at the prayers of the people. A votive tablet, picture, &c., is one dedicated in consequence of the vow of a worshipper; in classical Europe to some deity, in modern Roman Catholic countries to saints.

VOU'SSOIRS, in Bridges, are the stones which immediately form the arch, being of the shape of a truncated wedge. Their under sides form the intrados or soffitt. The length of the middle voussoir, or keystone, ought to be about 1-15th or 1-16th of the span, and the rest should increase all the way down to the imposts. Their joints should be cut perpendicular to the curve of the intrados; consequently the angle of the sides is determined by the curvature. (*Hutton's Tracts*, vol. i.)

VOW. (Lat. voveo, *I vow.*) A promise made to God of a thing which we believe to be agreeable to him, and which we are not on other grounds obliged to render to him. This is what the Theologians understand by it, when they say a vow is "promissio de meliore bono." To promise God to do what he commands, or to avoid what he forbids, is not a vow, because we are under an obligation so to act. (*Dict. de Theologie*, Toulouse 1817.) The use of vows is found in most religions. The Roman Catholics adduce numerous passages from the Old Testament to prove that vows are acceptable to God; the Protestants on the other hand reject the theory of vows as altogether untenable.

VOW'EL. In Grammar, a letter which can be pronounced alone, thus distinguished from consonants, which require to be sounded with the aid of a vowel. They are divided in ancient prosody into long, short, and common (ancipites), *i. e.* either long or short at pleasure. A diphthong consists of two vowels, of which the sounds run (or are supposed to run) into one another.

VU'LCAN. In Mythology, the Latin name for the divinity called by the Greeks Hephæstus, — the god who presided over the working of metals. He was also called Mulciber. He was the son of Jupiter who, incensed at his interference on the part of his mother Juno, cast him out of heaven: he fell in the isle of Lemnos, and broke his leg in the fall. His feats as the patron of armourers and workers in metal, his marriage with Venus, and her infidelities, form the subjects of many of the best known classical stories. (See Bryant, *Anc. Myth.* vi. 115.) There is about the character of Vulcan much of the usual confusion belonging to Greek mythology. Cicero mentions three Vulcans, besides the son of Jupiter: one, the child of Uranus; another, of Nilus, who reigned in Egypt; a third, of Mænalius. A peculiarity attending the worship of Vulcan was, that the victims were wholly consumed, in reference to his character as God of Fire. In sculpture, he is represented as bearded, with a hammer and pincers, and a pointed cap. He does not appear lame, as represented by the poets. Cicero, however, praises the sculptor Alcamenes for making his lameness observable without amounting to deformity. The description of his cavern in the Isle of Vulcan, or Hiera, in the 8th Book of the *Æneid*, is among the best known passages in classical poetry.

VU'LPES. (Lat. *a fox.*) This has been made a subgeneric term by those naturalists who so distinguish the foxes from the dogs, jackals, and wolves, to which they consequently restrict the term *Canis*. The grounds for the proposed distinction are chiefly the form of the pupil of the eye, which is vertical in the foxes, circular in the dogs; the lobes of the upper incisor teeth are less distinctly marked than in the dog; the tail of the fox is longer and more bushy; its head broader, and terminated by a narrower and more pointed muzzle; its gait and attitude crouching.

VU'LPINITE; so called from Vulpino, near Bergamo in Italy, where it is found. An anhydrous sulphate of lime, containing a little silica. It is sometimes employed by the Italian artists for small statues and other ornamental work, under the name of *marmo bardiglio.*

VU'LTUR. (Lat. *a vulture.*) The name of a Linnæan genus of diurnal Accipitrine birds, characterized by an elongated beak, curved only at the extremity, and by having a greater or less proportion of the head, and sometimes of the neck, denuded of feathers. To the brief Linnæan phrase descriptive of this genus it may be added, that the power of the claws does not correspond with the bulk of the body. The wings are so long that they are carried in the half-extended state when the vulture walks on the ground. In general, the birds of this group are of a cowardly nature, living on dead carcasses and offal; their gullet dilates into a considerable crop, which, when distended with garbage, projects above the furcular bone. When gorged with food a fœtid humour is discharged from the nostrils, and the bird is reduced to a state of stupidity. The vultures of Linnæus are divided into the subgenera *Vultur*, Cuv.; *Cathartes*, Cuv.; *Sarcoramphus*, Cuv.; *Percnopterus*, Cuv.; *Gypaëtus*, Storr.

W.

W. A letter found only in the alphabets of modern languages. In form, it resembles two Vs, and its English name is derived from the fact of the letter *v* being identical with *u* in the Latin, and in the more early form of the English language. In German, *w* is pronounced like the English *v*; the latter having the sound of *f*. When *w* commences a syllable, it is a consonant; but in all other positions a vowel.

WACKE. (German.) A modification of basalt.

WAD, or WADDING. In Gunnery, a bundle of paper, tow, old rope-yarn, or other loose matter, rolled up closely together, and rammed into a gun after the powder to keep it close in its chamber. From the experiments of Dr. Hutton it does not appear that the wadding has any effect in increasing the force of the charge.

WADD. A name occasionally given to plumbago, and also to an ore of manganese found in Derbyshire, which when mixed with linseed oil for the purpose of a paint is apt to take fire.

WA'DERS, WADING BIRDS, *Grallatores.* An order of birds, including those which have long legs naked from above the distal or lower extremity of the tibia downwards. *See* GRALLATORES.

WA'DSETT. In Scotch Law, a right by which goods are pledged for the recovery of a debt, answering to the English mortgage.

WA'GER OF BATTLE. The usage of deciding a civil suit by battle was common to the jurisprudence of many of the Teutonic tribes which established themselves in the provinces of the Roman empire. It was especially favoured among the Lombards; and there is a celebrated passage in the laws of their king Luitprand, in which, while he recognizes the impiety of the custom, he professes his inability to abolish it in consequence of the prejudices of his subjects. In England, battle trial is not mentioned in any Anglo-Saxon laws now extant; and its introduction is therefore attributed to William the Conqueror, although bearing in his laws the Saxon name of "orneste," probably *earnest.* (See *Sir F. Palgrave on the British Commonwealth*, chap. vii., who believes that the Conqueror did no more than confirm a usage already known to the inhabitants of England. He supposes that battle in civil suits was regularly joined in the Anglo-Saxon county courts.) Trial by battle, by the English common law, was used in civil cases only, where issue was joined upon a writ of right, in which the tenant pleaded the general issue, viz. that he had more right to hold than the demandant to recover, which he offered to prove by the body of his champion; for in civil actions the combat was not between the parties themselves. The champions were armed with batons and targets, and the combat took place before the judges and serjeants of the Court of Common Pleas. The combatants were bound to fight until the stars appeared in the evening; and if the champion of the tenant could either hold out so long, or obtain the victory, the tenant prevailed in his cause. Victory was obtained either by the death of the champion, or by his pronouncing the horrible word "craven," which caused his principal the loss of his land, and legal infamy to himself. The trial by battle was the only mode of deciding a writ of right, until Henry II. introduced the grand appeal or trial by inquest, and gave the tenant his choice between them. The last trial by battle in the Court of Common Pleas was in the 13th Elizabeth, 1571; but in the Court of the County Palatine of Durham

there was one in 1638. Trial by battle in criminal cases is explicitly noticed in the laws of the Conqueror. It took place on an *appeal*, when the appellee of felony pleaded not guilty, and declared he would defend the same with his body: as in *approvement*, when a party arraigned of treason or felony having become an approver by appealing, or accusing his accomplices, the latter might in the same manner demand trial by battle; in which case the combat was between the parties themselves. The last trial by battle awarded in this country was in the case of Lord Reay and Mr. Ramsay, in the 7th of Charles I.; but the king, after having appointed a constable to preside, revoked the commission. In 1818, William Ashford having brought an appeal against Abraham Thornton for the murder of his sister, the appellee waged his battle. Judgment was stayed, in consequence of a legal difficulty which arose in the case; and in the following year an act was passed, by which appeals of treason, felony, and other offences, and trial by battle on writs of right, were abolished.

WAGER. In Law, wagers are valid, and may be made subjects of action, unless they are on illegal matters. Illegal wagers are of two kinds: such as are rendered expressly void by statutes, and such as have an illegal or immoral tendency. To the first class belong wagers on the event of prohibited games; wagers on horse races, if the sum betted by either party be above 10*l*., or on any horse race not a bonâ fide race on the turf; of the latter class many instances might be given. Anything that incites to a breach of the peace or to immorality, or that has a tendency to annoy the feelings of another or cast ridicule on him, is not a legal subject of wagers. Wagers on merely speculative subjects, not arising out of circumstances in which the parties have an interest (for instance, on a point of law, or on the amount of a branch of the public revenue), are of too trivial characters to be enforced by legal proceedings. When a wager is illegal, both parties may recover back their deposits from a stakeholder.

WAGER OF LAW. *See* COMPURGATION.

WA'GES, in Political Economy, are the return made or compensation paid to those employed to perform any kind of labour or service by their employers.

In ordinary language, the term wages is usually employed to designate the sums paid to artizans or labourers employed in manufactures, in household services, and in agriculture, mines, and other manual occupations. Substantially and in fact, however, it has a much more extensive application: the salaries of public functionaries of all sorts, and the fees of lawyers, physicians, and other professional men, are as really wages as the sums paid by them to the menials in their service, and depend on the same laws and principles. "Every man," says Dr. Paley, "has his work. The kind of work varies, and that is all the difference there is. A great deal of labour exists besides that of the hands, many species of industry besides bodily operation, equally necessary, requiring equal assiduity, more attention, more anxiety. It is not true, therefore, that men of elevated stations are exempted from work; it is only true that there is assigned to them work of a different kind; whether more easy or more pleasant may be questioned; but certainly not less wanted, nor less essential to the common good." (*Assize Sermon*, July 29, 1795.)

Rates of Wages in different Employments. — The wages paid to the labourers engaged in different employments differ so very widely, that at first sight it may seem to be impossible to lay down any principles that should be generally applicable to them all. Such, however, is not the case. The differences in question are apparent rather than real; and when the various favourable and unfavourable circumstances connected with different employments are taken into account, it will be found that the wages or earnings of those engaged in them are very nearly the same.

If all employments were equally agreeable and healthy, if the labour to be performed in each was of the same intensity, and if each required the same degree of dexterity and skill on the part of those employed, it is evident, supposing industry to be quite free, that there could be no permanent or considerable difference in the wages of labour; for if those employed in a particular business were to earn either *more* or *less* than their neighbours, labourers would, in the former case, leave other businesses to engage in it; and in the latter, they would leave it to engage in others, until the increase or diminution of their numbers had lowered or elevated wages to the common level. In point of fact, however, the intensity of the labour to be performed in different employments, the degree of skill required to carry them on, their healthiness, and the estimation in which they are held, differ exceedingly; and these varying circumstances necessarily occasion proportional differences in the wages of the workmen engaged in them. Wages are the price paid to the labourer for the exertion of his physical powers, skill and ingenuity. They, therefore, necessarily vary according to the severity of the labour and the degree of skill and ingenuity required. A jeweller or engraver, for example, must be paid a higher rate of wages than a common farm-servant or a scavenger; for a long course of training being necessary to instruct a man in the business of jewelling and engraving, were he not indemnified for the cost of this training by a higher rate of wages, he would not think of learning so difficult an art, but would addict himself in preference to such employments as hardly require any instruction. Hence the discrepancies that actually obtain in the rate of wages are confined within certain limits, increasing or diminishing it only so far as may be necessary fully to countervail the unfavourable or favourable peculiarities attending any employment.

The following, according to Dr. Smith, are the principal circumstances which occasion the rate of wages, in some employments, to fall below or rise above the *general average* rate of wages: —

1st. The agreeableness and disagreeableness of the employments.

2d. The laziness or cheapness, or the difficulty and expense of learning them.

3d. The constancy or inconstancy of the employments.

4th. The small or great trust that must be reposed in those who carry them on.

5th. The probability or improbability of succeeding in them.

It would be useless even if our limits permitted to enter into any lengthened details with respect to the variations in the rates of wages arising out of the particular circumstances now enumerated. They have been fully illustrated by Smith in the 10th chapter of his first book. Every one must see that, *cæteris paribus*, those engaged in a disagreeable or disreputable employment must have greater wages than those engaged in such as are comparatively agreeable and respectable. Wherever a comparative disadvantage attaches to any branch of industry, it must be compensated to those engaged by higher wages or profits, or both, otherwise they would withdraw wholly from it. And on this principle it is plain that those engaged in a business or profession which it costs a great deal to learn must be more amply remunerated than those engaged in a business that may be learned with comparatively little trouble and expense. Inconstancy of employment must also, it is obvious, be indemnified by a higher rate of wages during the period of employment; and greater trust by requiring higher character must also be remunerated by higher wages. The probability or improbability of success in different employments applies mostly in the higher departments of industry. The instances are rare in which a person who is bound apprentice to a tailor, shoemaker, or other individual engaged in an ordinary business, fails of acquiring sufficient proficiency to enable him to live by it. But it is far otherwise in the higher departments; and supposing an individual is bound apprentice to a lawyer, physician, painter, sculptor, player, &c., the chances are more than twenty to one that he will not attain to distinction in his profession, and perhaps five to one that he will not be able to live by it. But, in professions where so many fail for one who succeeds, that fortunate one should gain not only what will indemnify him for the expenses of his education, but also all that has been laid out on the education of his unfortunate competitors. Hence the comparatively large earnings of successful lawyers, physicians, players, and so forth; though it be, after all, abundantly certain that they hardly compensate for the losses of the unsuccessful candidates for wealth and honours.

It will be found, therefore, taking all the circumstances into account, that the rates of wages in different employments approach pretty near an equality; and that the higher rate in some, and lower rate in others, is uniformly occasioned by certain contingent circumstances.

But without insisting farther on the causes of variation from the common standard, we shall now proceed shortly to inquire into the circumstances which determine this common standard, that is, into the circumstances which determine the rate of wages paid to labourers engaged in the common and ordinary departments of manufacturing and agricultural labour, or in such as require no peculiar skill or other superior quality, and have nothing peculiarly disagreeable about them.

To facilitate the acquisition of clear and correct views with respect to the circumstances which determine the price of ordinary labour, wages may be considered in a double point of view: viz. either (I.) as the sum which the labourers receive at any given period in return for their services, or (II.) as the sum which the habits of society render necessary to enable them to subsist and continue their race. Wages, considered in the first point of view, may be called market or actual wages; and considered in the second, they may be called natural or necessary wages.

I. Dr. Smith has said, (*Wealth of Nations*, p. 30, M'Culloch's edit.,) that the common or market rate of wages depends every where upon the terms of the contract

between the workmen and their employers. But we must not thence infer that these terms are adjusted on any arbitrary or capricious principle. In businesses of small extent, and placed under peculiar circumstances, this may occasionally be the case. But in the vast majority of cases, it is not possible for any combination, whether of the masters or the workmen, materially to affect the rate of wages. That must always depend on the amount of capital devoted to the payment of wages as compared with the number of labourers.

That portion of the capital, or wealth of a country, which the employers of labour lay out in the purchase of labour may be much larger at one time than at another; but whatever may be its absolute magnitude, it obviously forms the only source from which any portion of the wages of labour can be derived. No other fund is in existence from which the labourers, as such, can draw a single shilling. And hence it follows that the average rate of wages, or the share of the national capital appropriated to the employment of labour falling, at an average, to each labourer, must entirely depend on its amount as compared with the number of those amongst whom it has to be divided.

An increase of capital, or of the means of supporting and employing labourers, is not therefore, as is so generally supposed, always productive of an increased rate of wages. It has this effect when the number of labourers remains stationary or when it increases in a less proportion than capital; but not otherwise. Were capital and population to increase or diminish in the same proportion, the rate of wages, or the quantity of necessaries and conveniences falling to the share of the labourer, would undergo no change; but if the mass of capital be, on the one hand, augmented without a corresponding augmentation taking place in the population, a *larger* share of such capital will fall to each individual, or the rate of wages will be increased. And if, on the other hand, population be augmented faster than capital, a *less* share will be apportioned to each individual, or the rate of wages will be reduced. The well-being and comfort of the labouring classes are thus especially dependent on the proportion which their increase bears to the increase of capital. There are, in fact, no means whatever by which their command over the necessaries of life can be increased that do not, at bottom, resolve themselves into an increase of capital as compared with population; and every scheme for improving the condition of the labouring class, not bottomed on this principle, can hardly fail to prove nugatory and ineffectual.

It is needless to enter into any disquisition with respect to the circumstances which tend to increase capital. Suffice it to observe, that its increase is always of the greatest importance to the bulk of the population. It may not, indeed, occasion a corresponding increase in the demand for labour; but it is, notwithstanding, sure to increase it considerably, and consequently to improve the condition of the labourers. Their condition may also be improved by a greater prevalence of moral restraint or of foresight in the formation of matrimonial connections; for, by lessening the rate at which population was previously increasing, such increased restraint would tend to reduce the number of labourers as compared with the demand, and would contribute to improve their condition in the same way as an increase of capital. On this ground, it is believed, that the establishment of a proper system of education might be made to contribute, by enlightening the public as to the governing causes of the rate of wages, to increase their amount. It were right certainly that education should be made to embrace such subjects. The causes of national poverty should be explained to every one, that all may be made aware of their existence and enabled in some measure to provide against them. It should be impressed on the labouring classes that the means of increased comfort are, to a very great degree, in their own hands; that what others can do for them is but trivial compared with what they can do for themselves; that the best institutions, and the most tolerant and liberal system of government, cannot shield them from poverty and degradation, should their numbers become too great as compared with the means of subsistence; and that to obviate this, and to advance their individual and collective interests, they should exercise a reasonable degree of foresight in the formation of matrimonial engagements, and should, if possible, endeavour to make some previous provision against unfavourable contingencies. We have already seen (art. POPULATION in this work), that the native sagacity of the bulk of the people, and their laudable desire to preserve their present position or to rise to a higher are powerful enough to make the progress of population subordinate to the increase in the means of subsistence. And it seems reasonable to conclude, without overrating the power of education, that the prudential virtues would acquire greater strength were their importance and the influence they exercise over the condition of society explained to and enforced on the attention of every one.

The laws with respect to corporations, apprenticeships, combinations, &c., the effect of which on the market rate of wages has been ably pointed out by Dr. Smith, have of late years undergone very great modifications. The statute of the 5th of Elizabeth, regulating the duration of apprenticeships in most common trades in England and Wales, was repealed in 1814; the laws preventing voluntary combinations amongst workmen were repealed in 1824 (*see* COMBINATION), and the privileges of the different corporations have, in so far as matters of this sort are concerned, ceased to be oppressive. A similar change has been made in many of the continental states. The Revolution swept off all the vexatious enactments with respect to apprenticeships and corporations that formerly restricted the freedom of industry in France; and they have also disappeared in Prussia, the Netherlands, &c. The compulsory provision for the support of the able-bodied poor is the only institution now existing in England, that seems to have any very considerable influence over the rate of wages. *See* POOR.

II. But whatever fluctuations may take place in the rate of wages, there is in all countries a limit below which it is generally difficult to reduce wages for any considerable period; and below which they can never be permanently reduced, without a change taking place in the habits of the population. This limit forms what has been denominated the natural or necessary rate of wages, and consists of the various necessaries and accommodations, or the money sufficient for their purchase, required to enable the labourers to exist and continue their race according to the habits and customs prevailing in the countries to which they belong.

It is obvious from what has now been stated, that the natural or necessary rate of wages is susceptible of much variation. It varies in different countries according to the varying wants and necessities of the labourers; and it varies in the same country according to the perpetually occurring changes in their diet, dress, lodgings, and other accommodations.

The varieties in the climate of different countries occasion considerable variations in the necessary rate of wages. Humboldt states that there is a difference of about a third part between the wages of labour in the hot and temperate districts of Mexico. Nor is it difficult to see why this is the case. According as the severity of the climate increases, warmer, and for that reason, speaking generally, more expensive clothing, more substantially built houses, and a larger supply of fuel become necessary. The influence of these circumstances may, it is true, be either partially or wholly counteracted by others; such as the superior progress made by countries with a less genial climate in the arts of civilized life, the possession of unusually productive coal mines, &c. But abstracting from these circumstances, it is plain as a general proposition that the rate of necessary wages must vary with variations of climate; and that other things being equal, it will be highest in countries where the most expensive clothes and houses and the largest supplies of fuel are required.

The share of the wages of labour appropriated to the purchase of food necessarily differs in different countries. In all, however, it is very large; and even in Great Britain, where the labourers consider comfortable clothes and neat cottages as indispensable, it is commonly supposed that at an average from *two* to *three-fifths* of their earnings are laid out on food. It is obvious, therefore, that the necessary, and by consequence also the market rate of wages, must be especially dependent on the sort of food consumed by the inhabitants, and the cost at which it may be raised. Taking, for example, the present average rate of wages in agricultural employments in England at 25*l.* a year, and supposing three-fifths of this sum or 15*l.* to be expended on food, it is obvious that, if either by a reduction in the price of corn, or by substituting potatoes in its place, or any other means, the cost of food were reduced a half, the necessary rate of wages might be reduced in the same proportion, or from 25*l.* to 17*l.* 10*s.* Such a reduction in the price of corn, or such a change in the species of food as has been supposed, would lead to an increase in the means of subsistence; an additional stimulus would in consequence be given to population, and though the market rate of wages would not sink in the same degree that necessary wages are supposed to have sunk, it would sink to some extent; and were necessary wages to sink still more, market wages would also sustain a certain decline, which would be greater or less according to the habits and foresight of the people.

The state of the labouring classes in every country furnishes abundant proofs of what has now been stated. In Bengal, for example, where clothing, lodging, and fuel are of comparatively inferior importance, the necessary wages of labour are almost entirely determined by the cost of the food consumed by the labourer. And this food being the simplest and cheapest imaginable, consisting merely of boiled rice with split pulse, and salt to relieve its insipidity, a labourer is able to subsist on

the merest trifle; and in consequence the customary rate of wages in common employments is so low as $2\frac{1}{2}d$. a day. (Colebrooke, *On the Husbandry of Bengal*, pp. 20. 131.)

But it is not necessary to refer to distant countries or remote periods for an example of this principle. The contrast between the wages and the condition of the labouring classes in Great Britain, and the wages and condition of the same classes in Ireland, illustrates it in the most striking manner. In Great Britain the necessary rate of wages is principally determined by the cost of wheat and butcher's meat, and in a less degree by the rent of a comfortable cottage, the price of clothes, beer, tea, &c. In Ireland, on the contrary, the peasantry rarely taste butcher's meat; they do not even consider bread as necessary to their subsistence; they are generally without either beer or tea; and their hats, clothes, &c., are all of the most miserable description. The rate of necessary wages is there almost entirely determined by the price of potatoes; and as a quantity of these sufficient for the support of a family may be bought for a third part of the price of the bread and other articles required for that purpose, the necessary rate of wages is proportionally low. The market rate of wages, too, owing to the weakness in Ireland of moral restraint, and the nearly total non-existence of that prudent forethought and decent pride which distinguishes the labouring class in Great Britain, does not differ sensibly from the necessary rate. The principle of increase has filled up the population to the level of mere subsistence; so that while the wages of common labour may be taken on a rough average at 20*d*. a day in England, they are not supposed to exceed 6*d*. or at most 7*d*. a day in Ireland.

If we except the influence that would be exerted on the progress of population, and consequently also on the rate of wages, by the prevalence of a greater degree of moral restraint, an increased demand for labour, and a fall in the price of the articles consumed by the labourer, seem to be the only modes in which wages can be raised. From whatever causes an increased demand for labour may proceed, it must obviously raise the rate of wages; and it is hardly less obvious, that a fall in the cost of producing any article consumed by the labourer, or suitable for his consumption, must in so far improve his condition. The demand for labour is in most cases immediately increased, and it is never generally or permanently reduced, by a reduction in the cost of producing commodities. But supposing that the demand for labour continues the same after commodities fall in price, then, as the number of labourers in the market, and consequently the money wages paid them, must also be the same as before the fall, it is plain they will obtain a greater quantity of produce, and that their condition will be in so far improved. It is, no doubt, true, that were population to increase, as is sometimes alleged, proportionally to the increased demand for labour, or to the fall in the price of produce, the improvement in the condition of the labourer would only be temporary. But it is not improbable merely but next to impossible that population should increase in the same proportion. A period of about twenty years necessarily elapses before the stimulus which an increased demand for labour gives to population can occasion any increase in the number of labourers; and the labourers being accustomed, during this long interval, to an improved manner of living, the standard of natural or necessary wages becomes elevated; and the majority will be disinclined to do anything that might tend to sink themselves and their children below the new level to which they have attained.

The effects produced by a decreasing demand for labour, or by a rise in the price of the articles usually consumed by the labourer, are directly the reverse of those now stated. The number of labourers continuing for a while at least the same, the rate of wages is necessarily diminished when the demand for labour declines, and it necessarily continues at its old level when prices rise; so that in both cases the condition of the labourers is changed for the worse. In consequence, they are obliged to economise; and should the pressure continue for a considerable period, there is a risk lest their habits be degraded, or that they should learn to be satisfied with an inferior species of food, or a lower standard of comfort. Should this change unfortunately take place, the population would accommodate itself to the new state of things; and it would be difficult for the labourers to attain, at any subsequent period, to the elevation from which they had been cast down.

When the labourers are already subsisting, as in Ireland, on the lowest species of food, it is of course impossible for them to go to a lower in a period of scarcity; and should their wages, or the means of subsistence falling to their share, sustain any serious decline, an increase would necessarily take place in the rate of mortality. But in a country like England, where the inhabitants have been long accustomed to superior comforts, and enjoy various privileges, it is probable that they might pass through a pretty long period of privation, and that it would rather give new efficacy to the principle of moral restraint, and lessen the proportion of marriages and births, than induce them to submit to a lower scale of living or to relinquish comforts they have long possessed, and been taught to regard as indispensable. As the well-being of the labouring classes is essential to the tranquillity and happiness of the state, it is of the highest importance that this principle should be strengthened by every possible means. It is easy from this to see that a principal advantage of a compulsory provision for the support of the poor consists in the assistance it gives them in periods of adversity, and in its thereby contributing to prevent their tastes and habits or their standard of comfort from being lowered by the privations to which they might otherwise be compelled to submit.

WAHA'BEES or WAHA'BYS. A Mussulman sect, of which the founder was a learned Arabian, named Abd el Wahâb, who became persuaded of the corruption, both of doctrine and practice, prevalent among the professors of Islam, especially the Turks. His daughter married Mohammed Ibn Saoûd, the principal person of the town of Derayeh, who became his first convert and leader of the sect about 1760. Like the original prophet of their faith, Saoûd and his followers propagated their doctrines at once by persuasion and arms. Abd el Aziz and Ibn Saoûd, the son and grandson of the first Saoûd, carried their arms to the utmost extremities of Arabia, and, conformably with the old Mohammedan principle, established a spiritual and temporal leadership united in their persons. The Bedouins, or wandering tribes, formed the bulk of their converts. They acknowledged the Koran and the Sunne, or orthodox tradition, and they professed adherence to the liberal tenets of both; but they accused the other Mohammedans of an idolatrous veneration for the prophet and other saints, and denied the intercession of saints altogether. Like the early Protestants of Europe, their favourite taste was the destruction of the cupolas and tombs of saints. To this the mob of Wahabys added a strong aversion to the rich dress of the Turks, and to the practice of smoking tobacco, which had been prohibited by Abd el Wahâb much on the same bold principle which had induced Mohammed himself to condemn the use of wine. The province of Nedjd became the chief seat of the Wahaby power. Under the last Saoûd (a very handsome man, whom the Arabs called Abou Showareb, or the Father of Mustachios), it reached its greatest extent. Like the early Caliphs, he administered justice in person to great part of Arabia. The Wahabys, in the first twenty years of this century, extended their plundering expeditions to Syria, Irak, and Mesopotamia. In 1803 they took Mekka, and soon conquered the Hidjah. In 1809 Mehemet Ali began hostilities in Arabia; and in 1812 the Hidjah was restored, and the caravans of pilgrims once more arrived with their usual pomp at Mekka; but for some years afterwards the Wahabys maintained their superiority in the rest of Arabia. Saoûd died in 1814, and was succeeded in his political and religious authority by his son Abdallah, under whom the Wahabys were finally subdued by Mehemet Ali; but we possess no authentic account of their conquest, or their present condition. (See *Burkhardt's Travels in Arabia*; his *Notes for a History of the Bedouins and Wahabys*, 1830; and the *Travels of Ali Bey*; *Ed. Rev.*, vols. xxvii. xxxiv.)

WAIF. (From the Saxon wafian, *to abandon*.) In Law, goods stolen and abandoned by the felon were so termed, and were forfeited to the king, or lord of the manor having the franchise of waif; but if the owner made fresh pursuit after the felon, and sued an appeal of robbery, or gave evidence whereby he was concluded, within a year and a day, he was entitled to restitution.

WAINSCOT. In Architecture, the framed lining in panels wherewith a wall is faced. The wood originally used for this purpose being a species of foreign oak, that wood has acquired the name from the purpose to which it was thus applied.

WAIST. That part of the gun-deck between the fore and main masts.

WAITS, the popular name for the music played in our streets on the nights of the Christmas holidays, is thought to be only a corruption of "wake," the common name for a nocturnal solemnity. (See *Archæol.* vol. ii. p. 66.)

WAI'VER. In Law, a term used to signify a party's declining or refusing to accept to avail himself of something; as waiver of an estate, which may be made by infant or his heirs of an estate conveyed to him in his minority; waiver of tort, in some cases where action of tort and action of contract both lying, the aggrieved party declines the former and pursues the latter remedy.

WAKE. In Antiquities and popular usage, the word is of the same meaning as vigil; and the custom originated in the processions which took place early in the morning of feast days to the church, and were not uncommonly followed by revelling and drunkenness. At present most fast days are popularly called wakes by the English peasantry; but the peculiar "wake" or "revel"

of county parishes was, originally, the day of the week on which the church had been dedicated; afterwards, the day of the year. In 1536, an act of convocation appointed that the wake should be held in every parish on the same day, namely, the first Sunday in October; but it was disregarded. Wakes are expressly mentioned in Charles the First's *Book of Sports*, among the feasts which it was his majesty's pleasure should be observed. The wake appears to have been also held on the Sunday after the day of dedication; or, more usually, the day of the saint to whom the church was dedicated. In Ireland, it is called the "Patron Day." (*Brand's Popular Antiquities.*)

WAKE. The track of a ship which she leaves in the water. A vessel directly astern of another is said to be in her wake.

WALDE'NSES. In Ecclesiastical History, a remarkable religious sect, said to have derived their name from Peter Waldo, a merchant of Lyons, who preached what he regarded as the pure doctrine of the Scriptures about 1180. Historians have confounded them, on the one hand, with the Vaudois (see that article), who appear, although their history is involved in much obscurity, to be an older and separate people; and on the other (especially those of the Catholic party), with the Albigenses; and thus it has been endeavoured to throw on them the discredit of the Manichean tracts, which are commonly (but on very doubtful testimony) imputed to the latter. It seems clear, however, that the Waldenses were distinct from these, and probably from the Vaudois also. Their distinguishing character, it has been said, "seems to have consisted in a strict adherence to what they considered to be the doctrine originally delivered by Christ to his apostles." And out of their extremely literal interpretation of the Gospel appears to have arisen most of their peculiarities, whether good or evil. They seem to have rejected an established succession of the priesthood, and the distinguishing characteristics of the priestly office; the high Catholic doctrine of the sacraments, besides the common ecclesiastical abuses of their day; and are said in addition to have protested against oaths, warfare, lawsuits, and the accumulation of wealth. Their later history is obscure; and it may be said of them, as well as of other sects of the day, that they had little of the elements of permanence, the same opinions being continually promulgated afresh by new reformers, and then receiving new denominations. (*See* ALBIGENSES, PETROBRUSIANS, VAUDOIS.) The reader may consult *Milner's Ecclesiastical History* for the most favourable view of these and similar sectaries; and, among many other authorities, Faber, *On the Churches of the Waldenses and Albigenses. Mosheim*, cent. 12. vol. iii. There is a curious notice of an establishment of Waldenses in Kent in the *Archæologia*, vol. ix.

WALL. In Architecture, a body of stone, bricks, or other materials, serving to inclose a space, or carry superincumbent weights, or serving both these purposes.

WALL. In Horticulture, a fixed structure for the purpose of improving the climate of plants by shelter, by supplying heat, and by exposing them to the influence of the sun. Garden walls are formed either of brick, wood, or other materials; and are either solid, flued, or cellular, upright or sloping, straight or angular, according to the purpose intended by their erection. (See *Loudon's Encyc of Gardening*, p. 575, &c.)

WALL EYE. An opacity of the cornea of the eye. *See* GLAUCOMA.

WA'LLOWER. In Machinery, is used synonymously with lantern or trundle. *See* LANTERN WHEEL.

WALL PLATE. In Architecture, a piece of timber lying on a wall, on which girders, joists, and other timbers rest.

WALPU'RGIS NIGHT. The night of the 1st of May, a festival of St. Philip and St. James. Saint Walpurga was an English lady, sister of Boniface, the apostle of the Germans: her festival falls on the same day with that of the above-mentioned saints, and is a common day in Germany, like Lady-day in England, for the commencement of leases, &c. It is also known as the day on the eve of which, according to popular superstition, the great witch festival is held on the summit of the Brocken, in the Hartz mountains. This superstition is supposed to have originated in the rites performed by the pagan remnants of the Saxons to their gods, when their nation was forcibly converted to Christianity; which, being secretly celebrated in remote places, were supposed by the vulgar to be supernatural orgies.

WALTZ. (Germ. waltzer.) The name of the German national dance, and also of the species of music by which it is accompanied. Bohemia is said to be the original home of the waltz, whence it soon spread into other parts of Germany, and all over the Continent, and within the last few years it has become naturalised in England.

WA'PENTAKE. A territorial division in use among the Danish inhabitants of England: from wapen, *a weapon.* Yorkshire is subdivided into wapentakes instead of hundreds.

WAR, in International Law, is said to be "public," when it is a contest, by force, between independent sovereign states. A civil war is regarded by Grotius as "mixed" in its nature; being, according to him, public on the side of the established government, and private on that of the portion of the people resisting its authority. Public war is said to be perfect when one whole nation is at war with another, and all the members of each are authorized to commit hostilities mutually, subject only to the general laws of war. An imperfect war is limited as to persons, places, and things: to which class may be referred the hostilities of the United States against France in 1798; the hostilities between England, France, Russia, and Turkey, in 1827; and perhaps the recent proceedings against the Pacha of Egypt.

Formal declarations of war are now out of use: the latest example is said to be that by France against Spain, at Brussels, in 1635, which was announced by heralds. War is now usually preceded by the publication of what is termed a "manifesto" (see that word); and the permission of "reprisals" (which see) is usually the last step short of actual hostilities, and preceding them. The immediate effect of the commencement of hostilities would appear to be, on principle, the liability of all property belonging to subjects of one of the belligerent parties within the dominions of the other to seizure and confiscation; but many exceptions have been introduced by the practice of civilized states. (See Grotius, *De Jure B. & P.* lib. iii.; *Vattel*, lib. ii., &c.) In recent times, it has been the regular practice in Great Britain to seize and condemn, as droits of admiralty, property of the enemy found in our ports at the commencement of hostilities. Trade, and every species of contract between subjects of belligerent states, is in general unlawful, although often authorized for particular times and purposes. Subjects of hostile states, *domiciled* in the enemy's country, are held liable to reprisals; but not, it is said, mere travellers or temporary sojourners.

The "rights of war" are such as arise in times of hostilities,—1. Between enemies; 2. Between neutrals. As between enemies, it is a general law that subjects of a hostile state who are not in arms, or who have submitted, may not be slain. The killing of prisoners is only justifiable in very extreme cases. The usage of exchanging prisoners is now general, but was only firmly established in the 17th century; and it is not now considered obligatory. As to property, that belonging to the government of the vanquished nation belongs to the victorious state, wherever it is found; but private rights are unaffected by conquest, with the remarkable exception of private property when at sea, which is by general usage held lawful prize. Acts of hostility are only lawful, according to the modern usage, when committed by those authorized by the express or implied command of the state; such as the regularly commissioned military and naval forces of the nation, and all others called out by the government in its defence, as well as persons spontaneously defending themselves in case of necessity. Irregular bands of marauders are therefore denied the rights of war, and liable to be treated as banditti; and this distinction is generally only observed so far as suits the belligerent's purpose. For private citizens taking up arms, although in obedience to proclamations, are constantly liable to be treated as marauders; as by the French in the Peninsular war, and in numerous other cases. As to suspensions of hostilities, &c., see TRUCE, TREATY. As to the rights of war as to neutrals, see NEUTRALITY.

WARD. In Feudal Law, the heir of the king's tenant *in capite* during his nonage was so called; and, in general language, all infants under the power of guardians. (*See* GUARDIAN). The court of wards and liveries, for cognisance of various matters relating to the king's prerogative, was established by Henry VIII., and abolished at the Restoration. (See *Archæologia*, vol. ii.)

WARD-MOTE. A court in each ward of the city of London, which has power to present defaults in matters relating to the watch, police, &c.

WARDEN, LORD, OF THE CINQUE PORTS. (*See* CINQUE PORTS.) The constable of Dover Castle was created warden of the Cinque Ports, and guardian of the adjacent coast, by William the Conqueror: an office resembling that of the *comes littoris saxonici* in the decline of the Roman empire. The lord warden has the authority of admiral in the Cinque Ports and their dependencies, with power to hold a court of admiralty, and courts of law and equity: he is returning officer of all the ports. The salary is 3000*l.* a year. There is also a lord warden of the stannaries. *See* STANNARIES.

WARMTH. In Painting, a tone of colour arising from the use of colours expressive of heat.

WARP. In Weaving, the *longitudinal* threads of a woven fabric; they are crossed by the *transverse* threads, or *woof. Warp*, in Naval affairs, signifies a rope laid out for the purpose of moving the ship. *To warp* is to move a ship from one position to another by means of warps.

WA'RPING. (Fr. guerpier.) A mode of increasing the

fertility of tillage lands on the banks of rivers liable to be overflown by them. It appears to have been first practised in Britain on the banks of the Trent, Ouse, and other rivers which empty themselves into the estuary of the Humber. The water of these rivers, from passing through a great extent of alluvial country, are, after heavy rains, muddy to an excess; and they are in that state conducted over the adjoining surface in portions enclosed by banks, and there suffered to deposit their mud, which is technically called *warp*, and which being of the depth of an inch or two, adds greatly to the fertility of the soil, and ultimately to its quantity. The practice has existed on the banks of the Po, and other rivers in the north of Italy, from time immemorial.

Warping. In Architecture. *See* Casting.

WA'RRANT. In Law, a precept under hand and seal, directed to a proper officer, to arrest an offender.

WA'RRANT OF ATTORNEY, in Law, is a power given by a client to his attorney to appear and plead for him, or to suffer judgment to pass against him by confession. It authorizes a creditor to enter up judgment and levy execution, either instantly, or within a certain time specified in the instrument.

WARRANT OFFICERS, in the Navy, are the gunner, boatswain, and carpenter.

WA'RRANTY, in Law, as applied to lands, is a promise or covenant real annexed to lands or hereditaments, whereby the bargainor and his heirs are bound to warrant the same to the bargainee and his heirs against all men. But the ancient law of warranty of real property has been long obsolete in practice.

With regard to warranty of things personal, it is the general rule, that a purchaser of goods and chattels may have a satisfaction from the seller, if he sells them as his own, and the title proves deficient, without any express warranty for that purpose; but that with regard to the goodness of the things so purchased, the vendor is not bound to answer, unless he has expressly warranted them to be good, or unless he has in any way misrepresented them.

WA'RREN. (Fr. garenne; from the Teutonic wahren, *to protect or defend.*) In Law, a franchise or place privileged for the keeping of beasts and fowls of warren, which are said by some to be only hares and rabbits, partridges and pheasants; others add quails, woodcocks, waterfowl, &c. The franchise is from the crown by grant, or prescription which implies grant. It is often called *free warren*. In common language a warren is a surface of poor dry sandy soil on which rabbits are kept. In general, warrens may be described as the natural habitations of wild rabbits appropriated by man, and preserved for the breed of these animals; but they are occasionally formed in suitable situations. The rabbits are allowed to burrow in the soil at pleasure, and to crop the natural herbage which grows on the surface; but to render warrens profitable, the rabbits require to be supplied with clover, hay, corn, or other food, in the winter season.

WASH. The fermented liquor from which spirit is distilled.

WA'SHER. A circular piece of leather, or pasteboard, placed at the base of a screw, so as to prevent the metal surfaces from being injured when it is screwed home; it is also used to render screw and other junctions air-tight.

Washer. In Architecture, a flat piece of iron pierced with a hole for the passage of a screw, between whose nut and the timber it is placed to prevent compression on a small surface of the timber.

WA'SSAIL. (From the Ang. Sax. waes hael, *be in health.*) A common salutation used in drinking; whence the "wassel-bowl," which was anciently carried round on New Years' Eve. "A carol for a wakel bowl" will be found in *Ritson's Ancient Songs*, 1790, p. 304. (See *Brand's Popular Antiquities*, vol. i. p. 1.)

WASTE, in Law, is the destruction or material alteration of things forming an essential part of the inheritance; as houses, timber, &c. Neglect of repairs is termed *permissive* waste; active injury, *voluntary* waste. The action of waste, at common law, can only be brought by a person who has an estate of inheritance in immediate expectancy upon the devastator's estate.

WASTE LAND. Any tract of surface not in a state of cultivation, and producing little or no useful herbage, or wood. The quantity of this kind of land in Britain was estimated, about the end of the last century, at upwards of six millions of acres; four millions of which were considered capable of being brought under the plough, and the greater part of the remainder of growing wood.

WATCH. A well-known portable machine, moved by a spring, for measuring time. When executed in the most perfect manner, it is called a *chronometer*, and used in navigation for determining differences of longitude. *See* Longitude, Chronometer.

Watches are said to have been made at Nuremberg so early as 1477; but it is uncertain how far the watches then constructed resembled those which now go by that name. Some of the early ones were very small, in the shape of a pear, and sometimes sunk or fitted into th top of a walking-stick. As time-keepers, watches coul have very little value before the application of the spira spring as a regulator to the balance. The merit of thi excellent invention has been claimed by Hooke and Huygens; but it seems established by unquestionable evidence that the priority belonged to Hooke by at leas fifteen years. The date of the invention is about th year 1658. Hooke's first balance spring was straight, an acted on the balance in a very imperfect manner; bu he soon perceived its defects, and attempted to obviat them by adopting first the cylindrical, and afterwards th flat spiral. The latter appears to have been applied t watches before the publication of Huygens' claim in 1675 (*Encyc. Brit.* art. "Clock and Watch Work.") *See* Horology.

Watch. The portion of the ship's crew on duty a a time. This is usually half; and the watches are calle the *starboard* and *larboard* watches. Large crews ar put in three watches. The period of the time called a watch is four hours, the reckoning beginning at noon o midnight. Between 4 o'clock and 8 P.M., the time i divided into two short or *dog* watches, in order to break the constant recurrence of three watches at the sam hours.

WA'TER. (Germ. wasser.) The old chemists considered water as an element, and supposed it convertibl into earth, and into various organic products. This opinion was first questioned, and afterwards disproved, by th experiments of Watt and of Cavendish, in the years 1786 and 1787. (*Phil. Trans.*) And it has since been satisfactorily demonstrated that hydrogen and oxygen ar the elements of water, and that they are contained in it i the relative proportions by weight of 1 and 8, or by volum 2 and 1; the specific gravity of hydrogen being to that o oxygen as 1 to 16.

The electro-chemical decomposition of water is tha which affords the most satisfactory evidence of its nature. When made part of the volta-electric circuit, it i resolved into 2 measures of hydrogen and 1 of oxygen gas; the former evolved at the negative, and the latter at th positive surface; and if the gases thus obtained b mixed, and fired by the electric spark, they again combine and produce their weight of water. The analytic and synthetic evidence, therefore, of the composition of water i thus rendered complete.

But although perfectly pure water, such, for instance as has been boiled and very cautiously distilled, is in fact an *oxide of hydrogen*, and composed as above stated, all common water is more or less contaminated by foreign matters, which, if not in excess, or of an uncommon o injurious nature, render it, generally speaking, more fit for most of the ordinary uses to which it is applied. Of all water, *rain water* carefully and cleanly collected is most pure. But it absorbs air, and with it traces of carbonic acid; minute portions of certain ammoniacal salts are also found in it, and very near the sea it is seldom free from a trace of salt. During thunder-storms the rain which falls sometimes exhibits indications of nitric acid, formed, no doubt, by the passage of the lightning through the humid atmosphere. Next to rain water, *river water* is, generally speaking, most free from foreign matter. The water of the Thames, especially where it is not contaminated by drainage and manufactures, only contains about 2 grains of saline or soluble matter in each pint; and this is chiefly carbonate of lime, with a little sulphate of lime, chloride of sodium (common salt), and chloride of magnesium, and traces of organic matter. The saline contents of a gallon of Thames water, in its most impure state, do not exceed 24 grains; and when in its purest state, fall short of 16 grains. This statement refers only to matters *dissolved* in the water; for it is often loaded with substances *mechanically suspended* to a much greater extent, as is obvious from the muddy state in which it is often supplied to the houses of London and its vicinity by the water companies. These last impurities are separated either by subsidence or by filtration; hence the advantage of allowing the water to clarify itself in reservoirs before it is supplied for use, or of filtering it through fine sand, which imparts nothing to the water, and renders it clean and transparent. When water contaminated by animal or vegetable matter is kept for some time, it undergoes a spontaneous depuration, losing its odour and colour, and depositing more or less sediment. By this process, however, it becomes *hard*, in conquence of retaining certain indestructible saline matters in solution. The water for the supply of ships is well known to undergo this process of fermentation and purification, and the larger the quantity of destructible matter the more complete and rapid is the depuration: hence the preference given to Thames water for sea store, the purer river waters fermenting less rapidly, and remaining more or less foul and putrid for a much longer time. It is obvious, however, that for all ordinary purposes the purer the water the better; and it is quite clear that London ought to be supplied with Thames water from above Richmond, and out of the reach of the

tides, instead of from the heart of the metropolis, where it is loaded with the contents of the sewers, the offal of manufactures, and the mud stirred up by the steamers.

Spring water, as afforded by our common wells, may be considered as rain water modified by filtration through the superficial strata of the earth, and consequently containing more or less of the soluble substances which it meets with in its course. In and about London the purity of the water is very various at different depths from the surface. In the more superficial wells it is usually very hard, and abounds in sulphate of lime; in the deep wells, and especially the *artesian* and overflowing wells, the water is softer, and contains less foreign matter. These different states of purity may be judged of with a degree of accuracy sufficient for all common purposes by dropping into the water a solution of soap in spirit of wine: with pure water, such as rain or distilled water, it remains clear; but with river or spring water it becomes more or less turbid or milky, in proportion to the impurity. Water which is thus rendered decidedly opaque or milky is not fit for washing; but that which is only slightly troubled, or becomes merely opalescent, is usually called *soft water*. This simple experiment shows the cause of softness and hardness in water; for pure water perfectly dissolves soap, whereas in common spring water the salts are of such a nature as to form insoluble compounds with it, and these adhere to whatever is washed in it, and give that unpleasant sensation called *hardness* when we wash our hands. The application of a few other simple tests may be resorted to, to indicate more exactly the nature of the hardening impurities. The presence, for instance, of sulphate of lime is indicated by the production of a white cloud upon adding a few drops of a solution of *chloride of barium* (which shows the sulphuric acid), and of *oxalate of ammonia* (which detects lime). Such water generally leaves a white crust in the decanter in which it is kept, and incrusts boilers and kettles with a troublesome sediment; so that, unless frequently cleansed, they are soon destroyed by the action of the fire, in consequence of the sulphate of lime which coats their interior, and which prevents the transmission of heat. This impurity chiefly belongs to what are called *land springs*, and is derived from the blue clay upon which London is built, and which abounds in sulphate of lime. The deeper springs, especially those from the sandy deposits nearer to or upon the chalk, or those from the chalk itself, are more pure, especially where the land springs are excluded; and though they exhibit traces of sulphate of lime, common salt, carbonate of lime, and carbonate of soda, are yet pure enough for washing, brewing, &c. Traces of ammoniacal salts, and of nitrates, are also not uncommon in the waters from the deep wells of London and its vicinity.

Carbonate of lime, or chalk, is sometimes held in solution in spring water, by excess of carbonic acid; in this case the water becomes turbid upon the addition of oxalic acid, and slightly effervesces with muriatic acid; when boiled, the excess of carbonic acid which holds the carbonate in solution is expelled, and the water becomes more or less turbid. It is sometimes contained in such quantity as to be deposited upon substances thrown into the water, and upon the vessels containing it, as we see in the *petrifying* springs of Matlock in Derbyshire, and elsewhere; and the beautiful *stalactites* which line the caverns in limestone rocks are produced in the same way. Spring water which (*after having been boiled and filtered*) becomes turbid upon the addition of a few drops of nitrate of silver generally contains common salt, and the proportion may be judged of by the degree of milkiness thus occasioned. If water, after it has been evaporated to a small bulk, be tested by turmeric or violet paper, it often shows an alkaline reaction, and upon closer examination is found to contain carbonate of soda; and it occasionally evolves during its evaporation traces of carbonate of ammonia, and affords to delicate tests indications of organic matter. This is especially observed in the pump water from churchyards, in which most improper situation wells for the supply of the neighbourhood are often sunk.

Mineral springs or *waters* are of such a nature as to be unfit for common purposes, and often derive important medical efficacy from the substances which they hold dissolved. Those which have an inky and astringent flavour, and which become reddish brown and turbid by boiling, or by exposure, are usually called *chalybeate waters*, and contain carbonate or sulphate of iron: when examined as they flow from the spring, they blacken with a few drops of tincture of galls or of strong green tea. *Tunbridge water* is an instance of a chalybeate containing carbonate of iron, and the *Brighton chalybeate* contains sulphate of iron. There are some mineral waters which derive their efficacy from certain salts, and are called *saline waters*; such as *Cheltenham water*, *Leamington water*, &c. The salts which they contain are chiefly sulphate of soda and sulphate of magnesia; they have a bitterish salt taste, and are more or less aperient: when reduced to a small bulk by evaporation, and set aside for a few hours in a cool place, the salts generally crystallize. What are termed *sulphureous waters* are usually saline, and also contain *sulphuretted hydrogen*, which is presently recognized by its fetid smell, and by becoming black when a solution of sugar of lead is dropped into it; and turbid on the addition of a little muriatic acid, or by mere exposure to air, from the deposition of sulphur. *Harrogate* and *Aix-la-Chapelle* waters are instances. There are some waters which are occasionally resorted to medicinally, but which are only remarkable for extreme purity, such as *Malvern water*; and there are others which, exclusive of their chalybeate or saline qualities, are *effervescent* or sparkling, from the presence of carbonic acid, which gives them an agreeable and slightly pungent flavour: these qualities are entirely lost on boiling, in consequence of the escape of the gaseous acid; consequently they lose the power of reddening vegetable blues after they have been exposed to heat. In respect to *medical virtues*, the chalybeate springs are more or less tonic and astringent, and the saline springs aperient and alterative; and though they often contain their active ingredients in small relative proportions, they are perhaps on that very account more likely to be absorbed into the system, and to effect cures where larger doses of the same remedies fail. There are also some mineral waters which contain *iodine* and *bromine*, and which, though in very minute quantities, are powerful medicines; in others, baryta and strontia have been discovered. But a course of mineral water is often useful upon other principles: it generally is accompanied by strict attention to diet, by moderate bodily exercise, by mental relaxation, and by regular hours, all of which are powerfully curative resources; and with these aids the mere diluent effect of pure water (such as that of Malvern) may, in many instances, prove of eminent service: this is certainly often the case in the early stages of calculous complaints.

Sea Water.—The chemical history of sea water is extremely important, as involving that of sea salt (*see* SODIUM and CHLORINE), of *magnesia* and its most important combinations, and of those singular and powerful agents known to chemists under the names of *iodine* and *bromine*. It appears from the best authorities that the composition of sea water, when not influenced by adventitious or accidental causes, is nearly uniform in the vast extent of the ocean, which covers about two thirds of the globe, and probably has a mean depth of not less than half a mile (2640 feet). Its specific gravity varies from 10269 to 10285; and it contains rather more than three *per cent.* of solid matter, composed chiefly of common salt, muriate of magnesia, sulphate of magnesia, and sulphate of lime. These are the principal ingredients of sea water; besides which it contains traces of chloride of potassium, of muriate of ammonia, of carbonate of lime, of hydrobromate of magnesia, and often of hydriodate of magnesia. There is some difference of opinion as to the state of combination in which the acids and bases exist in sea water. The following tables show their proportions in a pint of sea water of the Frith of Forth, taken up near Leith, as obtained by evaporation, and as presumed to exist after and previous to evaporation:—

After Evaporation.		Before Evaporation.	
Common salt	180·5	Common salt	180·5
Muriate of magnesia	23·0	Muriate of magnesia	18·3
Sulphate of magnesia	15·5	Muriate of lime	5·7
Sulphate of lime	7·1	Sulphate of magnesia	21·6
	226·1		226·1

The other substances exist in such small quantities that they are omitted in this general statement. *See* OCEAN.

WATER BAILIFF. An officer in port towns, whose duties in general are with respect to the searching of ships: in London he has also the supervision of the fish market, gathering of tolls, &c.

WATER CLOCK. A contrivance for measuring time by the flow of water. *See* CLEPSYDRA.

WATER-COLOUR PAINTING. A species of painting, in which the medium of representation is colour levigated with water and gum, and which in our days has been carried to such extraordinary perfection as to rival oil painting in every thing but durability.

WATER DEVIL. A name given by some micrographers to the larva of a British species of *Hydrophilus*.

WATERLA'NDIANS. In Ecclesiastical History, a division of the Dutch Anabaptists, also called "Gross" (Grob), or "Moderate," in contradistinction to the "Fine," or "Rigid." They were so called from a district in North Holland denominated Waterland, and originated in the 16th century. John de Ries, in 1580, composed a confession of faith, which seems to have been pretty generally used among them. They still constitute (we believe) a portion of the general body of Mennonites. (See *Mosheim*, cent. 16., sec. 3., part ii.)

WATER LINE. The boundary of any horizontal section of the bottom of a ship. The uppermost one is called the load water line; the lowest the light water line.

WATER-LOGGED. A Nautical term, denoting the state of a ship when a quantity of water having been received into the hold by leaking, &c. she has in a great measure lost her buoyancy, and yields to the effect of every wave passing over the deck.

WATER MEADOWS. Meadows on low flat grounds, capable of being kept in a state of fertility by being overflown with water from some adjoining river or stream. The principal season at which this operation is performed is during winter, when the water is allowed to remain stagnant on the surface for some weeks; but meadows which can be watered are occasionally overflown during summer, especially after a crop of hay has been taken. The manner in which water so applied to grass lands is found beneficial has never been satisfactorily explained. By some it is attributed to the warmth retained in, or communicated to the soil, by the water during winter; by others to its effect in destroying insects, worms, &c.; and by some to the particles of manure deposited on the surface of the soil. During summer the effect is more readily accounted for, a supply of moisture being advantageous to all plants at that dry season. *See* IRRIGATION.

WATER OF CRYSTALLIZATION. Some crystallized salts contain more or less water, which, as it bears a definite proportion to the other components of the salt, may be considered as one of its essential constituents. Crystallized sulphate of lime, for instance, is a compound of 68 of dry sulphate and 18 water, or of one equivalent of anhydrous salt and two equivalents of water; one equivalent of crystallized sulphate of magnesia = 123, contains 7 of water = 63; and an equivalent of crystallized sulphate of soda = 162, contains 10 of water, = 90; the equivalent of water being 9. But it does not necessarily follow that a salt in crystals contains water, there being many crystals which are *anhydrous*, such as nitre, sulphate of potash, &c.

WATERSPOUT. A very remarkable meteorological phenomenon, observed for the most part at sea, but sometimes also on shore, though generally in the neighbourhood of water. Its general appearance may be described as follows: — from a dense cloud, a conical pillar, which appears to consist of condensed vapour, is seen to descend, with the apex downwards. When over the sea, there are usually two cones; one projecting from the cloud, and the other from the water below it. These sometimes unite, and the junction has been observed to be accompanied with a flash of lightning; but more frequently they disperse before the junction is effected. In calm weather the column maintains its vertical position while carried along the surface; but when acted on by the wind it becomes oblique to the horizon. The causes of this meteor are very imperfectly known. By some it is supposed to be formed by a whirlwind of extreme intensity, while others ascribe to it an electric origin. Dr. Young (*Nat. Phil.* vol. i.) thinks that some of the circumstances may be explained by considering the spout as a whirlwind, carrying up drops of water which it has separated from the waves, and that the remainder may perhaps be deduced from the co-operation of electricity already existing in a neighbouring cloud. (See also Pouillet, *Elémens de Physique*, tome ii.)

WATER TABLE. In Architecture, a projection or horizontal set-off in a wall, so placed as to throw off the water from the building.

WATER WAYS. Strong pieces of wood extending round the ship at the junction of the decks with the sides to carry off the water.

WATER WHEEL. In Hydraulics, an engine for raising water in large quantities. (*See* PERSIAN WHEEL.) Also a wheel turned by the force of running water. Of these there are two kinds: the *undershot wheel*, and the *overshot wheel*. In the case of the undershot wheel, the water strikes the float boards below the axle, and acts by the impulse due to its velocity; in the case of the overshot wheel, the water is brought over the top of the wheel, received in buckets, and acts solely by its weight.

WAVE. The alternate elevation and depression of parts of the surface of a liquid above and below the natural level.

When the surface of a liquid is unequally pressed, the columns which sustain the greatest pressure are shortened, and sink below the original level; and this pressure being communicated to the contiguous columns, these will be lengthened and rise above that level. But as the elevation is not sustained by a hydraulic pressure, the lengthened columns again fall, and acquiring in the fall a velocity due to the height, they descend below the original level, and communicate in their turn a pressure to those which are adjacent to them. In this manner a reciprocating motion is produced, the particles to which the primitive impulse was communicated being alternately the lowest and the highest; and a series of ridges and hollows is formed, which are called *waves* or *undulations*.

In passing from the columns which are shortened to those which are lengthened, and back again to those to which they originally belonged, the particles of the fluid acquire both a vertical and horizontal motion; but while the depth is sufficient to allow the oscillations to proceed unimpeded, no progressive motion takes place, each column being kept in its place by the pressure of the surrounding columns. If, however, free oscillation be prevented (by the shelving of the shore, or the interposition of a rock, for example), the columns in the deep water are not balanced by those in the shallower, and in consequence acquire a progressive motion towards the latter, or form *breakers*. Hence the reason why waves always break against the shore, whatever be the direction of the wind.

When waves are produced by the agitation of a small portion of the fluid, as for example by throwing a stone into stagnant water, they appear to advance from the disturbed point in expanding concentric circles, the height of the wave gradually diminishing as it recedes from the centre; but that there is no transference of any part of the mass from one place to another, is manifest from the motions of any light body floating on the surface. The appearance of progression is in fact an optical deception, produced by the form of the wave and the mode of oscillation. On attending closely to the phenomena it will be seen that the fore part is always in the act of rising, and the hinder part in the act of falling; and thus the whole system appears to roll onwards, while each particle of water in succession merely oscillates with a vertical ascent and descent.

If a second series of concentric waves take its origin from a different point at some distance from the first, the two sets will cross each other without the slightest interruption. Where a wave of the first series meets one of the second, and the two elevations correspond, the resulting elevation will be equal to the sum of the two; and the same is the case with the depressions. Where the elevation in the one series corresponds with a depression in the other, the surface will maintain its original level, at least if the waves of the two series have the same height. Thus, although different series of waves do not interfere with each others' propagation, they may nevertheless increase or neutralize each others' effects. The one series is in fact superposed on the other.

A series of waves meeting a vertical obstacle, as a wall or bank, is reflected; and the reflected waves are propagated in the same manner as those arising from the original impulse, but in an opposite direction. Waves proceeding in concentric circles are reflected in concentric circles, and in such a manner as to appear to diverge from a centre as far behind the obstacle as the original centre is in front of it, and in short appear to be subjected to all those laws which are usually noticed to belong to reflected light.

If the obstacle against which the waves strike have an opening in it of small horizontal breadth relatively to the breadth of the wave, the oscillating columns which reach it will act as an impulse originally exerted at that point, and a series of waves will diverge from the aperture as from a new centre; but when the aperture is considerably wider than the wave, the wave confines its motion in a great measure to its original direction, though with some small divergence, or the oscillation is continued principally in the direction of a sector, whose centre is at the point from which the original wave proceeded.

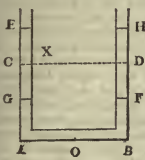
Waves which have been raised by the wind in the open sea proceed in parallel and nearly straight lines; and the original impulse being increased by the continued action of the wind, they will increase in height until the weight of the elevated column, together with the friction, becomes equal to the inciting cause. It has been inferred that the greatest height to which a single series of waves raised by the wind blowing constantly in one direction will attain does not exceed six feet. The force of the wind also tends to give a progressive motion to the mass of water raised above the general levél, and likewise to alter the shape of the wave by diminishing the acclivity of the side against which it strikes. In a strong gale this effect may be increased so far as to cause the top of the wave to project over the base, in which case it breaks and rolls over on the preceding wave. Hence, as is well known to sailors, a very strong wind will blow the sea down.

If the wind, after having given rise to a series of waves, suddenly veers about so as to strike the waves on the opposite side, it will produce a greater effect from its more direct impact; and hence the greatest waves are produced by sudden changes of wind, or by the wind blowing in an opposite direction to that in which the waves are propagated. In this manner the elevation of the waves may be greatly increased above the height to which they would be raised by winds of equal force blowing constantly in the same direction; and hence the ocean is comparatively smooth in regions where the winds are constant. And as it is by the friction of the wind on the water that the waves are raised and kept up, whatever diminishes the friction will tend to lessen the elevation. Hence the comparative tranquillity produced by

pouring oil on agitated water. The influence of the wind, which is exerted entirely at the surface, does not extend to a great depth, probably not more than 30 or 40 feet, below which the water suffers no agitation excepting that which arises from the motion of the tide wave.

Mathematical Theory of Waves. — In order to determine the time of an undulation and the velocity of the propagation of waves from the theory of hydrodynamics, Newton compares the undulatory motion of waves on the surface of water with the oscillations of the fluid in a siphon, with which they have a considerable, though not perfect analogy. Let the tube C A B D (fig. 1.), open and turned up at both ends, be filled with any liquid up to the level C D. Suppose the equilibrium to be disturbed, and that the liquid rises in consequence in the branch A C from C to E. The tube being supposed equally wide throughout, it is evident that the liquid will fall as much in the branch B D as it rises in A C; that is, making D F = C E, from D to F. Let C G = D F, then the difference of the height of the liquid in the two branches is E G;

(1.)



and according to the principle of D'Alembert, the accelerating force which acts on the fluid is the difference of the masses in the two columns divided by their sum, that is, proportional to E G divided by E A B F; or, bisecting A B in O, proportional to E C ÷ C A O. Now, C A O is constant; therefore the accelerating force is proportional to E C, or to the distance from the position of rest. Hence it may be inferred that when the fluid has been disturbed so as to rise from C to E, it will acquire, in falling to its level, a velocity which will carry it to an equal height H in the other branch, and that the oscillations, whether large or small, will be isochronous, or performed in equal times.

To prove this, and also to determine the time of the oscillation, let X be any point in C E, and make $EX = x$, $EC = a$, and $CAO = l$. Also let v = the velocity, and ϕ = the accelerating force when the liquid is at the point X, and g = the accelerating force of gravity. We have then, by what has been shown, $\phi = \frac{a - x}{l} g$. But from the theory of accelerating forces $\phi = \frac{dv}{dt}$, and $v = \frac{dx}{dt}$, (*see* FORCE), the substitution of which in the former equation gives

$$v\,dv = \frac{a - x}{l} g\,dx;$$

whence, by integrating and extracting the square root,

$$v = \frac{dx}{dt} = \sqrt{\left\{\frac{g}{l}(2ax - x^2)\right\}},$$

and consequently

$$dt = \sqrt{\frac{l}{g}} \cdot \frac{dx}{\sqrt{(2ax - x^2)}}.$$

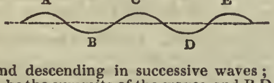
The general integral of the variable part of this expression is an arc whose cosine is equal to $(1 - \frac{x}{a})$; therefore between the limits $x = 0$ and $x = 2a$, the integral is

$$t = \pi\sqrt{\left(\frac{l}{g}\right)},$$

(π being the semi-circumference of a circle whose radius = 1). This gives the time which elapses during the passage of any particle of the water from the highest to the lowest point; and it is also the time in which a pendulum whose length is l, vibrating in an infinitely small arc, makes a single oscillation (*see* PENDULUM). Hence the time of passing from the highest to the highest again, or of a complete undulation, is the double of this, or equal to $2\pi\sqrt{(l \div g)}$, or to $\pi\sqrt{(4l \div g)}$, the time in which a pendulum whose length is $4l$ makes one oscillation.

To apply this solution to the undulatory motion of a fluid mass of indefinite extent, let A B C D E, &c. (fig. 2.) represent a superficies of stagnant water ascending and descending in successive waves; and let A C E, &c. be the summits of the waves, and B D, &c. the intermediate hollows. Now since the wave is produced by the alternate ascent and descent of the water, so that the particles at A C E, &c., which are at one instant the highest, become in their turn the lowest, and the moving

(2.)



power is the weight of the elevated water, the alternate rise and fall will be analogous to the reciprocating motion of water in a siphon, and will observe the same laws as to time; therefore if the distance between a summit A and the adjacent lowest point B be equal to $2l$, the highest points A C E, &c. will become the lowest in the time in which a pendulum whose length is equal to l makes one oscillation, and again become the highest in the time of the other oscillation. Hence the interval of time from the wave being the highest at any point to its being the highest at that point again will be equal to two oscillations, and the wave will describe its *breadth* (that is, the space between two successive summits or cavities, as from A to C or from B to D, which space is equal to $4l$) while the pendulum oscillates twice; or in the time to which a pendulum of quadruple the length, that is, equal to $4l$, or equal to the breadth of the wave, will oscillate once. (*Principia*, lib. ii. prop. 46.)

It must be admitted that the supposition on which this theory is founded, namely, that the vertical oscillations of waves are similar to that of water in a bent siphon, is a very precarious one; in fact, the theory itself is altogether insufficient for the explanation of the phenomena, as it gives no account whatever of the *form* of the wave. The subject is, however, one of great difficulty; and although it has been treated by the ablest mathematicians since the time of Newton, a complete theory is still a desideratum. Lagrange, in the *Mécanique Analytique*, has given an equation containing the general theory of waves formed by the successive and infinitely small elevations and depressions of stagnant water in a canal of small depth. Poisson (in the *Annales de Mathematique*, and *Mémoires de l'Acad.* tome i.) and Cauchy (*Mém. de l'Acad.*) have treated the subject more generally; and Professor Kelland (*Edin. Phil. Trans.* vols. xiv. and xv.) has endeavoured to obtain the equations of motion of a regular set of waves, without imposing any restriction whatever on the conditions. M. Kelland deduces from his analysis the following results, which apply to the motion of a wave in a canal whose depth is continually but slowly varying in the direction of its length: — 1. That the length of the wave is in direct proportion to the breadth. 2. That the velocity of transmission at any point varies as the square root of the depth. 3. That the elevation of the crest of the wave varies reciprocally as the total depth of the fluid. M. Kelland states that his endeavours to deduce a relation between the depth of the fluid and the length of the wave have been unavailing.

Experimental Researches on Waves. — In the *Reports of the British Association* for 1838, there is an account by Mr. Scott Russel of a series of observations on waves in the river Dee in Cheshire, and the Frith of the Clyde, and also in the open sea, which are interesting, as they establish the existence of waves of different kinds, following totally different laws. The most important results of these observations are the following: —

1. The progressive wave sent forward by a floating body in rapid motion (or generated in any other manner) differs entirely in its character and phenomena from the oscillatory waves of the sea, or those which ripple the surface of a lake, or are caused by the sudden elevation or depression of a small portion of the fluid. It is not necessarily followed either by a depression or elevation, but is a single elevation of a well-defined form, and transferred with a uniform velocity. This wave is called by Mr. Russel the *great primary wave of translation.* It is analogous to the tide wave of the ocean.

2. The velocity of the primary wave in channels of uniform depth is independent of the breadth of the fluid, and equal to the velocity acquired by a heavy body in falling freely through a height equal to half the depth of the fluid, reckoned from the top of the wave to the bottom of the channel. The velocity of the wave is accordingly proportional to the square root of the depth of the water, as the theory indicates, and it is not affected by the velocity of the impulse or the form of the body by which it is generated.

3. If waves be propagated in a channel whose depth diminishes uniformly, they will break when their height above the surface of the level fluid becomes equal to the depth below the surface. When waves of the sea approach the shore, or come into shallow water, they become waves of translation, and, in conformity with this law, always break when the depth of the water is not greater than the height of the wave above the level.

4. The great primary waves are reflected from surfaces at right angles to the direction of their motion, without suffering any other change but that of direction; and they cross each other without change of any kind, as the small oscillations on the surface of a pool.

5. In the primary wave of translation the displacement of the particles is uniform to the greatest depth; whereas in waves of the oscillatory kind the displacement of the particles of the fluid is greatest at the surfaces, and diminishes rapidly, and extends only to an inconsiderable depth.

6. The phenomenon called a *tidal bore* is produced in

two ways. First, if the water is so shallow that the first waves of the flood tide move with a velocity so much less than the succeeding ones that they are overtaken by them; and secondly, where the tide rises so rapidly, and the water on the shore or in the river is so shallow, that the height of the first wave is greater than the depth of the water.

The law by which the velocity of the primary wave varies according to the square root of the depth of the water gives rise to several other phenomena. Thus any change in the depth of rivers produces a corresponding change in the interval between the moon's transit and the hour of high water. A wave of high water of a spring tide travels faster than a wave of high water of a neap tide, &c.

The character and phenomena of the primary wave of transmission, and its importance as an element affecting the amount of the resistance of fluids on bodies moving through them, were first detected and examined by Mr. Russel in 1834. (*Transactions of the Royal Society of Edinburgh*, vol. xiv. part 1.). Its existence and laws are of great importance in reference to the construction and navigation of canals, and the improvement of tidal rivers. *See* HYDRODYNAMICS, TIDES.

WA'VELLITE. A mineral named after Dr. Wavell of Barnstaple, in which neighbourhood it was first found. It is a hydrated phosphate of alumina: it has also been called *hydrargillite*.

WAX. (Germ. wachs.) This is a common vegetable product, forming the varnish which coats the leaves of certain plants and trees. It is also found upon some berries, as of the *Myrica cerifera;* and it is an ingredient of the pollen of flowers. It was long supposed that bees merely collected the wax thus ready formed in plants; but Huber found that though excluded from all food except sugar, they still formed wax; and accordingly it has been found that the elementary composition of bees' wax and vegetable wax is slightly different. Bees' wax is prepared by draining and washing the honeycomb, which is then melted in boiling water, strained, and cast into cakes. English and foreign wax are found in the market; the latter being chiefly imported from the Baltic, the Levant, and the coast of Barbary. Fresh wax has a peculiar honey-like odour: its specific gravity is ·96. At about 150° it fuses, and at a high temperature volatilizes, and burns with a bright white flame. It is bleached by being exposed in thin slices or ribands to light, air, and moisture, or more rapidly by the action of chlorine; but in the latter case it does not answer for the manufacture of candles, which is one of its principal applications. Wax candles are made by suspending the wicks upon a hoop over the cauldron of melted wax, which is successively poured over them from a ladle till they have acquired the proper size,,so that the candle consists of a series of layers of wax; the upper end is then shaped, and the lower cut off. Attempts have been made to cast wax candles in moulds, but when thus made they burn irregularly. Bleached or white wax is generally adulterated with more or less spermaceti, and sold at different prices accordingly; in this case it has not the peculiar lustre of pure wax, and is softer and more fusible. It is also largely adulterated with stearine or stearic acid, which is detected by the odour of fat or tallow which it evolves when highly heated, and by its crumbly texture; it may also be separated to a certain extent by ether or alcohol. Wax is insoluble in water, and scarcely acted upon by the acids, so that it forms a good lute or cement: boiling alcohol and ether act partially upon it, and deposit the portion which they had dissolved on cooling. Some varieties of vegetable wax appear to contain two distinct principles, which Dr. John has termed *cerin* and *myricin;* the former soluble, and the latter insoluble, in alcohol. Heated with the fixed alkalies, wax forms a difficultly soluble soap.

WAY. The Sea term for progress. A ship in progress is said to have *way* upon her; when stationary, to have no *way*.

WEALDEN FORMATION and STRATA. *See* GEOLOGY.

WEAR. To put the ship on the other tack by turning her round, with her stern to the wind.

WEA'THER. (Germ. wetter.) The state or condition of the atmosphere with respect to heat, cold, dryness, moisture, wind, rain, snow, fogs, &c. The appreciation of the various causes which determine the state of the atmosphere, and produce those changes which are incessantly taking place in its condition, and which are popularly called the *weather*, forms the subjects of *Meteorology* and *Climate*. (See those terms; also ATMOSPHERE, BAROMETER, CLOUD, DEW, HAIL, RAIN, WIND, &c.)

In all ages of the world, mankind have attempted to explain and prognosticate the changes of the weather; but such is the complication of the subject, and the vast multitude of circumstances to be taken account of, that no theory can furnish rules for determining the order in which they succeed each other, or for predicting the state of the weather at a future time, with any approach to certainty. Nevertheless, all the different modifications of the atmosphere are the necessary results of principles, not only fixed and unalterable in their nature, but (many of them at least) well known in their separate and individual operation. The difficulty of tracing the results of their combined influences arises chiefly from their complexity and endless concatenation.

The principal cause of all the variations which take place in the state of the atmosphere is the heating action of the sun's rays; but in order to appreciate correctly its effect, it is necessary to know not only the extent of the atmosphere, but the properties of all the substances of which it is composed. Modern science has discovered that the atmosphere is composed of three different gaseous fluids, every where combined in the same proportions, and penetrated by an ever-varying quantity of elastic vapour. These two distinct envelopes of air and vapour mechanically mixed have different relations to heat; and therefore, in consequence of the unequal temperature of the surface of the earth, with which they are in contact, they cannot both be in a state of equilibrium at the same time. In consequence of the diurnal rotation, the different parts of the atmosphere are constantly receiving different quantities of heat, as the solar rays penetrate more or less obliquely. This inequality of temperature produces winds, which, if the surface of the earth were perfectly regular and homogeneous, would always blow in the same direction; but the surface of the earth being composed of materials of various kinds, and irregularly disposed, the distribution of heat over it is extremely irregular. The winds, sweeping along the surface, acquire its temperature; and hence the atmosphere also becomes irregularly heated. This produces an accumulation of air at one place, and a deficiency at another; and hence a subsequent rush to restore the equilibrium. As the air is cooled it becomes also incapable of holding the same quantity of aqueous vapour, a portion of which is therefore set free, and gives rise to clouds, mist, rain, dew, snow, &c. Besides all this, there is to be taken into account the development of electricity; the influences of light and galvanism; the agitation of the atmosphere produced by the rise and fall of the tides; and probably a variety of other circumstances with which we are entirely unacquainted. This very imperfect enumeration may serve to give an idea of the difficulties to be overcome in forming a theory of the weather. *See* CLIMATE.

It has always been a favourite prejudice that the weather is influenced in some mysterious manner by the moon. The moon can be supposed to act on the earth only in one of three ways; namely, by the light which it reflects; by its attraction; or by an emanation of some unknown kind. Now, the light of the moon does not amount to the 100,000th part of that of the sun; and the heat which it excites is so small as to b altogether inappreciable by the most delicate instruments, or the best devised experiments. No effect can be attributed, therefore, to the moon's light. With regard to the attraction of the moon, we see its influence on the tides of the ocean, and might therefore be disposed to allow it a similar influence on the atmosphere; but when we take into account the small specific gravity of atmospheric air in comparison with water, and the consequent smallness of the mass of matter to be acted upon, it will readily be perceived that this influence also must be extremely feeble. In fact, it has been demonstrated by Laplace that the joint action of the solar and lunar attraction is incapable of producing more than an atmospheric tide flowing westward at the rate of about four miles a day, and consequently scarcely, if at all, appreciable. As to the remaining supposition, that the moon may act on the atmosphere by some obscure emanation, it is sufficient to remark that no meteorological observations that have yet been made afford the slightest traces of any such connection between the earth and its satellite. The registers which are now kept in various observatories and other places also prove, contrary to the popular belief, that the changes of weather are in no way whatever dependent on the lunar phases. (See the *Annuaire du Bureau des Longitudes* for 1833; Kämptz, *Lehrbuch der Meteorologie;* Schubler, *Einfluss des Mondes auf die Veränderung unserer Atmosphare*, Leipzig, 1830.

WEATHER. The Sea term for that side on which the wind blows. *To weather*, to pass to windward of an object.

WEATHER BOARDING. In Architecture, feather-edged boarding nailed upright, whose boards lap over each other, so as to prevent the rain, &c. from penetrating them.

WEATHER GAGE. A ship to windward of another is said to have the weather gage.

WEATHER GLASS. A name commonly given to the barometer; but sometimes also applied to other instruments for ascertaining the state of the atmosphere, or measuring atmospheric changes. It is thus applied to the *thermometer*, the *hygrometer*, &c.

WE'AVERS, *Textoriæ*. The name of a tribe of spiders,

including those which fabricate webs in order to entrap their prey.

WEAVING, the art of forming cloth in a loom by the union or intertexture of threads. The art of weaving is of great antiquity: it has been practised in all ages and in all countries; but it would be impossible within our limits to give even a sketch of its history, progress, and successive improvements down to its present perfect state. We had intended to present the reader with a notice of the various improvements that have been made in the loom from its simplest construction, down to the elaborate invention of Jacquard; but it was found that this could not be effected without the introduction of numerous diagrams and details, which would have been foreign to the purpose of the work; and we must, therefore, content ourselves by referring to *Ure's Dictionary of Arts, &c.* for full particulars.

WEDGE. In Geometry, a solid having five sides or faces, three of which are rectangles, and the remaining two consequently triangles, and parallel to each other; hence the wedge, considered as a geometrical figure, is a prism with a triangular base. Its content is therefore equal to the area of the triangular base multiplied into the distance between the parallel planes.

WEDGE, in Mechanics, is one of the five simple engines or mechanical powers, and is used sometimes for raising bodies, but more frequently for dividing or splitting them. In the former case, if we suppose the wedge to be urged by pressure, the action of the wedge is precisely the same as that of the inclined plane; for it is evidently the same, in point of mechanical advantage, whether the wedge be pushed under the load, or the load be drawn over the plane. The power is therefore to the force to be overcome as the tangent of the angle of the penetrating sides to the radius, leaving the friction out of consideration: hence the thinner the wedge the greater is its effect. But when the wedge, as is generally the case, is driven forward by percussion, its power cannot be estimated with any degree of accuracy. The percussive tremor excited by the blow destroys for an instant the friction at the sides, and augments prodigiously the penetrating effect. Besides, when the wedge is used in rending wood or other substances, the parts of the block are generally separated to a considerable distance before the edge of the wedge, as in the annexed figure; in which case it acts besides as a lever, the power being applied at the end of the block or acting part of the wedge, and the resistance being at the point where the fibres begin to separate.

All the various kinds of cutting and piercing tools, as axes, knives, scissars, chisels, &c., nails, pins, awls, &c., are modifications of the wedge. The angle in these cases is more or less acute, according to the purpose to which it is applied. The mechanical advantage is increased by diminishing the angle of the wedge; but the strength of the tool is thereby also diminished. In tools for cutting wood the angle is generally about 30°; for iron it is from 50° to 60°; and for brass from 80° to 90°. In general, the softer the substance to be divided is, the more acute may the wedge be constructed.

WE'DNESDAY. (Sax. Woden's day; Lat. dies Mercurii.) The fourth day of the week, consecrated by our Scandinavian ancestors to Woden, the deity whose functions corresponded to those of Mercury in the Greek and Roman mythology.

WEEK. A period of seven days, of uncertain origin, but which has been used from time immemorial in eastern countries. The week did not enter into the calendar of the Greeks, who divided the civil month into three periods of ten days each; and it was not introduced at Rome till after the reign of Theodosius. By some writers the use of weeks is supposed to be a remnant of the tradition of the creation; by others, that it was suggested by the phases of the moon; while a third class, with more probability, refer its origin to the seven planets known in ancient times. This opinion explains the circumstance that the days of the week have been universally named after the planets, according to a particular order. In the ancient Egyptian astronomy, the order of the planets, in respect of distance from the earth, beginning with the most remote, is Saturn, Jupiter, Mars, the Sun, Venus, Mercury, the Moon. The day was divided into 24 hours, and each successive hour consecrated to a particular planet in the order now stated; so that one hour being consecrated to Saturn, the next fell to Jupiter, the third to Mars, and so on; and each day was named after the planet to which its first hour was consecrated. Now, suppose the first hour of a particular day to have been consecrated to Saturn, it is evident that Saturn would also have the 8th, the 15th, and the 22d hours. The 23d hour would therefore fall to Jupiter; the 24th to Mars; and the 25th, or the first hour of the following day, would belong to the Sun, from which it would take its name. By proceeding in the same manner, it is found that the first hour of the third day would fall to the Moon, the first of the fourth day to Mars, of the fifth to Mercury, of the sixth to Jupiter, and of the seventh to Venus. The cycle being completed, the first hour of the eighth day would return to Saturn, and all the others constantly succeed in the same order. According to Dio Cassius, the Egyptian week began with Saturday. The Jews, on their flight from Egypt, made Saturday the last day of the week. The Saxons seem to have borrowed the week from some eastern nation, substituting the names of their own divinities for those of the gods of Greece. In England, the Latin names of the days are still retained in legislative and judiciary acts. (See *Ency. Brit.*, "Calendar.")

WEE'PING CROSSES. In Ecclesiastical Antiquities, stone crosses, at which penances were commonly finished with weeping and signs of contrition, were so called. There was one close to the town of Stafford. (See Mr. Astle's "Observations on Stone Crosses," *Archæol.* vol. xiii.)

WEIGH. To take the anchor out of the ground.

WEIGHT. In Physics, that property of bodies in virtue of which they tend towards the centre of the earth. In this sense, weight is synonymous with gravity. *See* GRAVITY.

WEIGHT, in Mechanics, denotes the resistance to be overcome by a machine, whether in raising, or sustaining, or moving a heavy body. The force applied to the machine for this purpose is called the moving power; and where the equilibrium subsists, the difference between the weight and the moving power is the purchase of the machine. In all cases of equilibrium by the intervention of machinery, if the machine be put in motion by a small additional force, the space passed over by the moving power will be greater than that passed over by the weight, in proportion as the weight is greater than the moving power; or the product of the weight by its velocity will be equal to the product of the moving power by its velocity. *See* MOMENTUM, VIRTUAL VELOCITY.

WEIGHT, in Experimental Philosophy and Commerce, is the measure of the force by which any body, or a given portion of any substance, gravitates to the earth. The process by which this measure is obtained is called *weighing*; and when required, as in many philosophical experiments, to be performed with great accuracy, is a tedious and delicate operation. *See* BALANCE.

The measurement of weight, like that of extension, consists in the comparison of the thing to be measured with some conventional standard. But it is impossible to fix such a standard by written law or oral description; for it is impossible to communicate by words, and without reference to a sensible object, any adequate idea of a pound-weight, or foot-rule. Standards of linear measure, not accurately defined indeed, but having an average value sufficiently well known for the rude purposes of mankind in the early stages of society, were furnished by the different parts of the human body; hence the measures *foot, cubit, span, pace,* &c. (*See* MEASURES.) But the method of comparing the weights of bodies does not suggest itself so readily to the mind as the comparison of linear dimension, and is not so easily accomplished. A balance is necessary, the construction of which requires some degree of mechanical knowledge. Hence the art of weighing, though of great antiquity, (see Goguet, *Origine des Lois, &c.*) was probably practised at a later period, and in a still less accurate manner, than that of measuring. There has also been a much greater variety of standards of weight, still less definite than those of measure, as will be readily conceived by considering the origin and import of such terms as *stone, load, last,* &c. The term *pound* (pondus) implies only weight indefinitely. The *grain*, as a standard of small weight, being taken from the grains or corns of wheat, was perhaps the only denomination of weight that would universally convey any thing like a precise idea.

As there is a constant ratio between the volumes and weights of the same substances when placed in the same physical circumstances, it is obvious that standards of weight may be derived from those of measure. For example, a cubic foot or a cubic inch of distilled water, at the same temperature, and under the same atmospheric pressure, will always have the same weight. Advantage has been taken of this property of bodies to connect weights with measures in the metrical systems that have been adopted in this and other countries.

English Weights. — It was declared by the Great Charter that the weights should be the same all over England, but no ordinance, perhaps, was ever so ill observed; for the diversity that has prevailed, and which is still far from being remedied, has been so great as not only to produce confusion and inconvenience, but to render the system of weights adopted in one part of the country scarcely intelligible in another. The old English pound, which is said to have been the legal standard of weight from the time of William the Conqueror to that of Henry VII., was derived from the weight of grains of wheat: 32 grains

gathered from the middle of the ear and well dried made a pennyweight, 20 pennyweights an ounce, and 12 ounces a pound. Henry VII. altered this weight, and introduced the *troy* pound instead, which was 1-16th part, or 3-4ths of an ounce, heavier than the Saxon pound. The troy pound was divided in the same manner as the Saxon pound, into ounces, pennyweights, and grains; but the pennyweight contained only 24 grains, and consequently a grain troy became a much heavier weight than the grain of wheat. In fact the pound troy contains 5,760 grains, while the Saxon pound, which was divided into 7,680 grains, contained only 5,400 troy grains. Another weight, the *avoirdupois* pound, was introduced by a statute of 24 Henry VIII.; and though its first object was that of weighing butchers' meat in the market, it has gradually come to be used for all kinds of coarse goods or merchandize. Two legal measures of weight were thus established, and have continued to be used in the country ever since; the avoirdupois weight being used for common purposes, and the troy for the precious metals, and, with a different division, by apothecaries in compounding their drugs. The standard of these measures was at length definitely fixed by the act of parliament passed on the 17th June, 1824, cap. 74. George IV., entitled "An act for ascertaining and establishing Uniformity of Weights and Measures," which was partially amended by clause (A) of an act to prolong the time of the commencement of that act to January, 1826. The following are the terms in which the standard is defined by the act: — "That from and after the 1st day of May, 1825, the standard brass weight of 1 pound troy weight made in the year 1758, now in the custody of the clerk of the House of Commons, shall be, and the same is hereby declared to be, the original and genuine standard measure of weight; and that such brass weight shall be, and is hereby denominated, the Imperial standard troy pound; and shall be, and the same is hereby declared to be, the unit or only standard measure of weight, from which all other weights shall be derived, computed, and ascertained; and that 1-12th part of the said troy pound shall be an ounce, and that 1-20th part of such ounce shall be a pennyweight, and 1-24th part of such pennyweight shall be a grain, so that 5,760 such grains shall be a troy pound; and that 7,000 such grains shall be, and they are hereby declared to be, a pound avoirdupois, and that 1-16th part of the said pound avoirdupois shall be an ounce avoirdupois, and that 1-16th part of such ounce shall be a dram."

It follows from this that the weight of the pound troy to that of the pound avoirdupois, or common pound, is in the proportion of 5,760 to 7,000, or of 144 to 175. The retention of two different systems of weights was in compliance with the common usages of the country; and the motives which influenced the commissioners of weights and measures in recommending the system which has been adopted were thus explained by Mr. Davies Gilbert: — "The troy pound appeared to us to be the ancient weight of this kingdom, having, as we have reason to suppose, existed in the same state in the time of Edward the Confessor; and there are reasons, moreover, to believe that the word *troy* has no reference to any town in France, but rather to the monkish name given to London, of Troy Novant, founded on the legend of Brute. Troy weight, therefore, according to this etymology, is, in fact, London weight. We were induced, moreover, to preserve the troy weight, because all the coinage has uniformly been regulated by it; and all medical prescriptions and formulæ now are, and always have been, estimated by troy weight, under a peculiar subdivision which the College of Physicians have expressed themselves most anxious to preserve."

In the sixth clause of the act it is enacted, that if the standard troy pound should be lost or destroyed, it is to be restored by a reference to a cubic inch of distilled water, which has been found and is declared to be 252·458 troy grains, at the temperature of 62° of Fahrenheit, the barometer being at 30 inches. Hence the weight of a pennyweight troy is to that of a cubic inch of distilled water, in such circumstances, in the proportion of 24 to 252·458, or of 24,000 to 252,458; so that the weight of the cubic inch of distilled water must be conceived to be divided into 252,458 equal parts, and 24,000 of such parts will be the standard pennyweight; or 100 of such parts will be the standard pound. The restoration of the standard, however, in the manner prescribed by the act, is wholly impracticable.

Though the commissioners on this occasion probably acted wisely in accommodating their regulations to existing usages, it cannot be disputed that the circumstance of having different weights expressed by the same names, as the pound and ounce troy and avoirdupois, is a source of great inconvenience and confusion. Few persons, in fact, recollect the different standards and divisions well enough to have any clear or accurate ideas on the subject. The comparison of the weights is always a matter requiring care and calculation. The avoirdupois pound is greater than the troy pound, as has been already stated, in the ratio of 175 to 144; but in consequence of the different division, the ounce avoirdupois is *smaller* than the ounce troy, the former being equal to $437\frac{1}{2}$ grains while the latter contains 480 grains. The drachm in apothecaries' weight is 60 grains, while the dram avoirdupois is equal to only $27\frac{11}{32}$ grains.

For philosophical purposes and in delicate weighing troy weight only is used, and the weight is usually reckoned in grains. By this means fractional numbers are avoided, and no ambiguity can arise, as there are no other grains than troy grains. Dr. Kelly, in his *Universal Cambist*, an elaborate and useful work, states that the dram avoirdupois, like the drachm of the apothecaries, has sometimes been divided into 3 scruples and 60 grains; but as no such weight as an avoirdupois grain ever existed, the use of the expression is an instance of the confusion inseparable from having different systems of weights, in which the same names are applied to things totally distinct.

The irregular divisions which have been adopted and retained are also liable to much objection, on account of the great number of weights to be employed in practice. The most convenient system would probably be the decimal division, which requires weights of the following values: — 1, 2, 3, 4, &c. (grains for instance); 10, 20, 30, 40, &c.; 100, 200, 300, &c.; 1000, 2000, 3000, &c. up to 9000; and ·1, ·2, ·3, &c.; ·01, ·02, ·03, &c.; ·001, ·002, ·003, &c. By this means arithmetical calculations would be facilitated, and the number of weights in the scale would equal the digits in the number by which the grains or units of weight are expressed. Thus a load of 735·4 grains, would be counterpoised by weights of 700 grains, 30 grains, 5 grains, and 4-10ths of a grain. The composition according to the geometrical series, 1, 2, 4, 8, 16, &c. offers this advantage, that a smaller number of weights would be necessary than when any other system is adopted.

In consequence of the destruction of the parliamentary standards of weights and measures by the burning of the two houses of parliament in 1834, a commission (at the head of which was the Astronomer Royal) was appointed in 1838 to consider and report upon the steps to be taken for their restoration. The report of the commissioners, which is dated the 21st of December 1841, enters very fully into the subject, and recommends the adoption of considerable changes in the present system of weights and measures and coinage, chiefly with the view of introducing, at least partially, a decimal system. But as these recommendations may not be adopted by the legislature, or at all events will probably be considerably modified, it is unnecessary, in the present state of affairs, to state them in detail. With respect to weights in particular, the plan of the commissioners is briefly this: — that the troy pound be abolished, and that the use of the troy ounce and pennyweight be confined to gold, silver, and precious stones; that apothecaries' weight may continue to be used for the combination of drugs; that for all other purposes the only legal weights shall be derived from a pound, equal to the present avoirdupois pound, the distinctive term avoirdupois being abolished. The pound is to be divided into 16 ounces, and 7,000 grains, and no denomination is to be recognised lower than pound, except the ounce and the grain and the decimal parts of the pound. They also recommend that the weight of 14 pounds, or stone in common use, and its multiples 28 pounds, 56 pounds, 112 pounds, be abolished; and that the only legal weights above one pound be weights of multiples of 1 pound and not exceeding 10 pounds, and weights of 10 pounds and its multiples not exceeding 100 pounds. According to this plan there would only be decimal multiples of the standard; while, with respect to the submultiples, there would not only be a decimal system, but also a denomination of weight equal to a 16th and another equal to a 7-thousandth part of the standard. It is not easy to see what stronger reason there can be for retaining the ounce than the stone or the hundred-weight, which are so extensively used, particularly for purposes connected with agriculture. The quantity of iron weights of 14 lb. and its multiples in use in the country is estimated to be not less than 30,000 tons, and the expense of changing them for weights in the decimal scale to be between 100,000*l.* and 200,000*l.* With respect to the standard unit, the commissioners recommend that a platinum weight of 7,000 grains be constructed and declared to be the parliamentary standard of weight; but that it be not defined with reference to any natural standard, or to measures of length or capacity, as a cubic inch of distilled water.

Tables of British Weights.

1. *Imperial Troy Weight.* — Standard: One cubic inch of distilled water, at 62° Fahrenheit's thermometer, the barometer being 30 inches, weighs 252·458 troy grains.

grs.	dwts.	oz.	lb.
24 =	1		
480 =	20 =	1	
5760 =	240 =	12 =	1

Troy weight is used in weighing gold, silver, jewels, &c., and in philosophical experiments.

2. *Apothecaries' Weight.* — Standard: The same as in troy weight, with the ounce divided into 8 drachms and 24 scruples.

grs.	scrs. (℈)	drs. (ʒ)	oz. (℥)	lb. (℔)
20 =	1			
60 =	3 =	1		
480 =	24 =	8 =	1	
5760 =	288 =	96 =	12 =	1

Medicines are compounded by this weight; but drugs are usually bought and sold by avoirdupois weight.

3. *Imperial Avoirdupois Weight.* — Standard: The same as in troy weight; and one avoirdupois pound = 7000 troy grains.

drs.	oz.	lbs.	qrs.	cwts.	ton
16 =	1				
256 =	16 =	1			
7168 =	448 =	28 =	1		
28672 =	1792 =	112 =	4 =	1	
573440 =	35840 =	2240 =	80 =	20 =	1

This weight is used for the general purposes of commerce.

The preceding are the British statute weights; but numerous other discordant denominations of weight, generally multiples of the avoirdupois pound, are still used in different parts of the country for weighing particular kinds of merchandise. One of the most common of these is the *stone*, which has a great variety of different significations. In London, however, only two stones are generally understood; viz. the stone of 8 pounds for butchers' meat, and the stone of 14 pounds for other commodities. (For values of different local weights, see *Buchanan's Tables of Weights and Measures; General Paisley's work on the Measures, Weights, and Money used in this Country; M'Culloch's Commercial Dictionary; Kelly's Universal Cambist, &c.*)

A particular denomination of weight, a *carat*, is used for weighing diamonds. An ounce troy is equivalent to 151½ carats; whence a carat is nearly equal to 3⅙ grains. In expressing the fineness of gold by *carats*, the term rather denotes a proportion than a weight. Thus gold 22 carats fine signifies an alloy such that the proportion of the weight of pure gold to that of the whole weight is as 22 to 24; or such that it contains 22 parts by weight of pure gold, and 2 parts of some inferior metal.

French System of Weights.—The French denominations of weight occur so frequently in works connected with the physical sciences, that it is convenient to be acquainted with their values. The unit of weight is the *gramme*, which is the weight of the 100th part of a cubic mètre of distilled water at the temperature of melting ice. A gramme is equal to 15·434 troy grains; whence the following comparative table of French with troy weight: —

	grammes.	Troy grains.
Milligramme =	·001 =	·01543
Centigramme =	·01 =	·15434
Decigramme =	·1 =	1·5434
Gramme =	1 =	15·434
Decagramme =	10 =	154·34
Hectogramme =	100 =	1543·4
Kilogramme =	1000 =	15434
Myriagramme =	10000 =	154340

The kilogramme is equal to 2 lb. 3 oz. 4·428 drams avoirdupois weight. In the *Système Usuel* the standards are the same as the above, but the denominations are those which were anciently in use. It was found impossible to introduce the new terms. The divisions are binary. Half the kilogramme forms the *livre usuel*, which is divided into halves, quarters, eighths, &c., down to the *gros*, which is the eighth of the *once*, or the 1-128th of the *livre*. (For a comparative table of the weights and measures used in different countries of the world, see the *Encyc. Britannica*, art. "Weights.")

WELD. (*Reseda luteola*, Linn.) A plant cultivated for the use of the dyers. When the seeds are ripe, the plant is cut and dried: it yields a brownish yellow decoction, the colour of which is rendered paler by acids, and richer and deeper by alkalies. Alum throws down a yellow precipitate, and leaves the clear liquor of a fine lemon yellow; tartar also brightens its colour; and solutions of tin give it a dilute green tint. When a mixture of whiting and alum is added to a hot decoction of weld, a yellow precipitate is obtained, which, when collected, washed, and dried, is of a fine delicate colour, and much employed by paper-stainers.

WE'LDING. There are a very few of the metals which are susceptible of being united by pressure or hammering, or of being *welded* together. Two pieces of potassium may be welded at common temperatures (from 60° to 80°); but the term is generally applied to the junction of two pieces of iron at a white heat, or of iron and steel. Platinum, also, although infusible, may be welded at a white heat; and it is in this way that that valuable metal, when in the granular or pulverulent state, is worked into bars.

WELL. In Architecture, a deep pit sunk by digging, for the purpose of collecting and retaining the water of a spring or of a reservoir, by which it may be supplied. *See* WATER and ARTESIAN FOUNTAINS.

Before proceeding to dig a well, it ought first to be determined on, whether a mere reservoir for the water which oozes out of the surface soil is desired or obtainable, or a perpetual spring. If the former is the object in view, a depth of fifteen or twenty feet may probably suffice, though this cannot be expected to afford a constant supply, unless a watery vein or spring is hit on: if the latter, the depth may be various, there being instances of 300 and 500 feet having been cut through before a permanent supply of water was found.

The art of well-digging is generally carried on by persons who devote themselves exclusively to that department. The site being fixed on, the ground-plan is a circle, generally of not more than six or eight feet in diameter: the digger then works down by means of a small short-handled spade, and a small implement of the pick-axe kind; the earthy materials being drawn up in buckets by the hand or a windlass fixed over the opening for the purpose. Where persons conversant with this sort of business are employed, they usually manage the whole of the work, bricking round the sides with great facility and readiness; but in other cases it will be necessary to have a bricklayer to execute this part of the business.

There are two methods of building the stone or brick within the well, which is called the steining. In one of these a circular ring is formed, of the same diameter as the intended well; and the timber of which it is composed is of the size of the brick-courses with which the well is to be lined. The lower edge of this circle is made sharp, and shod with iron, so that it has a tendency to cut into the ground; this circular kirb is placed flat upon the ground, and the bricks are built upon it to a considerable height, like a circular wall. The well-digger gets within this circle, and digs away the earth at the bottom; the weight of the wall then forces the kirb and the brickwork with which it is loaded to descend into the earth, and as fast as the earth is removed it sinks deeper, the circular brick wall being increased or raised at top as fast as it sinks down; but when it gets very deep, it will sink no longer, particularly if it passes through soft strata: in this case, a second kirb of a smaller size is sometimes begun within the first. When a kirb will not sink from the softness of the strata, or when it is required to stop out water, the bricks or stones must be laid one by one at the bottom of the work, taking care that the work is not left unsupported in such a manner as to let the bricks fall as they are laid: this is called underpinning.

Well-diggers experience sometimes great difficulty from a noxious air which fills the well, and suffocates them if they breathe it. The usual mode of clearing wells of noxious air, is by means of a large pair of bellows, and a long leathern pipe, which is hung down into the well to the bottom and fresh air forced down by working the bellows.

The use of the auger is common in well-digging, both in ascertaining, before commencement, the nature of the strata to be dug into, and also in course of digging for the same purpose; and because, by boring in the bottom of a well to a considerable depth, the spring is sometimes hit upon, and digging rendered no longer necessary.

The use of the borer alone may procure an adequate supply of water in particular situations. This mode appears to have been long resorted to in this and other countries. From what we have already stated as to the disposition of strata, the conditions requisite for its success will be readily conceived; viz. watery strata connected with others on a higher level: the pressure of the water contained in the higher parts of such strata on that in the lower will readily force up the latter through any orifice, however small. All that is necessary, therefore, is to bore down to the stratum containing the water, and, having completed the bore, to insert a pipe, which may either be left to overflow into a cistern, or it may terminate in a pump. In many cases, water may be found in this way, and yet not in sufficient quantity and force to rise to the surface; in such cases a well may be sunk to a certain depth, and the auger-hole made, and the pipe inserted in it in the bottom of the well. From the bottom it may be pumped up to the surface by any of the usual modes.

As an example of well-digging combined with boring, we give that of a well dug at a brewery at Chelsea, Middlesex, in 1793. The situation was within 20 or 30 feet of the edge of the Thames, and the depth 394 feet, mostly through a blue clay or marl. At the depth of nearly fifty feet a quantity of loose coal, twelve inches in thickness, was discovered: and a little sand and gravel was found about the same depth. The well-digger usually bored about ten, fifteen, or twenty feet at a time lower than his

work as he went on; and on the last boring, when the rod was about fifteen feet below the bottom of the well, the man felt, as the first signal of water, a rolling motion, something like the gentle motion of a coach passing over pavement: upon his continuing to bore, the water presently pushed its way by the side of the auger with great force, scarcely allowing him time to withdraw the borer, put that and his other tools into the bucket, and be drawn up to the top of the well. The water soon rose to the height of 200 feet.

In a case which occurred in digging a well at Dr. Darwin's, near Derby, the water rose so much higher than the surface of the ground, that, by confining it in a tube, he raised it to the upper part of the house. (*Rees's Cyclopædia*, art. "Well;" and *Derbyshire Rep.*)

The process of boring the earth for spring-water has of late been practised with great success in various parts of England, chiefly by Mr. Goode of Huntingdon. In the neighbourhood of London, many fountains of pure spring-water have lately been obtained by these means. We may particularly name those at Tottenham, Middlesex, and Mitcham, Surrey, both of which afford a continuous and abundant flow of water, at one time equal to about eight gallons per minute; but now reduced to a much smaller quantity, in consequence of the great number of holes that have been bored into the supplying strata.

WELL. A small enclosed space near the mainmast, extending from the bottom of the ship to the principal gun deck, containing the pumps.

WE'REGILD. Among the Anglo-Saxons, the compensation paid by a delinquent to the party injured, or his relations, for offences against the person. This custom was common to all the Teutonic tribes, and to many Celtic. It is mentioned by Tacitus in his account of the ancient Germans. The great distinction between Saxon freemen was that between the "eorls," or nobility, and "ceorls," or commonalty; and the *were* of the former was usually rated at six times the amount of that of the latter.

WE'RNERITE. A mineral named after Werner. It is a silicate of alumina, lime, and oxide of iron; of a green or grey colour; and forms eight-sided prismatic crystals. It has been found in Norway and Sweden, and also in Switzerland.

WE'SLEYANS. The chief denomination of the Methodists; so called from John Wesley, their founder. *See* METHODISTS.

WE'STERN EMPIRE. The name given by historians to the western division of the Roman empire, when divided, by the will of Theodosius the Great, between his sons Honorius and Arcadius, A. D. 395. After the deposition of the emperor Augustulus by Odoacer, A. D. 476, the Western empire was definitively at an end. But when Charlemagne, in the year 800, assumed the imperial crown, it was with the view of reassuming the ancient dignity of the Cæsars in Western Europe; and after him the German emperors were considered by the jurists of their own country, and of their party in Italy, as representing the majesty of ancient Rome, the Italian states being looked on as feudatories of the empire.

WHALE. *See* BALÆNA.

WHEAT. (*Triticum*, L.; *Triandria Digynia*, L.; *Gramineæ*, Juss. Inflorescence spiked. Glume two-valved, many-flowered, shorter than the spikelet; the valves nearly equal, beardless, or with one beard enclosing the florets. Paleæ two, one of them bearded from the end. Seed enclosed in the paleæ, rarely otherwise.)

Wheat is by far the most important and most extensively cultivated species of bread-corn raised in England. It is sown after fallow, turnips, cabbages, potatoes, beans, &c. In light soils it follows clover and the cultivated grasses; but it never, at least in the best farmed districts, follows any other white crop. Wheat may be raised on all sorts of soils; but those of a clayey nature are the most suitable. So peculiarly, indeed, is wheat adapted to heavy stiff lands, that they are usually termed "wheat soils." The lighter the soil, the less is it suited to this species of grain; and it is an error in practice to force the cultivation of wheat on soils, and under circumstances, better suited to the production of other grain. In this country it does not admit of being raised at a great elevation. As it is a crop on which the farmer mainly depends, the preparation for it, in whatever rotation it comes, should be an object of great care and attention. If it be intended to sow wheat after fallow, the land is repeatedly ploughed, harrowed, and well manured; if after clover, only one ploughing is given, and seldom more after beans; where tares have been previously sown, they are got off the land in sufficient time to plough it more than once; when wheat follows turnips or cabbages, it must, unless they be stored or eaten, be sown in the spring months.

The kinds of wheat grown in England seem mostly all to be varieties of two species — the *Triticum hybernum*, or winter wheat, and the *Triticum turgidum*, or turgid wheat. The culture of the latter is mostly confined to clays; the cone or bearded wheat, being the most esteemed of its varieties: it enjoys this pre-eminence, not because it yields the finest flour, but because it is comparatively productive, and not subject to disease on wet soils.

The varieties of wheat are perpetually changing, in consequence of variations of culture, climate, and soil. Those most in use are distinguished by different local terms. They may, however, be divided into the two great classes of *red* and *white*, — the latter being superior as respects quality of produce, and the former of hardiness. In general, the thin and smooth-chaffed varieties are preferred to those that are woolly and thick-chaffed. Wheat sown in the spring is called *spring wheat;* but the species is quite the same as that sown before winter; though, by being sown in the spring, its period of ripening is changed. It is always sown before winter when the ground can be got ready; but when it follows turnips, cabbages, and such like crops, it has frequently to be deferred to the spring. (*Low on Agriculture*, pp. 222—228.)

Winter wheat is seldom sown in any part of England before the beginning or middle of September, or later than the end of November. Spring wheat is generally sown between the middle of March and the middle of April. The seed is invariably pickled or steeped; a process intended to prevent *smut*. The quantity of seed allowed to an acre, when sown broad-cast, usually varies from 2½ to 3, and even 4 Winchester bushels.

The drill husbandry, as applied to wheat, is practised to a considerable extent in many parts of England; and in some places it is not unfrequently planted with the dibble; but by far the greater portion is sown broad-cast. While growing, but little attention or labour is bestowed upon it. When drilled, it is generally hoed; and when sown broad-cast, it is sometimes hand-weeded, and occasionally, though rarely, harrowed and rolled in the spring. But these operations are generally, perhaps, prosecuted as much in the view of covering the clover and grass seeds that are then frequently sown in the wheat fields, as of improving the wheat crop.

Wheat harvest generally commences, in the south of England, about the 25th of July, or the beginning of August; in the midland counties it is about ten days, and in the northern counties from a fortnight to three weeks later. There is a striking difference in the harvest field operations, with respect to this as well as other kinds of grain, between the north and south of England; in the former, during harvest, the corn-field exhibits a large number of reapers, perhaps 50, 60, or even 100, all working together, and presenting an interesting and animating spectacle. In the south of England, on the other hand, and over the greater part of the midland counties, wheat is reaped by small sets of individuals, who contract to cut a field or a certain number of acres; so that, in general, the field merely exhibits one or two men, with, perhaps, their wives, working in different parts of it. Wheat is seldom or never cut down with the scythe, but is either reaped with the common sickle, or, as is the practice in some of the counties near the metropolis, as well as in some of the south western counties, it is *bagged*, that is, struck down near the ground with a large and heavy hook. It is universally bound in sheaves, which are set up in *shocks* or *stooks*, each containing twelve or fourteen sheaves. Perhaps no circumstance marks the difference of climate in the south and north of England more strongly than the difference in point of time during which it is necessary to keep wheat and other grain in the field before it is carried home. In the southern counties it is generally ready in a week or ten days; whereas in the north it is necessary to let it stand out for two or three weeks. In the southern, eastern, and midland counties, it is frequently put into barns: in the north, it is almost universally stacked.

As this grain is so extensively cultivated, frequently on very inferior soils, and after very imperfect preparation, the produce per acre varies materially in different counties and districts; it is also very liable to injury from a bad seed time, a wet winter, or a blight during the period of its flowering (which last is the most common cause of the failure or deficiency of our wheat crops); so that its produce varies as much in different seasons on the same farms, and under the same management, as it does during the same season on different farms. The lowest quantity of produce, except where an absolute deficiency from blight occurs, may, perhaps, be rated at from 10 to 12 bushels an acre; and the highest at from 48 to 56 or 64 bushels. Occasionally, indeed, even more than this has been reaped on the deep loams near Chichester, in Sussex, on the calcareous loams near Epsom, and in some of the more favoured and highly cultivated parts of Kent, Essex, Lincoln, Somerset, &c.

The wheat counties are Kent, Essex, Suffolk, Rutland, Hertford, Berks, Hants, and Hereford; that is, these are the counties most distinguished for the quality as well as the quantity of their wheat. In the north, this

grain is sometimes raised of a very fine quality; but generally it is inferior; being colder to the feel, darker coloured, thicker skinned, and yielding less flour. In the best wheat counties, and in good years, the weight of a Winchester bushel of wheat varies from 60 to 62 lbs. In the Isle of Sheppey, in Kent (where, perhaps, the best samples are produced), it sometimes weighs, in favourable seasons, 64 lbs. a bushel. Where the climate is naturally colder, wetter, and more backward, or in bad seasons, the weight of the bushel does not exceed 56 or 57 lbs. It is calculated that, at an average, a bushel of good English wheat weighs 58½ lbs.; and that the average yield of flour is 12½ lbs. of flour to 14 lbs. of grain. The weight of the straw is supposed to be about double that of the grain; so that an acre yielding 30 bushels of wheat, at 58½ lbs. per Winchester bushel, would yield 3,510 lbs. of straw. (*Statistics of British Empire*, i. 464.)

The increase of population, and the extraordinary extension and improvement of cultivation during the ten years ending with 1840, coupled with the inquiries we have made, have satisfied us that in average seasons the quantity of wheat raised in the United Kingdom for food cannot at present (1842) be less than 15,000,000 quarters, and adding to this ⅛th part for seed, the total produce will be 17,500,000 quarters; worth, at the low average price of 52*s*. a quarter, 45,500,000*l*. But notwithstanding its magnitude, the supply is, speaking generally, inadequate to meet the demand, and whenever the crops are below an average there is a large importation.

We incline to think that of the total produce of wheat in the United Kingdom, at least 15,000,000 quarters are furnished by England. The climate of Scotland and Ireland, especially of the latter, is, speaking generally, too cold and moist for the profitable culture of wheat. Along the east coast of Scotland, indeed, in Berwickshire, East Lothian, Fife, Perth, and Forfar, there are extensive tracts where the soil and climate are comparatively good, and the culture excellent, and where very good wheat is raised. But with these exceptions, the rest of Scotland, and the whole of Ireland, is more suitable for the growth of oats and barley than for that of wheat. Indeed its culture in Ireland has recently been declining. The following table gives a comprehensive view of the most important circumstances connected with the British trade in wheat from 1799 down to 1841, both inclusive: —

Account of the Total Quantities of Wheat and Wheat-Flour imported into and exported from Great Britain; distinguishing between the Quantities imported from Ireland and Foreign Parts, in each Year from 1799 to 1841, both inclusive, with the Average Prices of Wheat per Imperial Quarter, in England and Wales, during the same Period.

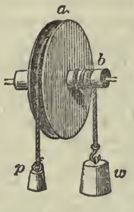
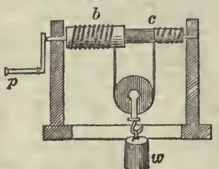
WHEEL AND AXLE. In Mechanics, one of the simple mechanical powers or machines, consisting of a wheel having a cylindrical axis passing through its centre, resting on pivots at its extremities, or supported in gudgeons, and capable of revolving. The power is applied to the circumference of the wheel, and the weight or force to be overcome to the circumference of the axle; and equilibrium takes place when the power and weight are to each other inversely as the radii of the circles to which they are applied. In the annexed figure, a is the wheel, b the axle, p the power, and w the weight. The power is applied by a rope passing round the wheel, and the weight attached to another rope coiled round the axle in a contrary direction. As the wheel and axle turn together, the wheel takes up or throws off as much more rope than the axle as its circumference is greater than that of the axle; or the space through which p descends is as much greater than that through which w is lifted up as the circumference or radius of the wheel is greater than the circumference or radius of the axle. Hence if a denote the radius of the wheel, and b that of the axle, we have, by the principle of virtual velocities, $p : w :: b : a$, or $p\,a = w\,b$.



The wheel and axle is a perpetual lever, so contrived as to have a continued motion about a fulcrum. When the thickness of the rope is taken into consideration, the force must be conceived as acting at the centre of the rope, and therefore the thickness of the rope which supports the weight must be added to the diameter of the axle, and the thickness of that which supports the power to the diameter of the wheel. But the manner in which the power is applied is very various, and frequently otherwise than by means of a rope. If the power acts not at the circumference of the wheel, but at the extremity of a handspike or projecting pins inserted in the wheel, the distance of that extremity from the centre of the axis is to be accounted the radius of the wheel. The common winch with which a grindstone is turned or a crane worked, the capstan, the windlass, the crank, and other contrivances of a similar kind, are only different modifications of the wheel and axle.

A form of the wheel and axle is represented in the subjoined figure, by which a great mechanical advantage is obtained. The axle consists of two parts having different thicknesses; and the rope after being coiled round one of the parts is carried round a pulley attached to the weight, and coiled round the other in the opposite direction. The power p is applied at the handle of the winch, which here takes the place of the wheel. In order to compute the advantage gained by this machine, let a denote the circumference described by the handle of the winch, b the circumference of the thicker part of the axle, and c that of the thinner part; then, while the winch makes one revolution in the direction which raises the weight, the part of the rope which passes from the one part of the axle to the other round the pulley will be shortened by the quantity $b-c$, and consequently the weight w will be raised through the height $\frac{1}{2}(b-c)$. But the space described in the same time by the power p is equal to that through which the handle of the winch passes, or equal to a; therefore, by the principle of virtual velocities, $p : w :: \frac{1}{2}(b-c) : a$, or $p\,a = \frac{1}{2} w\,(b-c)$. As the circumferences of circles are to their radii in a constant ratio, it is evident that the formula will equally apply if the letters a, b, c be taken to represent the respective radii.



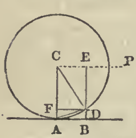
WHEEL. In a Ship, the wheel and axle by which the tiller is moved.

WHEEL ANIMAL, or WHEEL ANIMALCULE. *See* Rotifers.

WHEEL, BREAKING ON THE. A mode of capital punishment, said to have been first employed in Germany; according to some writers, on the murderers of Leopold, duke of Austria, in the 14th century. According to the German method of this savage execution, the criminal was laid on a cart-wheel with his arms and legs extended, and his limbs in that posture fractured with an iron bar. But in France (where it was restricted to cases of assassination, or other murders of an atrocious description, highway robbery, parricide, and rape), the criminal was laid on a frame of wood in the form of a St. Andrew's cross, with grooves cut transversely in it above and below the knees and elbows; and the executioner struck eight blows with an iron bar, so as to break the limbs in those places, sometimes finishing the criminal by two or three blows on the chest or stomach: thence

called *coups de grace*. He was then unbound and laid on a small carriage wheel, with his face upwards, and his arms and legs doubled under him; there to expire, if still alive. Sometimes the sentence contained a *retentum*, by which the executioner was directed to strangle the criminal, either before the first, or after one, two, or three blows. This punishment was abolished in France at the Revolution; but it is still resorted to in Germany as the punishment for parricide, the last instance of which took place in 1827 near Gottingen. The assassin of the bishop of Ermeland in Prussia, in 1841, was sentenced to the wheel.

WHEELS OF CARRIAGES. Wheels applied to carriages serve a twofold purpose. In the first place, they greatly diminish the friction on the ground by transferring it from the circumference to the nave and axle; and in the second place, they serve to raise the carriage more easily over obstacles and asperities met with on the roads. The friction is diminished in the proportion of the circumference of the axle to that of the wheel; and hence the larger the wheel, and the smaller the axle, the less is the friction. The mechanical advantage of the wheel in surmounting an obstacle may be computed from the principle of the lever. Let the wheel touch the horizontal line of traction in the point A, and meet a protuberance B D. Suppose the line of draft C P to be parallel to A B, join C D, and draw the perpendiculars D E and D F. We may suppose the power to be applied at E, and the weight at F, and the action is then the same as the bent lever E D F turning round the fulcrum at D.



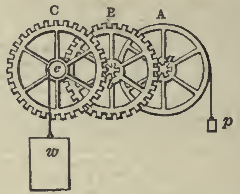
Hence P : W : : F D : D E. But F D : D E : : tan. F C D : 1; and tan. F C D = tan. 2 (D A B); therefore P = W tan. 2 (D A B). Now, it is obvious that the angle D A B increases as the radius of the circle diminishes; and therefore the weight W being constant, the power required to overcome an obstacle of a given height is diminished when the diameter is increased. Large wheels are therefore best adapted for surmounting inequalities of the road. There are, however, circumstances which prescribe limits to the height of the wheels of carriages. If the radius A C exceeds the height of that part of the horse to which the traces are attached, the line of traction C P will be inclined to the horizon, and part of the power will be exerted in pressing the wheel against the ground. The best average size of wheels is considered to be about 6 feet in diameter. The fore wheels of carriages and waggons in this country are usually much too small.

Cylindrical wheels are best adapted for level roads; and the breadth of the rim should be considerable (not less than three inches), to prevent their sinking into the ground. In hilly and uneven roads a slight inclination of the spokes, called *dishing*, tends to give strength to the wheel; but it is very frequently carried to excess.

WHEEL WORK, in Machinery, consists of a combination of wheels communicating motion to one another. Such combinations may be formed in various ways; but they are generally reducible to the principle of the wheel and axle, though the wheel which turns the other is not usually on the same axis with it. The motion in such cases is communicated from the one wheel to the other, either by belts or straps passing over the circumferences of both, or by teeth cut in those circumferences, and working in one another. In either of these ways the velocities of points in their circumferences are equal; and consequently their angular velocities, or the number of revolutions which they make in the same time, are inversely as their radii. When one wheel drives another by teeth, they necessarily turn in opposite directions; if united by a cord or belt, they will turn in the same direction, if the belt does not cross itself between the two wheels; but if the belt crosses itself, they will turn in opposite directions. The chief advantage of transmitting motion by cords or belts is, that the wheels may be placed at any convenient distance from each other, and be made to turn either in the same or in opposite directions.

Wheels may act on one another so as to communicate motion in various ways. When the resistance of the work is not great, the object may be accomplished by the mere friction of their circumferences. In order to increase the friction, the surfaces of the rims are faced with buff leather (caoutchouc might answer the purpose better), or wood cut against the grain, and pressed together with a certain degree of force. This method is sometimes used in spinning machinery, and has even been applied successfully to the saw mill; but is seldom adopted in works on a great scale. Motion communicated in this manner proceeds smoothly and evenly, and is accompanied with little noise.

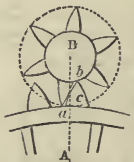
When motion is to be transmitted through a train of wheel work, toothed wheels are generally employed. It is usual to call a small wheel acted on by a large one a *pinion*, and its teeth the *leaves* of the pinion. Wheels and pinions are combined in the manner represented in the annexed figure. On the axle of the wheel A, which bears the power, is a pinion *a*, which drives the wheel B. The axle of this wheel carries a pinion *b*, which drives the wheel C. In the figure, the axle *c* of this wheel carries the weight; but the combination may be continued at pleasure.



When motion is communicated in this manner, the angular velocity of the first wheel is to that of the last pinion as the product formed by multiplying together the radii of all the wheels to the product formed by multiplying together the radii of all the pinions. Consequently, if R, R′, R″, &c. denote respectively the radii of the wheels, and r, r', r'', &c. the radii of the pinions, we shall have, by the principle of virtual velocities, $p\ (R \times R' \times R'', \&c.) = w\ (r \times r' \times r'', \&c.)$. As the size of the teeth of any wheel and the opinion into which it works must be equal, we may substitute for the radii the number of teeth in the wheels and pinions respectively.

Toothed wheels, as distinguished by the position of the teeth relatively to the axis, are of three kinds: *spur wheels*, *crown wheels*, and *bevelled wheels*. When the teeth are raised upon the edge of the wheel, or are perpendicular to the axis (as in the above figure), the wheel is a spur wheel; when they are raised parallel to the axis, or perpendicular to the plane of the wheel, it is a crown wheel; and when they are raised on a surface inclined to the plane of the wheel, it is called a bevelled wheel. The combination of a crown wheel with a spur wheel as pinion is used when it is required to communicate motion round one axis to another at right angles to it. Two bevelled wheels are employed to transmit motion from one axis to another inclined to it at any proposed angle. Wheels have also different names, according to their mode of action, as *heart wheel*, *sun-and-planet wheel*.

Form of the Teeth of Wheels. — In the construction of machinery, it is of the utmost importance that the several parts act on one another with a uniform force, and with the smallest possible amount of friction. When wheels act by teeth working into each other, every point of the side *a b* of the tooth which is in action comes successively into contact with the tooth of the pinion as the wheel turns round, and the force is necessarily exerted at the points *c*, which are in contact.



Hence the lengths and positions of A *c* (A being supposed the centre of the wheel) and B *c*, the levers by which they act, are constantly changing; and in order, therefore, that the force of the one tooth upon the other may be constant, it is necessary that the line drawn perpendicular to the surfaces of both teeth, at the point of contact *c*, always intersect the line A B of the centres in the same point. There are many different curves according to which the teeth might be formed so as to answer this condition; but that which has been most generally adopted, and which appears the most convenient, is the epicycloid generated by the revolution of a circle whose radius is equal to half the radius of the pinion on the circumference of a circle equal to the wheel. This was first proposed by Roemer, the celebrated Danish astronomer. The evolute of the circle was proposed, with other curves, by Euler. *See* TEETH OF WHEELS.

When the teeth are constructed according to the theoretical rules, the action is not only uniform, but there is little friction; for the teeth roll on one another, and neither slide nor rub. But as it is impossible to attain perfect accuracy in practice, the surfaces of the teeth will always present some inequalities, and there will consequently be some friction. In order, therefore, to equalize the wear, it is necessary that every leaf of the pinion should work in succession through every tooth of the wheel, and not always through the same set of teeth; and hence the number of teeth in a wheel and in a pinion which work into each other should be prime to one another. This precaution is more especially necessary in mill work, and where considerable force is used (*Willis's Principles of Mechanism*; *Buchanan on Mill Work*, by Rennie; *Lardner's Mechanics*, *Cab. Cyclop.*; *Gregory's Mechanics*, &c.)

WHELPS. Short upright pieces placed round the barrel of the capstan, to afford resting points for the messenger or hawsers.

WHE'TSTONE. A talcy slate containing silica, used for hones. *See* NOVACULITE.

WHEY. The limpid part of milk which remains after the separation of the curd and butter: it consists chiefly of water holding between 3 and 4 per cent. of sugar of milk in solution. *See* MILK.

WHIGS. The well-known designation of a political party in English history. It was first used in the reign of Charles II. The term, which is of Scottish origin (*vide infrà*), was first assumed as a party name by that body of politicians who were most active in placing William III. on the throne of England. Since that time it has been borne by successive generations of those who, by hereditary inclination, or by education, or party connection, have followed in the same political line. Generally speaking, the principles of the Whigs have been popular, and their measures, when in power, tending to increase the democratic influence in the constitution. It may not be out of place to subjoin a few of the various accounts of the origin of the term *Whig*, now incorporated indelibly in the political vocabulary of this country. It was introduced immediately after the failure of Hamilton's expedition into England, in the year 1648, for the rescue of Charles I. from the hands of the English levellers and fanatics. After Hamilton's defeat at Preston, the Westland Whigs raised an insurrection, which is thus alluded to: —

"The party appellation of *Whigamores*, or, briefly, *Whigs*, had its origin at this period; and the insurrection referred to was called the 'Whigamores' raid,' or incursion, that term being the common one for the predatory expeditions of the Borderers. This nickname being still preserved in the vocabulary of party, although there is truly none now existing that can be in any degree assimilated to the original faction, it seems proper to explain how the distinction originated. Mr. Laing, in his History (vol. i. p. 381. 2d ed. 1804), informs us that 'the expedition was termed the Whigamores' inroad, from a word employed by these western peasants in driving horses; and the name transferred, in the succeeding reign, to the opponents of the court, is still preserved and cherished by the Whigs as the genuine descendants of the Covenanting Scots.' And in a footnote he adds, 'According to others from whig or whey, the customary food of those peasants.'"

Sir Walter Scott, in his *Tales of a Grandfather* (*Prose Works*, vol. xxiv.), says, "This insurrection was called the Whigamores' raid, from the words *whig, whig*, — that is, get on, get on, — which is used by the western peasants in driving their horses; a name destined to become the distinction of a powerful party in British history."

In Daniel Defoe's *Memoirs of the Church of Scotland*, printed 1717, p. 173., speaking of the Covenanters, he says, "This is the first time that the name of a Whigg was used in the world,—I mean as applied to a man or to a party of men; and these were the original primitive Whiggs, the name for many years being given to no other people. The word is said to be taken from a mixed drink the poor men drank in their wanderings, composed of water and sour milk."

And Bishop Burnet, who lived nearer to the time in which the nickname was invented, gives the following explanation of it in the *History of his Own Times* (p. 26. imperial ed. 1837): — "The south-west counties of Scotland have seldom corn enough to serve them round the year; and the northern parts producing more than they need, those in the west come in the summer to buy at Leith the stores that come from the north; and from a word *whiggam*, used in driving their horses, all that drove were called Whiggamores, and, shorter, the Whiggs. Now, in that year, after the news came down of Duke Hamilton's defeat, the ministers animated their people to rise and march to Edinburgh, and they came up marching on the head of their parishes with an unheard-of fury, praying and preaching all the way as they came. The Marquis of Argyle and his party came and headed them, they being about six thousand. This was called the Whiggamores' inroad, and ever after that all that opposed the court came, in contempt, to be called Whiggs; and from Scotland the word was brought into England, where it is now one of our unhappy terms of distinction."

WHI'NSTONE. A species of basalt. *See* GEOLOGY.

WHIP. In sea language, a rope passed through a single block or pulley.

WHI'RLING TABLE. A machine contrived for representing several phenomena of centrifugal force, by giving bodies a rapid rotation. Mr. Robins invented a whirling machine for the purpose of determining the resistance of the air, which is described in the 1st vol. of his *Tracts*; and also in *Hutton's Tracts*, vol. iii., where the results of a series of experiments with it are detailed.

WHI'RLPOOL. A vortex, eddy, or gulf, where the water has a circular motion. Whirlpools are produced by the meeting of currents which run in different directions. Their danger to navigation is well known, but is perhaps not equal to the dread which sailors entertain of them. Some of the most celebrated are the Euripus, near the coast of Negropont; the Charybdis, in the straits of Sicily; and the Maelstrom, on the northern coast of Norway. (*Murray's Geography*, Introd.)

WHI'RLWIND. A revolving column or mass of air, supposed with most probability to be produced by the meeting of two currents of air blowing in opposite directions, but ascribed by some to electricity. It is analogous to the *whirlpool*. When the opposite currents have the same velocity, the circulation will be maintained at the same spot; but if the motion of one of them is more rapid than that of the other, it will transport the whirling motion with its excess of celerity, and a progressive and rotatory motion are thus maintained at the same time. Whirlwinds generally occur in summer, and are most violent in tropical countries, where they frequently produce most destructive effects. The diminution of atmospheric pressure arising from the centrifugal force of the revolving column is thus computed by Professor Leslie: — "If r denote in feet the radius of the extreme circle described by the whirlwind, and t the time of circumvolution in seconds, the elasticity, or pressure of the column at the verge, will suffer a diminution corresponding to the fraction $\frac{5\,r}{4\,t^2}$. The amount of this diminution over the whole base would be reduced to three fourths; and consequently, h expressing the height of the revolving column of air, $\frac{15\,r\,h}{16\,t^2}$ would represent the mean effect of centrifugal action. Suppose the whirlwind to have an elevation of 200 feet, and a radius of 50, and to circulate in 3 seconds, the diminished pressure would be equal to the weight of a column of $\frac{15 \times 50 \times 200}{16 \times 9} = 1040$ feet. This example, assuming a celerity of sixty-five miles an hour, might be reckoned an extreme case; but it would occasion the mercury to sink in the barometer more than an inch, or 1·12." (*Ency. Brit.*, "Meteorology.") *See* STORM; WINDS.

WHI'SKEY. (A corruption of the Gaelic word *usquebaugh*.) A species of corn spirit. *See* DISTILLATION.

WHI'SPERING DOMES, or GALLERIES, are places in which whispers or feeble sounds are communicated to a greater distance than under any ordinary circumstances. In order to produce this effect, the form of the roof or walls of the building must be such that sound proceeding from one part is transmitted by reflection or repeated reflections to another. The dome of St. Paul's church in London furnishes an instance. *See* SOUND.

WHITE. In Painting, a negative colour (if such definition may be allowed), whose opposite or antagonist is *black*, which may best serve as its explanation; because black is void of all colour, properly so called.

WHITE. The colour produced by the combination of all the prismatic colours mixed in the same proportions as they exist in the solar rays. This is proved both by decomposing white light by means of a prism, and by recompounding the primitive colours in due proportions. *See* COLOUR, LIGHT, REFRACTION.

WHITE ARSENIC. Oxide of arsenic, or arsenious acid. *See* ARSENIC.

WHITE BAIT. The name of a small and peculiar species of *Clupea*; confounded, until studied by Mr. Yarrel, with the young of the shad (*Clupea alosa*). The young fish of the white bait (*Clupea alba*, Yarrell) begin to ascend the Thames at the beginning of April, and continue in that part of the river where there is a mixture of salt with fresh water until September, when young fish of the year four or five inches long are not uncommon, though accompanied by others of smaller size; but the parent fish are believed not to ascend beyond the estuary. The young of the shad are not two inches and a half long till November, when the white bait season is over; and they are distinguished by a spotted appearance behind the edge of the upper part of the operculum, which the white bait never exhibits. Mr. Yarrel suggests that if a net sufficiently small in the mesh were used, the white bait might be taken in other rivers besides the Thames; but he states that the Hamble, which runs into the Southampton Water, is the only other river from which he has received this justly estimated fish.

WHITE COPPER. An alloy used by the Chinese, and called by them Packfong or Pakfong; it is composed, according to the analysis of Dr. Fife, of 40·4 parts of copper, 25·4 of zinc, 31·6 of nickel, and 2·6 of iron. *German silver* is a modification of this alloy.

WHITE EAGLE, ORDER OF THE. An order of knighthood in Poland, instituted by Uladislaus V. in 1325; revived by Frederic Augustus I. in 1705.

WHITE LEAD. Carbonate of lead. *See* LEAD. Thi

important compound, of which from 16,000 to 17,000 tons are annually manufactured in England, is chiefly used as the basis of white oil paint; it is also employed to a small extent in the manufacture of cements. It is chiefly made in two ways: either by precipitation, as when carbonic acid or a carbonate is used to decompose a soluble salt, or a subsalt of lead; or by exposing plates of cast lead to the joint action of the vapour of acetic acid, air, and carbonic acid: it is by the latter process only that the resulting carbonate of lead is obtained of that degree of density and opacity, and perfect freedom from crystalline texture, which fits it for paint. This last, commonly called the *Dutch process*, was introduced into England about the year 1780. It is described, together with the other processes, in *Brande's Manual of Chemistry*, fifth ed. p. 844. White lead is often largely adulterated with sulphate of baryta, which is detected by insolubility in dilute nitric acid, whereas pure white lead is entirely dissolved by it.

WHITE LEG. A disease which generally occurs in women soon after delivery, and which has been erroneously supposed to arise from redundancy of milk. It comes on with stiffness and pain of the limb, which afterwards becomes tumid and tense from the effusion of serum, and in some instances goes on to suppuration. Leeches, fomentations, friction, and gently stimulating liniments, with the internal use of mild aperients and remedies calculated to allay the febrile symptoms that attend it, are the principal points of treatment. Those women who during pregnancy have suffered very much from swellings of the lower extremities are generally most liable to its attacks.

WHITE PRECIPITATE. The white powder which falls on adding ammonia to a solution of corrosive sublimate: it is a compound of peroxide and bichloride of mercury with ammonia: it is virulently poisonous, and is chiefly used in ointments and for killing vermin.

WHITE STONE. A granite abounding in white felspar.

WHITE SWELLING. A term vulgarly applied to indolent tumours in scrophulous habits.

WHITE VITRIOL. The old name of sulphate of zinc. *See* ZINC.

WHI'TEWASH. A mixture of whiting, size, and water, for whitening ceilings, walls, &c.

WHITFIE'LDIAN ME'THODISTS. The name given to the most numerous body of the Methodists after the Wesleyans; so called from Whitfield, whose early connection with the Methodists will be found noticed under that term. Soon after the return of Mr. Whitfield from America in 1741, he withdrew connection with Wesley on account of religious tenets; the former holding the high doctrine of Calvinism, and differing from the latter chiefly on the subjects of election and general redemption. But though they differed in sentiments, these good men lived and died united in heart. Whitfield devoted his life to itinerant preaching, and was, if possible, more popular as an energetic and eloquent pulpit orator than his former coadjutor. He did not confine his labours to Great Britain and Ireland, but visited North America no fewer than seven different times; and died there at Boston, in 1770, in the fifty-sixth year of his age. But he can scarcely be said to be the founder of a sect: his chief object was itinerating. At several places, indeed, he erected chapels, or *tabernacles*, as he called them; but these he invariably left to the care of any orthodox clergyman, whether in the establishment or among the dissenters, who was prepared to occupy them. Since his death the members of these congregations have been nominally, but only nominally, classed together as a distinct body, under the title of the *Tabernacle Connection*. They are not governed by a general conference, nor is their cause supported by a common stock; but each congregation is virtually independent in itself, and provides for its own expenses. The lay-preachers are few, most of their ministers being ordained among themselves; but, like the Wesleyans, they have a periodical change of pastors. (*Dr. Gillies's Life of Whitfield*.)

Among the most zealous of Whitfield's followers was Selina, Countess of Huntingdon, in whose family he had at one time officiated as chaplain. She devoted her ample funds to the erection of chapels in different parts of England, and invited clergymen of the established church to occupy them; but finding the supply of pastors from that source deficient, she founded a college at Trevecca, in South Wales, for the education of pious young men for the ministry. She thus became the foundress of a distinct sect, under the name of *Lady Huntingdon's Connection*. The college has, since her death, which took place in 1791, been transferred to Cheshunt, in Hertfordshire. In her chapels, about sixty in number, the service is performed according to the ritual of the church of England. (*Dr. Haweis's Hist. of the Church*, vol. iii.; *Adam's Religious World*, vol. iii. 146-56.)

Another sect of Methodists, whose name is frequently found in connection with that of Whitfield, are the Welsh Calvinistic Methodists. This body, which, though not founded by Whitfield, received much countenance and support from him in its earlier stages, had its origin so early as 1735, but was not finally organized till 1785. Its founder was Mr. Howell Harris of Trevecca. The field of the operations of this sect is chiefly Wales; and there is scarcely a village in the principality in which one of their chapels is not to be found.

WHI'TING. The name of a species of the Cod tribe (*Merlangus vulgaris*, Cuv.), and the type of a subgenus, distinguished from the true cod by the absence of the barbules at the chin. It is esteemed for the delicacy of its flavour and its easiness of digestion.

WHITING. Chalk carefully cleared of all stony matter, ground, levigated, and made up into small oblong cakes. As it is often used as a polishing material, it should be very carefully freed from all particles of flint or sand.

WHI'TLOW. (Sax.) A painful inflammation, tending to suppuration, at the ends of the fingers.

WHI'TSUNDAY, in the Calendar, is the seventh Sunday, or 49th day after Easter. *Whitsuntide* corresponds with *Pentecost*. This Sunday was called in the ancient church *Dominica Alba*, White Sunday; or *Dominica in Albis*, the Sunday in which *white garments were worn*, it having been formerly a custom with those who were baptized on this day to dress in white for the occasion. The term, however, has been differently derived from the Saxon "utas," octave, the eighth from Easter. (*Hamon l'Estrange*. See *Riddle's Christian Antiquities*.)

WI'CKLIFFITES. In Ecclesiastical History, the followers of the reformer Wickliff, who are better known by their popular name of Lollards (which see). The memory and opinions of Wickliff were solemnly condemned by the council of Constance in 1415. His bones were dug up and publicly burned in 1428, an event finely commemorated in one of the sonnets of Wordsworth.

WILL, or TESTAMENT, is, in Law, the legal declaration of a man's intentions as to what he wills to be performed after his death. In strictness of language, the term *will* is limited to land; *testament*, to personal estate.

Wills, according to the law up to a recent period, were either nuncupative or written. A nuncupative will could not revoke one that is written; it must be proved by the oaths of three witnesses present at the making of it, must have been made in the last sickness of the testator, and at his house; and was subject to various other restrictions. A written will to dispose of personal property was good, if sufficient proof could be obtained of the writing of the testator, even without his signature or the attestation of any witnesses. A will of real property must, by 29 C. 2. c. 3., be in writing, signed by the testator, or by some other person in his presence, and by his express direction; and witnessed or subscribed, in the presence of the testator, by three or four credible witnesses. This state of the law gave rise to considerable inconvenience. Much litigation was occasioned by the uncertainty as to what was, or was not, a paper sufficient to convey personal property as a will: much fraud was supposed to have been caused by the facility with which such testaments might be forged, or surreptitiously obtained; while, on the other hand, the rules respecting the publicity of wills of real property were thought more stringent than the case required. These considerations induced the legislature to pass the statute 7 W. 4. & 1 Vict. c. 26. (in 1837), by which the making of wills is now regulated. All wills (except those of seamen and soldiers on service), whether of real or personal property, must be in writing, and signed at the foot by the testator or some other person in his presence and by his direction; and such signature must be made and acknowledged by the testator in the presence of two or more witnesses present at the same time; and such witnesses must attest and subscribe the will in the presence of the testator; but no form of attestation is necessary. All appointments by will, whatever formalities may have been required by the creator of the power, must now be made according to the provisions of this statute, and require no further form.

The same statute enacts that no will of a minor shall be valid. All devises and gifts by will to an attesting witness are void. To put an end to the various questions which had arisen respecting the revocation of wills, it is provided that they shall be revoked only by the marriage of the party, or by another will duly executed, or some writing declaring an intention to revoke, and executed with similar formalities, or by burning, tearing, or otherwise destroying, with intention to revoke. All wills now speak from the death of the testator, unless they show on the face a contrary intention, that is, they act upon the property which he possesses at his death. And various important alterations are introduced in the effect of the ordinary language used in devises and bequests.

A married woman cannot make a will of lands or tenements; nor, without the consent of her husband, of personalty.

A disposition by will of real property is termed a *devise;* of personal property, a *bequest* or *legacy*. *See* DEVISE, EXECUTOR.

WI'LLOW. *See* SALIX.

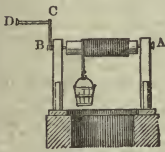
WINCH. In Mechanics, a bent handle or rectangular lever, for turning a wheel, grindstone, &c. The term *winch* is also popularly applied to the *windlass*. *See* WINDLASS.

WIND. *See* WINDS.

WINDAGE OF A GUN. The difference between the diameter of the bore of a gun and the diameter of the ball. Formerly it was usual in the English service to allow a very considerable windage, 1-20th of the diameter of the bore; but it has been found that the shot will go much truer, and that a smaller quantity of powder is required, when the above allowance is considerably diminished. (*Hutton's Tracts*, vols. ii. iii.) *See* GUNNERY.

WIND GAGE. An instrument for measuring the force or velocity of the wind. *See* ANEMOMETER.

WI'NDLASS. A machine used for many common purposes. It is a particular modification of the wheel and axle, the power being applied by means of a rectangular lever or *winch*. The arm B C of the winch represents the radius of the wheel; and the power is applied to C D at right angles to B C. The windlass is frequently used in merchant ships or small trading vessels instead of a *capstan* for heaving the anchors, &c. In this case it consists of a large cylindrical piece of timber laid in a horizontal position, and supported at its two ends by two pieces of wood called *knight-heads* placed on opposite sides of the deck near the foremast. This axle is pierced with holes directed towards the centre, in which long levers are inserted, called handspikes. It is furnished with strong *pauls* to prevent it from turning backwards when the pressure on the handspikes is intermitted.

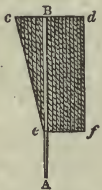


WI'NDMILL. In Mechanics, a mill which receives its motion from the impulse of the wind. The general appearance of the windmill is familiar to every one. The building containing the machinery is usually circular. To the extremity of the principal axis, or wind-shaft, are attached rectangular frames (generally five), on which cloth is usually stretched to form the sails. The surfaces of the sails are not perpendicular to the axis, but inclined to it at a certain angle, about 72° at the extremities nearest the axle, and 83° at the farther extremities; so that their form is in some degree twisted, and different from a plane surface. Suppose the axis to be placed in the direction of the wind; the wind will then strike the sails obliquely, and the force may therefore be resolved into two parts, one of which, acting in the direction perpendicular to the axis, gives a motion of rotation to the sails, and consequently to the wind-shaft, from which it is communicated to the machinery. The wind-shaft is inclined to the horizon in an angle of from 8° to 15°, principally with a view to allow room for the action of the wind at the lower part, where it would be weakened if the sails came too nearly in contact with the building.

As the direction of the wind is constantly changing, some apparatus is required for bringing the axle and sails into their proper position. This is sometimes effected by supporting the machinery on a strong vertical axis, the pivot of which moves in a socket firmly fixed in the ground; so that the whole structure may be turned round by a lever. But it is now usual to construct the building with a moveable roof, which revolves upon friction rollers; and the shaft being fixed in the roof is brought round along with it. The roof is brought into the required position by means of a small vane wheel furnished with wind sails, which turns round when the wind strikes on either side of it, and drives a pinion which works into the teeth of a large crown wheel connected with and surrounding the moveable roof.

Of the Form and Position of the Sails.— From the investigations of Parent and Belidor, it appears that the maximum effect of the wind on the sails is produced when their inclination to the axis of rotation is about $54\frac{3}{4}$ degrees; or when the *angle of weather*, that is to say, the angle formed by the plane of the sail and the plane of its revolution, is $35\frac{1}{4}$ degrees. But this result, being obtained from considering the effect of the wind on the sails when at rest, does not agree with that which is found by experiment. In fact, as the velocity of the sail tends to withdraw it from the action of the wind, it is necessary to counteract the diminution of force by diminishing the angle of weather, or to bring the sail into such a position that the wind strikes its surface more directly; and since the velocity of the different parts of the sail is in proportion to their distance from the axis, it follows that in order to produce the greatest effect every elementary portion of it ought to have a different angle of weather, diminishing from the centre to the extremity of the sail. Euler has given a theorem which determines the law of variation. Let a be the velocity of the wind, and b the velocity of any given part of the sail; then the action of the wind upon that part of the sail will be a maximum when the tangent of its inclination to the axis, or the cotangent of the angle of weather, $= \sqrt{2 + \left(\frac{3b}{2a}\right)^2} + \frac{3b}{2a}$. Suppose that at a given part of the sail the velocity of the sail is equal to the velocity of the wind, we have then $a = b$; and the formula becomes $\sqrt{2+\frac{9}{4}} + \frac{3}{2} = 3{\cdot}561 =$ tangent of 74° 19′, which gives 15° 41′ for the angle of weather.

This subject was investigated experimentally by Smeaton (*Philosophical Trans.* vol. li.), who found that the common practice of inclining the sails from 72° to 75° to the axis is much more efficacious than the angle assigned by Parent, the effect being as 45 to 31. When the sails were weathered in the Dutch manner, or with their surface concave to the wind, and the angle of inclination greater towards the extremities, the effect was greater than when weathered either in the common way or according to Euler's theorem. But the effect was greatest of all when they were enlarged at their extremities, and had the form $c\,d\,f\,e$, represented in the annexed figure; so that $c\,d$ was one third of the radius A B, and c B to B d as 5 to 3. If the sails be farther enlarged, the effect is not increased in proportion to the surface; and besides, when the quantity of cloth is great the machine is much exposed to injury from sudden squalls. In Smeaton's experiments the angle of weather varied with the distance from the axis; and it appeared from several trials that the most efficacious angles at the different parts of the sail were those in the following table:—



Parts of A B, which is divided into Six equal Parts.	Angle with the Axis.	Angle of Weather.
1	72°	18°
2	71	19
3	72	18
4	74	16
5	$77\frac{1}{2}$	$12\frac{1}{2}$
6	83	7

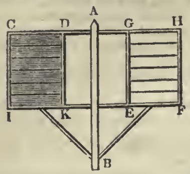
If the radius A B of the sail be 30 feet, then the sail will commence at 1-6th of A B, or 5 feet from the axis, where the angle of inclination will be 72°. At 10 feet from the axis, the angle will be 71°; and so on, as in the table.

Of the Effect of Windmill Sails.—The following maxims relative to the effect of the sails were deduced by Smeaton from his experiments:—

1. The velocity of windmill sails, whether loaded or unloaded, so as to produce a maximum effect, is nearly as the velocity of the wind, their shape and position being the same. 2. The load at the maximum is nearly, but somewhat less, as the square of the velocity of the wind, the shape and position of the sails being the same. 3. The effects of the same sails at a maximum are nearly, but somewhat less, as the cubes of the velocity of the wind. 4. The load of the same sails at the maximum is nearly as the squares, and their effects as the cubes of their number of turns in a given time. 5. When the sails are loaded so as to produce a maximum effect at a given velocity, and the velocity of the wind increases, the load continuing the same, then the increase of effect, when the increase of the velocity of the wind is small, will be nearly as the square of those velocities; when the velocity of the wind is doubled, the effect is nearly as 10 to $27\frac{1}{2}$. When the velocities compared are more than double of that where the given load produces a maximum, the effects compared increase nearly in the simple ratio of the velocity of the wind. 6. In sails where the positions and figures are similar and the velocity of the wind the same, the number of turns in a given time will be reciprocally as the radius or length of the sail. 7. The load at a maximum that sails of a similar figure and position will overcome at a given distance from the centre of motion will be as the cube of the radius. 8. The effects of sails of similar figure and position are as the square of the radius. 9. The velocity of the extremities of Dutch sails, as well as of the enlarged sails in all their usual positions, when unloaded, or even loaded to a maximum, is considerably quicker than the velocity of the wind.

Horizontal Windmills.—Windmills are sometimes constructed in such a manner that the planes of the sails intersect each other in the wind-shaft, in which case they are called *horizontal windmills;* because the wind-shaft being usually vertical, the sails have a horizontal motion. The wind-shaft, however, might be placed with equal advan-

tage in the horizontal position. In this construction



A B is the wind-shaft or arbor, which moves upon pivots. Cross bars are fixed in this arbor, which carry the frames C D E F and G H I K. The sails C E and G I are stretched on these frames, and are carried round the axis A B by the perpendicular impulse of the wind; and a toothed wheel fixed upon the arbor gives motion to the machinery. Two sails only are represented in this figure, but there are always other two at right angles to these. When the wind impels the two sails C E and G I equally, it is obvious that no motion can ensue. In order, then, that motion may be communicated to the machine, the impulse of the wind on the returning sail must be removed by screening it from the wind, or at least diminished by making it present a less surface when returning against the wind. The first of these methods is said to be practised in Tartary, and some provinces in Spain; it is the simplest, and probably the best. The other method requires the sail to be formed of several flaps moveable on hinges, and so adjusted that on one side of the axis they present their surfaces to the wind, and when returning on the other only their edges. Other contrivances have been proposed; but horizontal windmills are greatly inferior, in point of effect, to those which have vertical sails, and are accordingly seldom met with.

On account of the irregularity of the moving force, and the interruption from calm weather, machines impelled by the wind can only be used advantageously for purposes which are not urgent, and where regularity is not indispensable. The chief purposes to which they are applied are grinding corn, expressing oil from seeds, bruising oak bark for tanning, sawing wood, raising water, &c. Windmills were brought into Europe from the East about the time of the Crusades. (*Phil. Trans.* vol. li.; *Smeaton's Miscellaneous Papers; Ferguson's Lectures*. by Brewster; *Gregory's Mechanics*.)

WI'NDOW. (Quasi wind-door.) In Architecture, an aperture in a wall for the admission of light and air to the interior. In distributing windows so that there be had a sufficiency of light, it is usual to make the piers or intervals between them never less than the width of the window, and never more than two widths of the same. Where it is required to ascertain the total area of light necessary for a room, the following empirical rule is frequently used:— Multiply together the length, breadth, and height, and extract the square root of the product, which will be the area of light required.

WINDS. Currents in the atmosphere, conveying the air, with more or less velocity, from one part to another. Notwithstanding all that has been written on the subject of the winds, their theory is still involved in considerable obscurity. The subject is exceedingly complicated; and no attempt that has yet been made to derive a general law from the observations has been attended with much success. Nevertheless we can discern, clearly enough, certain prevailing causes of the disturbances which are constantly taking place in the equilibrium of the elastic fluid which envelopes the earth, though their influence is modified, and sometimes altogether concealed, by disturbing causes, the effects of which we have no means of adequately appreciating.

The principal cause of wind may be ascribed to the unequal and variable distribution of heat through the atmosphere, the temperature of which is mainly determined by that of the surface of the earth. The distribution of heat at the surface is determined by the manner in which it is received from the sun, and radiated from the earth to the celestial spaces. If we consider the whole earth, or the state of any given portion of it through a long series of time, the quantity of heat received from the sun and the quantity lost by radiation exactly balance each other, and the mean temperature remains an invariable quantity. But, on considering any particular portion of the earth, it is easy to see that though a balance is effected in the long run between the heat received and parted with, the two quantities are never precisely equal at the same time, or only so for very short intervals, the one alternately exceeding and falling short of the other. The radiation goes on continually, though not uniformly; but the supply of heat from the sun, on a given surface, is interrupted entirely while the sun is below the horizon, and during the day varies with the sun's altitude. It varies also at the different seasons of the year, in consequence of the unequal lengths of the days and nights, and the greater or less obliquity with which the rays strike against the surface.

But the effect of the solar rays depends not only on the obliquity with which they fall upon the surface, but also in a great degree on the nature of the surface. The daily illumination of the sun warms the land to a very small depth, scarcely exceeding, perhaps, an inch. The heat is therefore accumulated at the surface, the temperature of which is rapidly increased when the heat received exceeds that which is radiated away, and as rapidly cooled in the reverse circumstance. In water, however, the calorific rays penetrate to a considerable depth, twenty or thirty feet. If we suppose a tenth part of the incident light to be intercepted by a stratum of water one foot in thickness, while it is totally intercepted by 1·2 inch of dry land, it would follow that the sun's rays communicate every day a hundred times less heat to the surface of a body of water than to an equal expanse of level ground. Now the effect of the two surfaces in heating the superincumbent atmosphere will be in proportion to their respective temperatures; but in the present instance the general conclusion is modified by two circumstances. In the first place, a portion of the solar light, perhaps a fiftieth of the whole, is intercepted in its passage through the atmosphere, and converted into heat; and it is obvious that the increase of temperature caused by this portion is independent of the nature of the surface. In the second place, a small portion of the light which falls upon water is reflected from the surface into the atmosphere, and converted into heat. On the whole, it may be concluded that the change of temperature in the air caused by the succession of day and night is about thirty times less over water than over land. Hence, if the whole surface of the globe had been covered by the ocean, the effect of the alternation of day and night in producing atmospheric currents would have been scarcely sensible. Hence, also, over a great part of the surface of the ocean, the winds are reducible to fixed and determinate laws; while on continents, and also on the ocean in high latitudes, the order and periods of their recurrence are irregular and anomalous.

Besides the effects arising from the disturbance of the equilibrium of temperature, we have also to consider the mechanical effect of the earth's rotation about its axis. If the earth were a sphere of uniform temperature, and at rest in space, the atmosphere would also be at rest; its height would be constant over every point of the earth's surface, and its density and elasticity at equal altitudes every where the same. But if the temperature of the motionless sphere, instead of being equal at every point, were greatest at the equator, and decreased towards the poles, though the pressure on every point of the surface would still continue the same, the altitude of the atmospheric column would become greatest at the equator, and consequently its specific gravity less there than at the poles. The heavier fluid at the poles would then, by virtue of its greater weight, pass beneath and displace the lighter, and a current be established in the lower part of the atmosphere from the poles towards the equator. In the higher regions of the atmosphere the effect would be reversed. The lower stratum of air in the equatorial regions being heated by its contact with the earth, becomes rarified and ascends, and thus produces an accumulation, and causes a counter current in the higher regions from the equator towards the poles. The height at which this change in the direction of the motion takes place under certain circumstances may be computed. Professor Daniell (*Meteorological Essays*) computes that the lower current, from the poles to the equator, extends to the height of 2¼ miles, diminishing in velocity from the surface upwards.

If we now suppose the sphere to revolve about its polar axis, an apparent modification will take place in the directions of the currents. The lower current, coming from a zone where the velocity of rotation is less than that of the parallel at which it arrives, will appear to be affected with a motion contrary to that of the diurnal rotation; while the upper current, flowing from the equator to the poles, would be apparently affected in an opposite manner. On this theory it is usual to explain the *trade winds*, which prevail within and to a considerable distance beyond the tropics in both hemispheres. These easterly currents, however, receive important modifications, both as to their direction and the distance to which they extend from the equator on either side, from the annual variations of the sun's declination and the configuration of the land. They prevail in the open ocean, in the Atlantic and Pacific, between the latitudes of 30° N. and 27° S. On entering these from either side, the deviation arising from the rotation of the earth, towards the east is greatest; and this deviation becomes less and less as the equatorial zone is approached. In the immediate vicinity of this zone, the wind is nearly due N. on the northern side of the equator, and nearly due S. on the southern side. *See* TRADE WINDS.

In the Indian Ocean the trade winds receive a curious modification from the position of the surrounding land, and the effect of the solar heat on it. During one half of the year, from November to April, the winds blow in the ordinary direction of the trades, that is to say, from the north-east; but from April to November they blow

in the directly opposite direction. These periodical winds are called the *Monsoons*. (*See* MONSOONS.) Between the equator and 10° south latitude, north-west winds prevail from October to April, and south-west the rest of the year. In other parts of the tropics, the regular trade winds are also modified by the configuration of the land. On the coast of Guinea the wind almost constantly blows from the south-west, in the opposite direction to the trades. Near the Cape Verd Islands calms and variable winds are usually experienced.

Between the parallels of 30° and 40°, in both the North and South Pacific Oceans, westerly winds blow almost constantly, excepting only for a short time after each equinox. In the North Atlantic Ocean the prevalence of westerly winds between those parallels is less constant, in consequence of the comparative narrowness of that ocean, and the consequent influence of the opposite continents; they are still, however, the prevailing winds, except in the months of April and October, when a north-east wind is more frequent. In consequence of these winds, the voyage from Europe to America is much more tedious than the opposite one.

Upon the continents the diurnal and annual changes of temperature are much more rapid and extensive than over the ocean; hence there is little constancy in the direction or intensity of the winds, even in equatorial countries. In high latitudes the inequalities are still greater, and extend even to the open seas. Beyond the latitude of 40°, the winds do not seem to be reducible to any fixed laws.

The different manner in which land and water are affected by radiation and the direct heat of the sun gives rise to the *land* and *sea breezes* which prevail on the coasts, particularly in tropical countries, though they are not confined to any particular latitude, and are perceptible sometimes as far north as Norway. During the day the surface of the land becomes more heated than that of the adjacent ocean, and the air over the land, in consequence of its greater rarefaction, is displaced by the denser air rushing from the sea. Hence a current, or *sea breeze*, beginning at some hour in the morning, and continuing till the sun is near setting, will flow from the water towards the land. At night the water remains warm, while the surface of the land cools rapidly; and hence the current sets from the land towards the water, and forms the *land breeze*. Winds of this sort are more frequent about islands and small peninsulas than in other situations.

A variety of *local winds* are observed, the circumstances occasioning which are either too complicated or too imperfectly known to admit of their being satisfactorily explained. The *Etesian* is a northerly or north-easterly wind, which prevails very much in summer all over Europe. The *Sirocco* is a hot, moist, and relaxing wind, which visits Naples and the south of Italy from the opposite shores of the Mediterranean. The *Samiel* or *Simoom* of Arabia is a hot, arid, pestilential blast, generally coming from the south. The *Kamsin* of Egypt is of the same kind. The *Harmattan* is a dry east wind, also of an unwholesome description, occurring in Guinea and some other countries.

In the preceding remarks the winds have been considered as produced by the unequal distribution of temperature in the atmosphere, combined with the earth's diurnal rotation. Other causes, however, depending on the physical constitution of the atmosphere, must be assigned for those sudden and irregular blasts which occasionally spring up, and rage for some time with tremendous fury. Among these causes, one of the most powerful is, doubtless, the rapid condensation of vapours in the bosom of the atmosphere. An inch of rain has sometimes been observed to fall within the space of an hour over a great extent of country, particularly in the equinoctial regions. Suppose the superficial extent over which rain has fallen to the depth of an inch to be only 100 square leagues; if the vapour necessary to produce this quantity of rain existed in the atmosphere at the temperature of 50° of Fahrenheit, it would occupy a space 100,000 times greater than in the liquid state; that is to say, it would occupy a space equal to a column of which the base is 100 square leagues, and the altitude 100,000 inches, or nearly 10,000 feet, and such would be the dimensions of the vacuum created by the condensation. Some abatement must be made from this estimate, inasmuch as the vapour existing in the atmosphere is in the vesicular, and not the elastic state; but in any case its condensation into drops and precipitation must create an immense void, the filling up of which must necessarily occasion violent atmospherical concussions. On this principle may be explained a fact, the observation of which is often of great importance at sea, that an unusual fall of the barometer is generally followed by a gale of wind. *See* STORM.

The velocity of wind varies from nothing to upwards of a hundred miles an hour; but the maximum is variously stated by different experimenters, and, in fact, it is not easy to see by what means its velocity can be ascertained within moderate limits of accuracy. The best method seems to be that of deducing its velocity from its force, observed by means of an anemometer. In vol. li. of the *Philosophical Transactions* a table is given of the different forces and velocities of winds, drawn up by Smeaton from a considerable number of facts and experiments. The following extract from it will give the reader a general idea of the velocity of the wind in different circumstances:—

Velocity of the Wind.	Perp. Force on 1 Sq. Foot, in lb. Avoirdupois.	Common Appellation of the Force of such Winds.
Miles in an Hour.		
1 -	·005	Hardly perceptible.
4 -	·079	Gentle pleasant wind.
5 -	·123	
10 -	·492	Pleasant brisk gale.
15 -	1·107	
20 -	1·968	Very brisk.
25 -	3·075	
30 -	4·429	High wind.
35 -	6·027	
40 -	7·873	Very high.
50 -	12·300	A storm.
60 -	17·715	A great storm.
80 -	31·490	A hurricane.
100 -	49·200	A violent hurricane.

Of late years the theory of winds (in common with other meteorological phenomena) has received much attention; and through the recommendation of the British Association, self-registering anemometers have been erected at the principal observatories and other places, with a view to obtain systematic series of observations. The principal points to be determined are the mean duration of the different winds, the law of their succession, and their connection with the state of the barometer, thermometer, and hygrometer. (See *Prof. Forbes' Reports on Meteorology* to the Brit. Association for 1831 and 1840; Experiments by Col. Beaufoy in the *Annals of Philosophy*, vol. viii. p. 94.; *Daniell's Meteorological Essays; Murray's Geography*, Introd.; Pouillet, *Elemens de Physique*.)

WIND SAIL. A tube or funnel of canvass, employed to convey a stream of fresh air down into the lower part of a ship.

WINE. (Germ. wein.) All spirituous products of fermentation are occasionally denominated *wines*. The term, however, is more generally limited to fermented grape juice, or *must;* and the theory of the process has been noticed under the word FERMENTATION. There are many circumstances which influence the general characters or quality of wine; among which are principally climate, soil, and aspect, the nature and maturity of the grape, and the mode of fermentation. In regard to climate, for instance, it may be observed that that which is best suited to the culture of the vine extends from the 35th to the 50th degrees north latitude; in more northerly situations the grape seldom ripens perfectly, and the wines that it yields are of a less generous character than those produced in more congenial districts. In warmer climates, on the other hand, the juice becomes too rich and saccharine. It often happens, however, that a very luscious grape transplanted to a colder climate yields a good wine, and that vines carried from a cold to a warmer climate, within the latitudes mentioned, afford excellent liquors; it is said, indeed, that we are indebted for some of our most choice wines to such judicious transplantations. Chaptal has stated that the *must* obtained from grapes grown in the south of France was richer than that from the northern departments. With respect to soil, it may be observed that no fruit is more remarkably influenced by its qualities than the grape. Light and porous soils are best suited to it; and although the plant will grow vigorously in rich and moist ground, the fruit is by no means excellent in proportion to its luxuriance. Dr. Henderson states (*History of Wines*), that strong argillaceous soil not only checks the extension of the roots, but keeps them too moist, and often imparts to the wines a peculiar earthy taste, such as we perceive in Cape wine. A stony or gravelly soil is preferable to all others; it allows of the free growth of the roots, and is sufficiently retentive of moisture. Volcanic soils are also favourable to the growth of the vine, as shown in the island of Madeira, Italy, Sicily, and the south of France. The quality of the grape is also greatly influenced by differences in the exposure and inclination of the ground. Hills are preferable to plains, especially where the aspect is such as to be duly exposed to the sun and sheltered from cold winds; hence the advantage of a south-eastern aspect. The influence of season, so important in regard to the ripening and perfection of all fruits, is especially so with respect to that of the vine, its consequences going beyond the mere temporary perfection of the grape as fitting it for the table, and extending in a very striking manner to the qualities of the wine; hence the notoriety and high character of the vintages of particular seasons, as, for instance, that of the comet in 1811. In a cold year the wine is weak and

acescent. "When the season is rainy," observes Dr. Henderson, "the produce will be increased; but it will be poor and insipid, and generally found to contain a large portion of malic acid, which gives to it a peculiar flavour, always most perceptible in those wines which are most devoid of spirit. A moderate degree of humidity, however, is essential to the welfare of the vine. In those climates, accordingly, where great droughts prevail, as in Persia, and in the neighbourhood of Malaga, the earth is formed into a dish around the plant, in order to collect and retain the rain which falls during the spring. High winds and fogs are always very injurious to the vine." Manures are generally regarded as prejudicial in warm climates; but in colder aspects, as upon the Rhine, they are often not only useful, but necessary. Different methods of planting and training the vine are adopted in different countries; but it is generally found advantageous to keep the plant as low as possible, for the same vine yields fruit of very different qualities, depending upon the mode in which it is trained and trimmed. But there are no circumstances by which the quality of the wine is more affected than those dependent upon the state of maturity of the grape. When grapes are fully ripe they generally yield the most perfect wine as to strength and flavour: if suffered to shrivel to a greater or less extent, the wine will be more saccharine; and if they are not fully mature, it will be brisk, and often tart. "In general, dry and clear weather ought to be chosen for the vintage; but when a slow and imperfect fermentation is required, as in the case of the brisk champagne wines, the grapes that are collected during a fog, or before the dew that has settled on the vines is dispersed, are found to answer best, and to yield the largest quantity of *must.*" The few facts which have now been stated will show how many minute circumstances must be attended to in the selection and cultivation of the vine; and it is astonishing how much the character and excellence of the produce depend upon causes which often appear so trifling as to be beneath notice. But the ultimate production of good wine involves a variety of other considerations connected with the process of fermentation, in the due management of which much practical skill is often requisite, and the utmost cleanliness always indispensable. The component parts of *must*, and the changes which they undergo in the fermenting vats, have already been noticed (*see* FERMENTATION); so that it only remains here to add a few remarks upon the general characters and composition of the principal varieties of wine. The colour of the wine almost always depends upon the husks of the grape; for the pulp, even of the blackest fruit, is, with very few exceptions, equally colourless with that of the green grape. The seeds of the grape, and more especially the stalks, containing tan and extractive matter, also modify the taste of the wine; hence they are added to Port wine, but generally excluded from the delicate wines of Bourdeaux and of the Rhine. The peculiar aroma or perfume is sometimes dependent upon very recondite causes, as in the fine wines of Burgundy. In some cases it is acquired by age, and appears to depend upon some chemical change, perhaps connected with the formation of something like a variety of ether; but it also depends upon the quality of the grape, as in the Muscadine and Frontignac wines. The leading character, however, of wine must be referred to the *alcohol* which it contains, and upon which its intoxicating powers principally depend: not exclusively, however; for some of the lighter wines, if brisk and effervescent, seem to derive from the admixture of carbonic acid a peculiar exhilarating power not directly proportional to their alcoholic contents. And again, we find other wines, among which certain Burgundies stand foremost, which are eminently heating, though not very strong. The following table shows the quantity of alcohol (of the specific gravity of 825 at 60°), by measure, contained in 100 parts by measure of the respective wines. Some other vinous and spirituous liquors have been added, for the purpose of showing the relation which they bear to wine in the proportion of alcohol which they contain.

It is necessary, however, to observe that the proportion of alcohol in the same wine varies materially according to the age of the wine and other circumstances, and that wines having the same quantities of alcohol in each, may, notwithstanding, differ essentially in every other respect. Practically wines are distinguished by their colour, hardness or softness on the palate, their aroma, and their being still or effervescing. In many cases, too, the same variety of wine may be distinguished into a number of sub-varieties, differing more or less in one or more of these particulars. Thus, in the case of champagne, some varieties are red, and others white or straw-coloured; some are dry and others sweet; the aroma of one variety differs from that of another; and, while some are still, others have every different degree of effervescing power.

The same variety exists in the case of clarets, and, indeed, of almost every description of wine.

The differences in the quality of wines depend partly on differences in the vines, but more on the differences of the soils in which they are planted, in the exposure of the vineyards, and in the treatment of the grapes, and the mode of manufacturing the wine. Though the vine grows in every sort of soil, a rising ground, or gently-sloping hill facing the south, with a loose, gravelly, or rather volcanic soil, is by far the best situation for a vineyard: —

"——— apertos
Bacchus amat colles."

It is in such situations that all the finest wines are produced.

It would be useless in a work of this kind to attempt characterizing the different sorts of wine used in Great Britain. Port and sherry have long enjoyed a decided preponderance in our markets; and it must be admitted that, when of good quality and sparingly used, they are very unexceptionable wines. But they are often harsh, and have the disadvantage of being strong and heating, so that they cannot be taken, to anything like excess, by most persons with impunity. They are well enough for a glass or two, but they are not wines for conversation or society. It is not probable, indeed, had it not been for the high differential duties with which French wines were so long burdened, that the use of port and sherry would ever have been so general in England; and since the abolition of the differential duty in 1831, French wines have begun gradually, though slowly, to make their way from the highest, to which they have hitherto been mostly confined, amongst the middle classes. They are, indeed, superior, in almost all respects, to every other variety. The best growths of claret, champagne, and Burgundy, seem to unite all the qualities required to constitute perfect wines. Had they been known in antiquity we apprehend they would have engrossed most part of the praise so profusely lavished on the Pramnian, Cecuban, Falernian, and other renowned wines of Greece and Rome. We subjoin

An Account of the Quantities of the different sorts of Wine imported into and exported from the United Kingdom; the Quantities entered and retained for Home Consumption; and the Rates of Duty in 1840.

WINGS. In Naval matters. Passages along the sides of the ship between the fore and after cockpit.

WINGS, in Plants, are membranous expansions of different parts. The two lateral oblong petals of a Papilionaceous corolla, the two lateral sepals of a Polygam, the expansion from the back of the fruit of the ash tree, from the sides of the seed of a Bignonia, and from the surface of many Umbelliferous fruits, are all called *wings*.

WINGS. In Architecture. *See* ALÆ.

WI'NTER. One of the four seasons of the year. Winter is usually understood to begin with the shortest day, and to end when the sun returns to the vernal equinox.

WI'PERS, in some kinds of machinery, as oil-mills, powder-mills, fulling-mills, are pieces projecting generally from horizontal axles, for the purpose of raising stampers, pounders, or heavy pistons, in vertical directions, and then leaving them to fall by their own weight. The principal object to be attended to in the construction of wipers is to give them such a form that the weight shall be raised with a uniform force and velocity. (*Gregory's Mechanics; Appendix to Ferguson's Lectures*, by Brewster; *Willis's Principles of Mechanism.*)

WIRE-DRAWING. The art of extending the ductile metals into wire. The operation is performed by casting or hammering the metal into a bar, which is then successively drawn through holes in a steel plate, each being smaller than the other, until the requisite fineness is attained. The holes through which extremely fine wires of platinum, gold, or silver are occasionally drawn, are sometimes made in a diamond or ruby. *See* GOLD, &c.

WIT (Germ. witz), has been defined briefly to be the unexpected combination of distant resemblances. The term *wit* has in the course of two centuries passed through more significations than most others in the English language. Without going further back than the reign of James I., wit is used by Sir J. Davies as the most general name for the intellectual faculties, of which reason, judgment, wisdom, &c. are subdivisions. In the time of Cowley and Hobbes, it came to denote a superior degree of understanding, and more particularly a quick and brilliant reason. By Dryden it is used as very nearly synonymous with talent or ability; but after his time, and more particularly by Addison in his papers on Wit, we find a gradual approximation to the modern signification of the term.

The forms of wit are so various that it would be impossible to include them all within the circle of a precise definition; but the following comprehensive enumeration of these forms by the celebrated Dr. Barrow may be interesting to the reader. "Sometimes it lieth in pat allusion to a known story, or in seasonable application of a trivial saying, or in forging an apposite tale; sometimes it playeth in words and phrases, taking advantage from the ambiguity of their sense, or the affinity of their sound; sometimes it is wrapped in a dress of humorous expression; sometimes it lurketh under an odd similitude; sometimes it is lodged in a sly question, in a smart answer, in a quirkish reason, in a shrewd intimation, in cunningly diverting, or cleverly retorting an objection; sometimes it is couched in a bold scheme of speech, in a tart irony, in a lusty hyperbole, in a startling metaphor, in a plausible reconciling of contradictions, or in acute nonsense; sometimes a scenical representation of persons or things, a counterfeit speech, a mimical look or gesture, passeth for it; sometimes an affected simplicity, sometimes a presumptuous bluntness giveth it being; sometimes it riseth only from a lucky hitting upon what is strange; sometimes from a crafty wresting obvious matter to the purpose. Often it consisteth in one knows not what, and springeth up one can hardly tell how. Its ways are unaccountable and inexplicable, being answerable to the numberless rovings of fancy and windings of language." (See, as to the difference of meaning between *wit* and *bulls*, *Edin. Rev.* vol. iii. p. 399.)

WITCH, WITCHCRAFT. It has been a subject of much controversy whether the verse, "Thou shalt not suffer a witch to live," in the 22d chapter of Exodus, is correctly rendered in modern versions. The Septuagint render it by φάρμακος, *a poisoner*. It is, however, generally held, that the latter interpretation is not the true one, and that the practice here condemned was that of pretended divination by means of supernatural agency. This was, by the Jewish law, an act of rebellion against the Almighty Ruler of the Jewish nation, and punished as such. (See also Deuteronomy, xviii. 10, 11.) The only detailed and particular narrative of witchcraft in the Old Testament is that of the evocation of Samuel by the witch of Endor. (See on this subject *Sir W. Scott's Second Letter on Demonology and Witchcraft.*)

Among the Greeks, a general belief prevailed in magical practices and incantations, especially by women; and Thessaly was the region most celebrated for the pursuit of these arts by its inhabitants. The same superstition was equally prevalent among the Romans. But, in the sense in which the word is used in modern times, a witch is supposed to derive her power from a peculiar compact with evil spirits; and this species of witchcraft is of course posterior to the rise of Christianity, although the belief in demoniacal possession was common from the first ages of the Christian church, and a particular class of the clergy was early set apart for the purpose of conjuring devils, with the name of exorcists. The first traces of the modern superstition respecting witchcraft are perhaps to be found in *Augustine*, who speaks of magicians as living in society with devils, and having a compact with them. The ancient witchcraft of the classical times became easily connected in vulgar belief with the superstitions arising out of Christian theology. As early as the Council of Ancyra (308), the belief in transformations by magical art (of which we find so remarkable an instance in the romance of Apuleius) is condemned as heretical. The gods of the ancient mythology, by the zealous preaching of the Christian clergy, acquired in popular imagination the attributes of demons; and there is little doubt that many of the supposed assemblies of witches and devil-worshippers, which terrified the imaginations of the chroniclers and historians of saints in the early part of the dark ages, originated in the secret meetings of the proscribed worshippers of Pagan deities, who endeavoured to secure their privacy by terrifying their orthodox neighbours. (See a poem of Goëthe's on this subject.) From all these causes combined, the belief in witchcraft grew, as has been observed, side by side with the prevailing worship of saints and relics. About the time of Charlemagne

and his successors, we find one species of imaginary witchcraft peculiarly prevalent. Storms and tempests were attributed to certain magicians (defensores), who were believed, as in the classical mythology, to have acquired a power of controlling the elements; but this belief was condemned by the church as superstitious. The very general superstition (which also is mentioned by Augustine) of assemblies of females riding through the air with the demon Diana, Minerva, or Herodias (from which, in later days, the notions of the witch festival on the Brocken in Germany, the French sabbat, &c., were all derived), is also reprobated by the divines of this period. It has been supposed by some that the sudden spread of intelligence, and the cast of noble and more liberal sentiment which prevailed in Europe about the time of the Crusades, checked for a time, at least among the higher orders, the spread of debasing superstitions; but if this was really the case, the effect was but temporary. Up to this time we have found the church generally condemning most of the popular fancies respecting demoniac agency as superstitious; but from the end of the 12th century we find them gradually gaining ground, so as to become articles of religious credence. At the coronation of Richard I., Cœur de Lion, Jews and women were forbidden to attend: the latter because so many of them were suspected of witchcraft. The works of Gervase of Tilbury (at the beginning of the 13th century) give perhaps the best picture of the extent to which similar opinions prevailed about that epoch. In the same century, witches and heretics were first connected in the eye of the church: the commissioners who tried the various sectaries of the time were equally directed to inquire into and punish magical practices. In the 14th century the persecution of witches assumed a more regular and severe character. The well-known accusations against the Templars (1309), in which all the common charges of compacts with the devil, witch-assemblies, &c., were mingled with those of atheism and heresy, were but the prelude to a long series of similar proceedings. About this time the south of France, north of Italy, and some parts of Germany seem to have been most infested with demoniacal agency. The female sex seems from the earliest times to have been most implicated in the public horror of witchcraft; and from the commencement of the 15th century we find this common notion become a confirmed doctrine: almost all the decrees of councils, &c., which speak of witchcraft, and the prosecutions which are carried on, henceforward are directed against women only. From this time, therefore, we may date (as far as accuracy is practicable on such subjects) the separation in popular belief of the higher magic practised by learned and distinguished men, from the petty witchcraft of which the great performers were poor, old, and ignorant women. Many of the great magicians were believed to operate their wonders by the control which they had acquired over inferior spiritual agents, without any express compact with the devil; and although such practices were often condemned by the church, always liable to suspicion, and sometimes brought those who indulged in them (together with alchemists and astrologers) under the cognizance of criminal tribunals, yet they were always considered as of a different order altogether from the feats of common witches. In 1484 appeared the famous bull of Innocent VIII., "Summis desiderantes affectibus." In this remarkable instrument all the absurdities of the popular superstition are formally recapitulated, and a commission directed to three individuals (Institor, Sprenger, and Gremper) to examine and punish witches in the German empire. Although immediately relating to Germany only, this bull is rightly considered by Herzog (the author of the article on witchcraft in *Ersch and Gruber's Encyclopædia*, from whom we have borrowed largely on the present subject) as forming a period in the history of this superstition. Although much cruelty had been committed before in the pursuit of this imaginary crime, it is from this solemn confirmation of the vulgar superstition that we must date the continuous course of legal persecution which lasted for two centuries over the greater part of Europe.

The details of these legal proceedings bear a striking similarity in all the countries in which this baleful superstition so long prevailed. It has been seen that by the bull of Innocent VIII. witchcraft was rendered a crime peculiarly cognizable by ecclesiastical authorities: so it remained for the most part in Catholic countries, especially where the Inquisition was established; and this constituted the chief difference between the procedure in those regions and that which prevailed in Protestant districts, where the civil magistrate took cognizance of the offence. Thus the various forms of religious observance which were interwoven with the judicial proceeding in the former, exorcisms and so forth, were for the most part disused by Protestants. In other respects, the mode of investigation and punishment was much the same. Every where they exhibited a singular mixture of legal refinement with popular violence. Thus the various ordeals by which suspected witches purged themselves (one of the most vulgar superstitions connected with witchcraft) were conducted with gravity and regularity under the eye of the law. The best known in England was that of water: if the accused swam when thrown in, it was held as a proof of guilt. On the Continent a favourite mode, among many others, was by weighing. In the scales set apart for this purpose a true witch was always found to weigh more than her previously ascertained weight. There was in the 17th century a weighing beam at Budewater in Holland, of such celebrity that persons accused of witchcraft in many neighbouring provinces used to appeal to it. When, however, the suspected person was in the hands of the tribunal, there was in general one only mode of procedure, — by torture. This was carried to the most horrible and unheard-of excesses; and as it was generally recognized that witchcraft was a crime entirely out of ordinary rules, the various provisions of the civil or municipal laws by which that dreadful practice was mitigated were wholly neglected, and the accused abandoned to all the cruelty with which fear or fanaticism might inspire the judges. In England, which forms in this respect a solitary exception, torture was not judicially practised; but the various severities to which the unfortunate prisoners were subject had probably nearly equal effect. And thus every where the witch persecutions produced the same result — confessions, namely, of all the strange and monstrous crimes with which the accused lay charged. These appear to have grown more voluminous and more utterly incredible in every generation; and this may be naturally accounted for: for when a witch had made up her mind to confess, it cost her nothing to promulgate the most extravagant inventions; and these being regarded as undoubted truths, formed the basis of interrogatories to be administered to other unhappy beings who might be brought under the same accusation. The punishment was uniformly death, usually at the stake.

Much has been said concerning the connection between religious fanaticism and the superstition of witchcraft. It has already been seen that the cruelties and absurdities of witch persecution had reached a great height even before the Reformation; but it can scarcely be denied that the strong religious excitement which produced and accompanied that event was in some way connected with the rapid spread and development of that atrocious system. The more intense the belief in the overruling providence of God, and his immediate interference in the course of ordinary events (which especially characterized the revival of religion), the more does the parallel belief in the agency of evil spirits, and their dealings with man, appear to take root in the imagination. Sir W. Scott observes that, among Protestant sects, the Calvinists (whose views of religion were at once the most gloomy and the most engrossing) seem to have afforded the most terrible examples of this prevailing mania.. There seems also to have been a constantly recurring tendency to treat witchcraft and heresy as allied offences. It appears, upon the whole, that the persecutions during the 16th and 17th centuries were most violent in those countries which were the scene of much strife between the two religions, or in which the Calvinist opinions were pushed to an extreme,—France, the Netherlands, Northern and Western Germany, Switzerland, Scotland, England under the Commonwealth, and at a still later period New England. A singular example of the contagion of fanaticism suddenly spreading with extraordinary violence, and subsiding again after one terrible outbreak, is to be found in the history of the witch persecutions in Sweden, in the end of the 17th century. In Italy, with the exception of one or two northern districts, the superstition was generally less prevalent, or at least less distressing in its effects; and the same may be said of Spain, after the first period of the history of the Inquisition.

Among many and voluminous authors who wrote disquisitions on witchcraft with a full conviction of its reality, we may cite, as some of the most remarkable, Sprenger, one of Pope Innocent's three inquisitors, whose celebrated *Malleus Maleficarum* (Hammer of Witches) contains a complete code of precedents for inquisitors, which was adopted, varied, and extended through succeeding generations; Delrio the Jesuit, the author of *Magical Disquisitions*; Bodinus; and Remigius, a judge in the duchy of Lorraine, who put to death eight hundred witches in sixteen years, and was at last himself burnt as a conjuror. In England, King James I. has acquired an unenviable celebrity by his literary zeal against witchcraft. Even from the earliest times, there were not wanting here and there bold and enlightened individuals, who ventured to publish their sentiments against the vulgar delusion. Ulric Molitor, a distinguished divine at the period of the Council of Constance, avowed his doubts of the very existence of the crime of witchcraft. In 1556 appeared the book of Wier (a native of Brabant), *De Præstigiis Dæmonum*, in which he exposes the cruelty

and absurdity of the judicial proceedings; but either from caution, or from his own imperfect enlightenment, he ascribes the confessions of the witches to their own melancholy, or the delusion of the devil so working on them as to make them believe they had seen and done what they avowed. In England, Reginald Scot, in the reign of Elizabeth, was still more advanced beyond his age. Even at the end of the 17th century, Balthazar Bekker, a Dutch Jesuit, for having ventured to assail the prevalent superstition in his *Monde Enchanté*, was persecuted, and died in want. The writings of Thomasius, about 1700, had much effect in Germany, and prepared the way for the abolition of witch persecutions in all her Protestant states. But the public mind was at that period rapidly changing. Louis XIV. had already put an end to them by edict in France. The last execution on account of witchcraft in England was probably in 1682; although the statute against it was not repealed until the 9th of Geo. 2. In Scotland, a woman was executed in Sutherlandshire in 1722. But the practice lingered on later in some Continental districts, as in Catholic Germany, Spain, and Switzerland. The subprioress of a convent was burnt at Wurtzberg in 1749. And the last, probably, of all the victims of this superstition, was burnt at Glarus in Switzerland in 1783. It now exists only as a vulgar delusion, which it will probably require some centuries more wholly to extirpate. It is prevalent to a degree little suspected among the English peasantry in remote districts. The writer of this article has seen a horse-shoe suspended inside over the door of a gaol in a Cornish borough, as a protection against the "ill wishes" to which the guardians of such an establishment naturally considered themselves exposed. The most pains-taking collection of learning on this strange subject will be found in *Horst's Zauber-Bibliothek*. An amusing essay on it is contained in the *Quarterly Review*, vol. xlviii. See also *Grimm's Deutsche Mythologie*, passim.

WI'TENA GEMO'TE, or MEETING OF THE WISE MEN. The great national council of the Anglo-Saxon kings; also termed the "Mycel-getheaht," or Great Thought. Who composed the "witan" cannot now be ascertained: bishops, abbots, earls, aldermen, thanes of the Danish burghs, &c. attended. It seems that in East Anglia the possession of forty hides of land was necessary to entitle a person to rank among those termed in the Latin of the age "proceres," who appear to have been members of the great council. The powers and character of the witena gemote passed to the great council of the early Norman kings, which are called by the same name by Saxon writers. The subject has been abundantly discussed by older and more recent antiquarians; the reader may consult an article in the *Ed. Rev.* vol. xxxiv.

WI'THERITE. In Mineralogy, a name applied to carbonate of baryta, in honour of Dr. Withering, who first discovered it at Anglesark in Lancashire.

WI'TNESS. In Law, one who gives evidence in a judicial proceeding. In civil cases, witnesses are compelled to attend by the process called *subpœna ad testificandum* (which see), and punishable if they neglect to do so by attachment or action. In criminal cases, by subpœna or by recognizance taken by the magistrate before whom the information is given.

By the law as it at present stands, witnesses are disqualified or rendered "incompetent" by reason, 1. of want of reason or understanding; 2. Want of religious principle; that is, their want of belief in a God and a future state of rewards and punishments; 3. Infamy; that is, conviction of an infamous crime, and judgment thereupon; the crimes which fall within this class being treason, felony, and other offences which involve the charge of falsehood. The suffering of the punishment, if so provided by statute, restores the witness to competency, as does also pardon; the only exception being the case of convictions for perjury or subornation of perjury, which disqualify for ever unless reversed; 4. Interest; on which grounds the heads of exclusion are numerous, and the distinctions very refined; the general principle being, in civil causes, in courts of common law, that every one interested in the event and in the verdict is excluded. *See* EVIDENCE.

The policy of these exclusions has been matter of much debate; and perhaps the only practical reason which can really be given for this is, that the time of courts of justice being limited, it is advisable to exclude at once from consideration all those classes of evidence which, from their peculiar deficiency, must be of less weight than the testimony of witnesses at once upright and disinterested. This year (1842) Lord Chief Justice Denman has brought in a bill for the abolition of all incompetency by reason of infamy or interest, except in the case of parties to the suit, and one or two other special exceptions.

WI'ZARD. (Seems to be from the old verb witan, *to know*, and of the same derivation with *wise* and *witch*: Glanvile, *Sadduismus Triumphatus*.) The popular name in England for a sorcerer. *See* SORCERY, WITCHCRAFT.

WO'DEN, or WUOTAN. An Anglo-Saxon divinity, considered to correspond with the Mercury of the ancient Greeks and Romans; from whom Wednesday derives its name. (See *Mém. de l'Ac. des Inscr.* vol. xxiv.) He is sometimes also, though erroneously, considered as identical with Odin. *See* ODIN.

WOLF FISH. The name of a species of fish (*Anarrhichas lupus*, Linn.), which subsists on whelks and other shell-fish, which it seizes by means of strong conical slightly curved anterior teeth, set in the jaws like grappling hooks, and bruises by the action of very powerful posterior molar teeth. The flavour of this forbidding-looking fish is much superior to what might be supposed from the general low estimation in which it is held.

WO'LFRAM. A native tungstate of iron and manganese.

WO'LLASTONITE. A name applied by some mineralogists to a species of prismatic augite, in honour of Dr. Wollaston.

WOOD, in Plants, physiologically considered, is the support of all the deciduous organs of respiration, digestion, and impregnation; the deposit of the secretions peculiar to the individual species; and also the reservoir from which the newly forming parts derive their sustenance until they can establish a communication with the soil. It consists organically of woody tissue, and various kinds of vessels surrounded by cellular matter, and more or less carefully arranged. In the youngest state it is succulent and brittle, and is of nearly the same quality in all plants; but as it gains age the sides of the woody tissue become hardened and thickened by the deposit within them of matter of solidification, and wood then assumes the colours and appearances peculiar to different species. In the young state it is called *sapwood* or *alburnum*, when hardened and coloured it becomes *duramen* or *heartwood*. It abounds in nitrogen, which may be removed by simple washing; and it is supposed that the perishable quality of wood is owing to the presence of this element. It is believed that the preserving power of certain agents employed to render wood durable depends upon their rendering the azotized matter insoluble.

WOOD, or TI'MBER. The trunks or main stems of ligneous plants, which attain such dimensions as to be fit for use in architectural construction. In general, every country has its appropriate timber, which is produced by its indigenous trees; but there are some kinds of timber, such as that of the oak and that of the pine, which, in consequence of their durability and of commercial intercourse, are used in all countries. The most useful timbers of Europe are the oak, the ash, the Scotch pine, the larch, and the spruce fir; those of North America are the hiccory, the different species of pine, and some species of oak; those of tropical countries are the teak tree, the different species of bamboo, and the palm. The oak, the teak, and the larch are throughout the whole world found the most suitable timbers for shipbuilding; and the pine, and fir, and the bamboo those most conveniently adapted for civil architecture.

WOOD COAL. A synonym of brown coal.

WOOD-ENGRAVING. *See* ENGRAVING.

WOOD-OPAL. An opalized quartz occurring in various vegetable forms.

WOO'DSTONE. Petrified wood.

WOOD-TIN. An opaque, fibrous, and nodular variety of oxide of tin of a brown colour, hitherto only found in Cornwall.

WOODY FIBRE. Very slender transparent membranous tubes, tapering acutely to each end, lying in bundles in the tissue of plants, and having no direct communication with each other. They are of extreme tenuity, and form the substances called hemp and flax.

WOOL. (Germ. wolle.) A term used very indefinitely, being applied both to the fine hair of animals, as sheep, rabbits, some species of goats, &c., and to fine vegetable fibres as cotton (called in German baumwolle, or *tree-wool*); but when used without restriction it is generally confined to the wool of sheep — a substance which, from the remotest period of history, has been of primary importance to mankind. In reference to textile fabrics, sheep's wool is of two different sorts, the short and the long stapled; each of which requires different modes of manufacture in the preparation and spinning processes, as also in the treatment of the cloth after it is woven, to fit it for the market. Each of these is, moreover, distinguished in commerce by the names of fleece wools and dead wools, according as they have been shorn at the usual annual period from the living animal, or are cut from its skin after death. The latter are comparatively harsh, weak, and incapable of imbibing the dyeing principles, more especially if the sheep has died of some malignant distemper. The annular pores, leading into the tubular cavities of the filaments, seem, in this case, to have shrunk and become obstructed. The time of year for sheep-shearing most favourable to the quality of

the wool, and the comfort of the animal, is towards the end of June and beginning of July—the period when Lord Leicester holds his celebrated rural fête for that interesting purpose.

The wool of the sheep has been surprisingly improved, by its domestic culture. The *mouflon* (*Ovis aries*), the parent stock from which our sheep is undoubtedly derived, and which is still found in a wild state upon the mountains of Sardinia, Corsica, Barbary, Greece, and Asia Minor, has a very short and coarse fleece, more like hair than wool. When this animal is brought under the fostering care of man, the rank fibres gradually disappear; while the soft wool round their roots, little conspicuous in the wild animal, becomes singularly developed. The male most speedily undergoes this change, and continues ever afterwards to possess far more power in modifying the fleece of the offspring, than the female parent. The produce of a breed from a coarse-woollcd ewe and a fine-woolled ram, is not of a mean quality between the two, but half-way nearer that of the sire. By coupling the female thus generated, with such a male as the former, another improvement of one-half will be obtained, affording a staple three-fourths finer than that of the grandam. By proceeding inversely, the wool would be as rapidly deteriorated. It is, therefore, a matter of the first consequence in wool husbandry, to exclude from the flock all coarse-fleeced rams.

Long wool is the produce of a peculiar variety of sheep, and varies in the length of its fibres from 3 to 8 inches. Such wool is not carded like cotton, but combed like flax, either by hand or appropriate machinery. Short wool is seldom longer than 3 or 4 inches; it is susceptible of carding and felting, by which processes the filaments become first convoluted, and then densely matted together. The shorter sorts of the combing wool are used principally for hosiery, though of late years the finer kinds have been extensively worked up into merino and mousseline-de-laine fabrics. The longer wools of the Leicestershire breed are manufactured into hard yarns, for worsted pieces, such as waistcoats, carpets, bombasines, poplins, crapes, &c.

The wool of which good broad cloth is made should be not only shorter, but, generally speaking, finer and softer than the worsted wools, in order to fit them for the fulling process. Some wool-sorters and wool-staplers acquire by practice great nicety of discernment in judging of wools by the touch and traction of the fingers. Two years ago I made a series of observations upon different wools, and published the results. The filaments of the finer qualities varied in thickness from $\frac{1}{1100}$ to $\frac{1}{1500}$ of an inch; their structure is very curious, exhibiting, in a good achromatic microscope, at intervals of about $\frac{1}{300}$ of an inch, a series of serrated rings, imbricated towards each other, like the joints of *Equisetum*, or rather like the scaly zones of a serpent's skin. (See *Philosophy of Manufactures*, *figs*. 11, 12., p. 91. 2d ed.)

There are four distinct qualities of wool upon every sheep; the finest being upon the spine, from the neck to within six inches of the tail, including one-third of the breadth of the back; the second covers the flanks between the thighs and the shoulders; the third clothes the neck and the rump; and the fourth extends upon the lower part of the neck and breast down to the feet, as also upon a part of the shoulders and the thighs, to the bottom of the hind quarter. These should be torn asunder, and sorted, immediately after the shearing.

The harshness of wools is dependent not solely upon the breed of the animal, or the climate, but is owing to certain peculiarities in the pasture, derived from the soil. It is known, that in sheep fed upon chalky districts, wool is apt to get coarse; but in those upon a rich loamy soil, it becomes soft and silky. The ardent sun of Spain renders the fleece of the Merino breed harsher than it is in the milder climate of Saxony. Smearing sheep with a mixture of tar and butter, is deemed favourable to the softness of their wool.

All wool, in its natural state, contains a quantity of a peculiar potash-soap, secreted by the animal, called in this country the *yolk;* which may be washed out by water alone, with which it forms a sort of lather. It constitutes from 25 to 50 per cent. of the wool, being most abundant in the Merino breed of sheep; and however favourable to the growth of the wool on the living animal, should be taken out soon after it is shorn, lest it injure the fibres by fermentation, and cause them to become hard and brittle. After being washed in water, somewhat more than lukewarm, the wool should be well pressed, and carefully dried. England grows annually about 1,000,000 packs of wool, and imports 100,000 bags. (*Ure's Dict of Arts.*)

The woollen manufacture was the early staple of England. The first impulse towards the improvement of the woollen manufacture was given in the 14th century, by Edward III., who invited a number of Flemish manufacturers to settle in England. But the manufacture laboured, down almost to our own day, under a number of vexatious and oppressive restrictions; and it did not begin to make any very rapid progress, or to participate in the wonderful improvements made in the cotton trade, till the introduction of the gig-machine, &c., in 1802, and the repeal of the prohibitory acts of Edward VI. and Mary, in 1807. The total value of the exports of woollen goods in 1839 amounted to 6,271,645*l.*, of which the exports to the U. States made 2,142,352*l.* The woollen factories of England and Wales employed, in 1838, 30,115 males, and 18,387 females.

WOOLSACK. The seat of the Lord Chancellor of England, in the House of Lords, is so called, from its being a large square bag of wool without back or arms, covered with red cloth.

WOOTZ. A species of steel imported from Bengal, peculiarly excellent for some cutting instruments. It appears to contain minute portions of silicium and aluminum.

WO'RMING. An operation performed on puppies, consisting in the removal of a vermiform ligament from under the tongue; it is sometimes supposed to prevent madness, but, in fact, merely breaks them of their habit of gnawing.

WOULFE'S APPARATUS. A series of two or three-necked bottles, connected by intermediate tubes, used in the chemical laboratory for impregnating water and other liquids with various gases or vapours.

WRA'NGLER. At Cambridge, those who attain the highest honours in the public mathematical examinations for the degree of bachelor of arts are so called. At the close of the last day of examination, those who have most distinguished themselves (to the number of thirty at least) are arranged in order of merit by the examiners, and divided into three classes: wranglers, senior optimes, and junior optimes. The first or senior wrangler is the most distinguished mathematician of his year. The name is probably derived from the public disputations in which candidates for degrees were formerly required to exhibit their powers; of which the "exercises" still held at Cambridge retain the form.

WRECKS. Goods cast up by the sea after a shipwreck, and left on land within the limits of some county. The goods so brought to land belong at common law to the king, or to the lord of the manor enjoying the franchise of wreck. It was ordained by Henry I. and II. that such forfeiture should not take place if any man or beast escaped alive from the wreck; and we find in Bracton (Henry III.) that in his time if the goods could be known by marks to appertain to any owner, it was no wreck, even if no living creature escaped. The limitation of claims by the owner, by stat. Westm. 1. (3 E. 1.), was within a year and a day. By 7 & 8 G. 4. plundering wrecked vessels or goods stranded is felony. Goods cast overboard at sea, and not stranded, are divided into *jetsam*, *i. e.* things sunk to the bottom; *flotsam*, things found floating; and *ligsam*, things sunk, but fastened to a buoy or cork in order to be found again. These are all the king's, if no owner appears to claim them; and they do not pass by the ordinary grant of wreck.

WRIT. In Law, a precept in writing under seal, in the name of the king, judge, or other person having jurisdiction in the particular subject matter, and directed to some public officer or private person, requiring him to do something in relation to a suit or action. Writs, though still very multifarious, have been within the last few years much reduced in number. The original writ issuing out of Chancery for the commencement of actions in the three courts of common law is now superseded by three judicial writs, which issue in the name of the chief justices of the respective courts; namely, the writ of *summons*, the writ of *capias ad respondendum*, and the writ of *detainer*. The first of these is the one in ordinary use; the second is only used when it is intended to arrest the defendant, and the last when he is already in prison for some other cause.

WRITERS TO THE SIGNET. A numerous society of lawyers in Scotland, equivalent to the highest class of attorneys in England. They possess several privileges. *See* SIGNET.

WROUGHT. In Architecture, a term applied to any material to denote that it is brought to a fair surface.

WUOTAN. *See* WODEN.

X.

X. A letter borrowed from the Greek, and used chiefly in words derived from that language. Numerically it signifies 10; and as an abbreviation it is used for Christ: Xmas for Christmas, &c.

XA'NTHIC. (Gr. ξανθος, *yellow*.) Tending towards a yellow colour, or some colour not green of which yellow forms a part; as orange, which is a mixture of yellow and red; scarlet, which is another mixture of the same colours, &c.

XA'NTHIC ACID. (Gr. ξανθος, *yellow*, and γεννάω,

I generate.) An acid composed of sulphur, carbon, hydrogen, and oxygen, obtained in combination with potassa by agitating sulphuret of carbon mixed with solution of pure potassa in strong alcohol. Its compounds are mostly of a yellow colour, whence its name. The relative proportions of its component parts have not as yet been satisfactorily obtained.

XA'NTHIC OXIDE. (Gr. ξανθος, *yellow.*) A yellow substance found by Dr. Marcet, composing a urinary calculus; its solution in nitric acid, when evaporated to dryness, left a bright lemon-coloured residue.

XE'BEC, a small three-masted vessel, constructed for conveying merchandize or stores: it is chiefly found in the Mediterranean and on the coasts of Spain and Portugal.

XENELA'SIA. (Gr. *the expulsion of strangers.*) A Spartan institution which prohibited strangers from dwelling in Sparta beyond a certain time, and also from entering the city except on stated days. The object of this institution was to preserve the simplicity of manners of the nation, and prevent foreigners from prying into their measures; but it acquired for Lacedæmon the reputation of great inhospitality.

XE'NIA. (Gr. ξενος.) In Classical Antiquities, the presents given by friends connected by the rites of hospitality as pledges of that singular relation. In the *Iliad*, the mutual gifts which pass between Glaucus and Diomede are so called.

XEROPHA'GIA. (Gr. ξηρος, *dry*; φαγω, *I eat.*) In Ecclesiastical Antiquities, a name given to the rigorous practice of certain fasts, during which nothing was consumed but bread with salt, and water. It was particularly observed in Holy Week.

XIPHIRHY'NCHS, *Xiphirhynchi.* (Gr. ξιφος, *a sword*, 'ρυγχος, *a beak.*) The name given by Latreille to a family of Acanthopterygious fishes, of which the swordfish (*Xiphias*) is the type.

XI'PHOSURES, *Xiphosura.* (Gr. ξιφος, and ουρα, *a tail.*) A name of a tribe of Crustaceans, comprehending those in which the body terminates posteriorly in a long, hard, sword-shaped appendage.

XYLO'GRAPHY. (Gr. ξυλον, *wood*, and γραφω, *I draw.*) The same as wood-engraving. *See* ENGRAVING.

XYLO'PHAGANS, *Xylophaga.* (Gr. ξυλον, and φαγω, *I eat.*) The name of a tribe of Coleopterous insects, comprehending those of which the larvæ devour the wood of trees in which they are developed; also applied to a family of Dipterous insects, the larvæ of which have similarly destructive habits.

XYLO'PHILANS, *Xilophili.* (Gr. ξυλον, and φιλεω, *I love.*) The name of a tribe of beetles, consisting of those which live on decayed wood.

XYLO'TROGES, *Xylotrogi.* (Gr. ξυλον, and τρωγω, *I gnaw.*) The name of a tribe of Serricorn beetles, comprehending those which perforate timber.

XYNO'ECIA. In Classical Antiquities, an Athenian festival in commemoration of the union by Theseus of the little townships of Attica into one commonwealth: whence the name, derived from ξυνος, *common*; and 'οικεω, *I inhabit.*

XYST, or XY'STOS. (Gr. ξυστος, from ξυω, *I polish.*) In ancient Architecture, an open, or sometimes covered court, of great length in proportion to its width, with porticoes on three sides, for the performances of the athletic exercises of wrestling, running, &c.

Y.

Y. A letter borrowed from the Greek υ, is considered a consonant at the beginning, and a vowel in every other place, in English words. As a vowel, it has exactly the sound of *i*, being short or long, according to its position.

YACHT. A vessel of state or pleasure.

YA'GERS, or JAGERS. (Germ. *hunters.*) Light infantry armed with rifles (*chasseurs, riflemen*). In the Prussian service, the Yagers form a distinct corps with peculiar discipline; in that of Austria, light infantry generally from the mountain districts. In Germany the term *jager* is applied to a peculiar species of higher servant attached to the families of the aristocracy.

YA'NKEE, the popular name for the New Englanders in America, and among English people pretty indiscriminately applied to all inhabitants of the United States, a word for which many ridiculous etymologies have been assigned, is, according to *Dr. Welsh's Dictionary*, "a corruption of the word English by the Indians of North America."

YA'NOLITE. A mineralogical synonym of AXINITE, which see.

YARD. The British standard measure of length. *See* MEASURES.

YARD. A beam or rod suspended by a rope called the halliards, for the purpose of extending a sail, signals, &c. A yard is called a *square yard* when hung horizontally by the middle: such a yard is turned round by braces.

YARD-ARM. In Naval language, the extremity of the yard. *Yard-arm and yard-arm* is a term descriptive of two ships engaging each other as close as possible.

YAW. The Sea term for temporary deviation from a direct course.

YAWL. A particular kind of carvel-built boat, rather narrow, and not carrying many oars.

YAWS. A disease in which eruptions form upon the skin, somewhat resembling a raspberry. *See* FRAMBŒSIA.

YEAR. A period of time determined by the revolution of the earth in its orbit, and embracing the four seasons. The year is either *astronomical* or *civil*.

The astronomical year is determined by astronomical observations, and is of different kinds, according to the celestial body or the point of the heavens to which the earth's revolution is referred. When the earth's motion in its orbit is referred to an immoveable point in the heavens, to a fixed star, for example, the time of revolution is that which elapses from the instant at which the star, the sun, and the earth are in a straight line, till the earth returns again into the same straight line with the sun and the star. This interval is called the *sidereal year*. But when the earth's motion is referred to a point of the ecliptic, as one of the equinoctial points, or the tropics, the time of revolution is that in which the earth returns to that point, and is called the *equinoctial*, or *tropical*, or *solar year*. On account of the precession of the equinoxes (*see* PRECESSION) the equinoctial and solstitial points, in reference to the fixed stars, have a retrograde motion on the ecliptic, in consequence of which the earth returns to one of these points in a shorter time than it returns to the same fixed star.

The length of the *sidereal year* is 365·2563612 mean solar days; or 365 d. 6 h. 9 m. 9·6 sec.

The length of the *equinoctial* or *tropical* year is 365·2422414 mean solar days, or 365 d. 5 h. 48 m. 49·7 sec. (*Baily's Tables*, p. 16.)

The difference is 19 minutes 19·9 seconds of mean solar time, being the time in which the earth describes in its orbit an arc of 50·1″, the annual precession of the equinoxes. *See* EARTH.

The earth's motion may also be reckoned by the time in which a revolution is completed with respect to the line of the *apsides* or the line of the *nodes*. In these cases the times of revolution may be called respectively the *anomalistic year* and the *nodical year*: the former term is sometimes met with.

The *civil year* is the year of the calendar. As it is always supposed to begin with the beginning of a day, the civil year contains a whole number of days; and hence, in order that the seasons may always correspond with the same parts of the year, it is necessary from time to time to vary the length of the year, or to intercalate a day when the fractional parts neglected have accumulated to a whole day. The ancient Egyptian year consisted invariably of 365 days, and hence was called a *vague* or *erratic* year, because the first day of the year in the course of 1460 years *wandered* as it were over all the seasons.

The *Julian year*, which is frequently employed in chronological reckoning, consists of 365¼ days. Julius Cæsar ordered that the civil year should consist of 365 days for three successive years, and that the fourth year should contain 366 days. This practice of intercalating a day every fourth year has been adopted in all European countries, with the modification introduced by the Gregorian calendar. The mean Julian year is longer than the true tropical year by 11 m. 10·3 sec., a difference which amounts to a whole day in about 120 years. The years which contain 365 days are called *common* years; those which contain 366 days are called *leap years*. *See* LEAP YEAR.

According to the regulations of the Gregorian calendar the intercalations are omitted on years in which centuries end, excepting when the number of the year is divisible by 4, after leaving out the two zeros. Thus the years 1700, 1800, 1900, which would be leap years in the Julian calendar, are common years in the Gregorian; but 1600 and 2000 are leap years in both calendars. (*See* CALENDAR.) The mean length of the Gregorian year is 365 d. 5 h. 49 m. 12 sec., exceeding the true tropical year by 22·38 sec., which amounts to a whole day only in about 3866 years.

The civil or legal year, in England, formerly commenced on the 25th of March, the day of the Annunciation, though the historical year began on the 1st of January, the day of the Circumcision. Between these two epochs it was usual to date the year both ways, as 1745-6, or $174\frac{5}{6}$. By the act of parliament for the alteration of the style in 1751, the beginning of the year was transferred to the 1st of January. It is frequently necessary to keep this circumstance in mind in referring to old dates.

The fraction by which the tropical years exceed 365

days is ·2422414; and the series of approximating vulgar fractions alternately greater and less than this quantity is,

$$\frac{1}{4}, \frac{7}{29}, \frac{8}{33}, \frac{39}{161}, \frac{281}{1160}, \text{\&c.}$$

The fractions in this series indicate the intercalations by which the coincidence between the civil and solar year may be restored to any degree of exactness. The third, $\frac{8}{33}$, offers a very convenient mode of intercalation which would preserve the coincidence with great accuracy. It requires eight intercalations to be made in thirty-three years; that is to say, one at the end of four years seven times in succession, and the eighth at the end of the fifth year. The mean length of the civil year would by this arrangement differ in excess from the solar year only by 15·38 seconds, while the Gregorian year is too long by 22·38 seconds. In a period of thirty-three years, it therefore produces a nearer coincidence between the civil and solar years than the Gregorian method does in 400 years; and by reason of its shortness it also confines the evagations of the mean equinox from the astronomical within much narrower limits. The modern Persians are said, but not on very good authority, to intercalate in this manner. (Delambre, *Astronomie Moderne*, tom. 1.) *See* CALENDAR.

Lunar Year. — Though the return of the seasons obviously depends on the motion of the sun, or rather of the earth in its orbit, some nations have chosen to regulate their civil year by the motions of the moon; and many others have formed luni-solar years, by combining periods determined by the revolutions of both bodies. The proper lunar year consists of twelve lunar months or lunations, and consequently contains only 354 days: its commencement, therefore, anticipates that of the solar year by upwards of eleven days, and passes through the whole circle of the seasons in about 34 lunar years. The inconvenience attending this circumstance has been so universally perceived that, excepting the modern Jews and Mohammedans, almost all nations which have regulated their months by the moon have employed some method of intercalation for the purpose of retaining the beginning of the year at nearly the same place in the seasons. These methods are founded on certain luni-solar periods or cycles, which were established in the most ancient times, and which, with other relics of a barbarous age, are still preserved in our ecclesiastical calendars. *See* CHRONOLOGY, CALENDAR, CYCLE.

YEAST. The substance produced during the vinous fermentation of vegetable juices and decoctions, rising partly to the surface in the form of a frothy, flocculent, and somewhat viscid matter, insoluble in water and alcohol, and gradually putrefying in a warm atmosphere. It excites fermentation, and accelerates the process when added to saccharine and mucilaginous liquors. It appears closely allied to *gluten;* and, like that vegetable principle, it contains nitrogen as one of its ultimate elements.

YE'LLOW. In Painting, a colour of golden hue, and of many varieties. It is one of the seven primary colours. *See* COLOUR, LIGHT.

YE'LLOW FEVER. A bilious remittent fever. *See* FEVER.

YE'NITE. A ferruginous silicate of lime, from Elba; named by Lelièvre, its discoverer, in honour of the battle of Jena.

YEO'MAN. (From the Anglo-Saxon gemen; Germ. gemein, *common*.) Camden ranks yeomen as the next class to the gentlemen; and calls them "ingenuos." The name seems to have been generally appropriated in the middle ages to small freeholders. In the king's household, the yeomen of the different departments have a middle place between the sergeant and the groom.

YEOMAN. A seaman appointed to certain duties, as to attend to the storerooms.

YEO'MANRY CAVALRY. A denomination given to those troops of horse, which were embodied during the Revolutionary wars of France and afterwards among the gentlemen and yeomen of this country. They were called out annually, and disciplined for three weeks; and as they consisted entirely of volunteers, and were not called upon to leave their homes, or to quit their ordinary employments, except for the short period they were in quarters, the duty was not found to entail any serious privation. Several troops of yeomanry are still kept up, though most of them have been disbanded. The infantry troops that voluntarily enrolled themselves for similar purposes to the yeomanry, were called *volunteers*. These were all disbanded at the peace.

YEOMEN OF THE GUARD. *See* GUARD, YEOMANRY OF THE.

YOKE. A piece of wood or light frame of two arms, placed over the head of a boat's rudder instead of a tiller, and having two lines (*yoke lines*), by pulling on which the boat is steered.

Y'TTRIUM. The metallic base of an earth, discovered in 1794 by Professor Gadolin in a mineral found at *Ytterby* in Sweden, whence it was called *Yttria*. The metal was first obtained by Wöhler in 1828: it is of a dark grey colour, and brittle. The salts of Yttria have a sweetish taste, and some of them a pale purple colour. Yttria is distinguished from glucina by the amethystine colour of its sulphate, by its insolubility in pure potassa, and by yielding a precipitate with ferrocyanate of potassa. According to Berzelius, the equivalent of Yttrium is about 32; and that of Yttria, which is probably a protoxide, 40.

YTTROTA'NTALITE. A mineral from Ytterby in Sweden, containing Yttria and oxide of columbium.

YU. (Chinese.) Nephrite or jade (which see).

YULE. The common Scottish name for Christmas. It appears to be a very ancient Celtic word. In Welsh, wyl or gywl signifies a holyday; whence also the old phrase "Gule of August," the first day of August, or fast of St. Peter and Vincula, for which various absurd etymologies have been found. Perhaps the old French word "Noel," for Christmas (used also generally as a popular cry of rejoicing), has the same original. (See *Archæol.* vol. ii.) Count de Gebelin, however, derives yule from a supposed primitive word, connected with the idea of revolution or "wheel." (See *Brand's Popular Antiq.* vol. i. p. 364.)

Z.

Z. The last letter in the alphabets of all the modern languages, usually regarded as a double consonant, from its having the sound in some languages of *ts* or *ds*. Like the letter *x*, it begins no word originally English; and Dr. Johnson has remarked, that although it is found in the Saxon alphabets, set down by grammarians, it is read in no word originally Teutonic.

ZA'FFRE. An impure oxide of *cobalt*, obtained by exposing the native arseniuret of cobalt broken into small pieces to the action of heat and air in a reverberating furnace, by which its elements are oxidized, and the greater part of the arsenic driven off.

ZA'MITE. Fossil zamia.

ZA'NTHOPI'CRIN. A bitter principle, obtained from the bark of the *Zanthoxylon caribæum*. It forms yellow acicular crystals, insoluble in ether, but readily soluble in alcohol, and sparingly in water.

ZAX. In Architecture, a tool for cutting slates.

ZE'CHSTEIN. (Germ.) A magnesian limestone, lying under the red sandstone.

ZE'IN. A substance of a tough elastic nature, resembling gluten, but said to be destitute of nitrogen, contained in Indian wheat; the produce of the *Zea mays*.

ZEMINDA'R. (From the Persian zemin, *land*.) A title introduced into India by its Mohammedan conquerors, conferred in Bengal, and generally throughout the Mogul empire, on the agent employed to collect that share of the produce of the soil which belongs to it. The zemindars were the great landholders of the Mogul empire; but the nature of their tenure has given rise to much dispute. Whether they were hereditary absolute owners of the soil, or only tenants of the sovereign at a fixed rent by way of land-tax for which they were personally responsible, was a question much agitated by writers on Indian subjects at the period of the "Permanent Settlement" in 1793. By that settlement the rent was to be fixed in the first instance by custom, and the zemindar was then to give the ryot a lease restricted to himself and his assignees on performance of its conditions; his own share being fixed as before at 10 per cent. of the assessment, and his hereditary right secured. A zemindary, *i. e.* the district of a zemindar, is liable to be sold by government for arrears of revenue, and existing leases with the ryots to be set aside. At present the land-tax of India is levied in three methods, which prevail in different districts: — the "zemindar settlement," by which the zemindar is responsible to government; the "mouzawar" or village settlement, by which the collector contracts with the head man of the village; and the "ryotwar" or cultivator settlement, by which the tax is collected immediately from the peasantry. (See, as to the effects of the zemindary settlement, *Mill's History of British India*, vol. v.; M'Culloch's Edition of *Smith's Wealth of Nations*, note 19.; *Ed. Rev.* vols. xxxi. lxxi.) *See* RYOTS.

ZE'ND-AVE'STA. (Pers. *Living Word*.) The sacred books of the Parsees in India, and Guebers in Persia, who profess the religion of the ancient Persians. According to the popular belief among them, these books are attributed to the famous Zoroaster. Their real history is much disputed; but it is generally supposed that they are not of great antiquity, and that the belief of the modern Guebers is for the most part a compound of legendary notions drawn from various religions. (*See* MAGIANS.) Sir William Jones thought the *Zendavesta* a forgery of the learned adventurer Anquetil du Perron. (See *Mém. de l'Ac. des Inscr.* vol. xxxi.; *Milman's Hist. of Christianity*, vol. i. p. 68., for the arguments for and against its authenticity; and the *Conv. Lex.*, article "Per-

sian Religion." See also *Bryant's Mythology*, vol. ii. p. 390. 401.) It is certain, at all events, that the Zend language, in which it is written, is of great antiquity, and radically allied to the Sanscrit. *See* Sanscrit, Parsees.

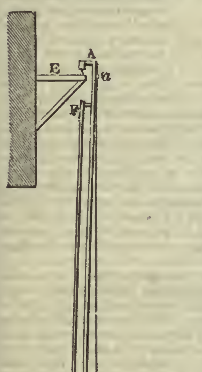
ZE'NDIK. In Arabic, a name given to those who are charged with atheism, or, rather, disbelief of any revealed religion; or with magical heresies. The sect of Zendiks opposed the progress of Mohammedanism in Arabia with great obstinacy. It appears to have had many features in common with Sadduceeism among the Jews.

ZE'NITH. (From the Arabic.) In Astronomy, the top of the heaven, or vertical point; the point directly overhead. The zenith is that point of the celestial sphere which would be intersected by the plumb line, supposed to be indefinitely extended. It may also be defined as the pole of the horizon, from which it is 90° distant. All vertical circles or azimuths necessarily pass through the zenith.

ZE'NITH DISTANCE. The distance of any celestial object from the zenith; or the complement of the altitude of the object above the horizon.

ZE'NITH SECTOR. An astronomical instrument, contrived for the purpose of measuring with great accuracy the zenith distances of stars which pass near the zenith. It was by means of a zenith sector that Bradley discovered the existence and magnitude of two most important astronomical elements,—the aberration of light, and the nutation of the earth's axis. The instrument has also been generally used (in this country at least) in trigonometrical surveys for determining the difference of latitude of two stations, a purpose for which it is very convenient; for the difference of the zenith distances of the same star, observed at its meridional passages at two places, gives the difference of the astronomical latitudes of the places without any regard to the star's declination. The general description of the zenith sector has been given by the present Astronomer Royal as follows (*Ency. Metr.*, art. "Figure of the Earth"): —

"In the annexed figure A B is a bar of iron with a cross piece C D, the whole in one piece. The top A is formed in such a way that the instrument can be turned half round in azimuth when suspended at the top, and that the bottom can be moved freely in the directions D C or C D. The bracket or other support E, on which it rests, is attached to some firm part of the building. To the bar A B is firmly attached a telescope F G. At a point *a*, near A, is attached a plumb line *a* H; sometimes it is fastened at a point of attachment which is moveable, in order that by moving the point of suspension the plumb line may be made to pass over a fine dot at *a*. The limb C D is graduated, sometimes on a circular arc of which *a* is the centre, and sometimes on a straight line. L D is a screw passing through a block strongly connected with the floor, and acting with its point against the end D of the piece C D; and M N O are a string and weight pressing the sector against the point of the screw."



The method of observing with the zenith sector is this: — A clock being regulated by transits or equal altitudes, the direction of the meridian is found, and guides fixed to compel the sector to move in the meridian. When a star is to be observed, the screw L D is turned till the plumb line falls exactly on some point K of the graduated arc, such that the telescope is very nearly directed to the point through which the star will pass when it comes to the meridian. When the star enters the field of view, the screw is again turned till the star appears to glide exactly along the wire fixed in the focus of the eye-glass; and the motion of the screw being ascertained, and the value of the division known, the apparent zenith distance of the star is found. But it is evident that this is not the true zenith distance, unless the zero point of the division on the scale be quite accurate; that is to say, so placed that when the plumb line falls on it the optical axis of the telescope is exactly vertical. It is impossible to insure this accuracy; but it is easy to see that if the instrument be turned half round in azimuth, and the same observation made, the apparent zenith distance will be just as much greater than the true as in the former determination it was less. The mean of the two will therefore be the true zenith distance of the star.

The advantages of the zenith sector are these: — The stars observed being very near the zenith, the tremor and dancing which generally affect stars in other positions are seldom seen; there is no uncertainty about the effects of refraction; the telescope and the whole instrument are not subject to flexure; and the variation of temperature produces no sensible effect.

(For a detailed account of Ramsden's zenith sector used in the measurement of the English arcs of the meridian, see the second volume of the *Trigonometrical Survey of England and Wales*, or *Phil. Trans.* for 1803. This superb instrument was unfortunately burnt in the great fire which took place in the Tower of London in October, 1841. Another sector, on a different plan from that above described (the zenith point being determined by levels instead of a plumb line) has recently been constructed for the use of the survey by Troughton and Simms, under the directions of the Astronomer Royal. A description of the new instrument is given in the *Monthly Notices of the Royal Astronomical Society* for May, 1842.)

ZE'OLITE. (Gr. ζεω, *I boil*, and λιθος, *stone*.) A name given to a family of minerals, which, when heated before the blowpipe, melt with considerable ebullition. They mostly consist of silica, alumina, lime, and water.

Natrolite. A species of zeolite containing soda: from *natron*, or soda.

ZE'PHYRUS. (Gr. ζεφυρος.) The west wind, a mythological divinity, child of Astræus and Aurora, according to Hesiod; to whom Anchises sacrifices a ram. It is said to be the same wind with the Latin Favonius; but Vegetius distinguishes between the two.

ZERI'NTHIA. (Gr. Ζερινθια, one of the names of the goddess of love.) The name of a subgenus of butterflies in Treitschke's system, where it is erroneously written *Zerynthia*.

ZE'RO. (Ital. ?) A term generally used in reference to the thermometer, implying the point at which the graduation commences. The zero of Reaumur's and of the centigrade thermometer is the freezing point of water. The zero of Fahrenheit's scale is 32° below the point at which water congeals, being about the temperature of a mixture of salt and snow. *See* Thermometer.

ZE'THES. In Classical Mythology, Zethes and Calais were the sons of Boreas, king of Thrace, and Orithyia. They accompanied the Argonauts, and were afterwards slain by Hercules.

ZEU'GMA. (Gr. ζευγμα, *yoke*.) A figure in grammar, by which an adjective or verb which agrees with a nearer word is referred also, by way of supplement, to one more remote.

ZI'MOME. (Gr. ζυμωμα, *a ferment*.) That part of the gluten of wheat which is insoluble in alcohol. When rubbed in a mortar with powdered guaiacum, it produces a fine blue colour.

ZINC. A metal, first mentioned by Paracelsus; but its ores were known at a much earlier period. In commerce it is often called *spelter;* and is obtained either from the native carbonate of zinc, called *calamine*, or from the native sulphuret or *blende* of mineralogists. These ores are roasted and mixed with charcoal or carbonaceous flux: the mixture is put into a kind of crucible closed at top, and perforated at bottom by an iron tube, which passes through the grate of the furnace into water; the vapour of the zinc distils downwards through this tube, and is condensed in the water. The first portions are impure, containing arsenic, and often cadmium, in which case the vapour burns with what the workmen call a *brown blaze;* when the *blue blaze* appears the zinc is collected. The zinc of commerce (which is not quite pure) has a peculiar blueish colour and lustre, a lamellar and crystalline texture, and its specific gravity is about 7. At common temperatures it is tough and intractable under the hammer; and when heated to above 500° it becomes brittle, and fuses at about 770°. But at temperatures between 220° and 320° it becomes malleable and ductile; so that it may be beaten out under the hammer, and rolled into sheets and leaves, and drawn into wire, in a manner extremely remarkable when its highly crystalline texture is considered. Being a cheap and light metal, and one which, after having been superficially oxidized, long resists the further action of air and water, it has lately been much employed as a substitute for lead in lining water cisterns and covering buildings; it has also been lately employed in the curious operation of transferring printing (under the name of *zincography*). It is a very inflammable metal, burning in the flame of a spirit lamp with a brilliant white light; but the oxide which forms interferes with its continuous combustion,

which can only be carried on at a high red heat, when the vapour of the metal burns with an intensely bright flame, and yields at the same time a quantity of flocculent oxide, which floats about in the surrounding air, and was formerly called *philosopher's wool*, *pompholix*, and *nihil album*. The equivalent of zinc is 32, and that of its oxide 40. Though zinc is apparently without action upon water, yet it is a most oxidable metal; but the insolubility of its oxide protects it from further action, so that when a film is once formed upon it, it resists further change; but when a little acid is present in the water, and the zinc not quite pure, it is rapidly acted upon, and oxidized at the expense of the water, which evolves abundance of hydrogen (when dilute sulphuric acid is used), and the oxide of zinc is removed and dissolved by the acid. It is this action which renders zinc so powerful a generator of electricity in the voltaic pile. The salts of zinc are mostly soluble, and have a nauseous, astringent, and metallic taste. The *sulphate of zinc*, or *white vitriol*, is employed in medicine as an emetic and tonic, and the oxide and carbonate are externally used in the form of ointment. The *chloride of zinc* is a colourless compound, fusible at a heat a little above 212°, and known to the older chemists under the name of *butter of zinc*. Brass is an alloy of zinc and copper.

ZINGIBERA'CEÆ (Zingiber, one of the genera), or SCITAMINEÆ. A natural order of Herbaceous Monandrous Endogens, inhabiting the tropics. It is distinguished from the Musaceous order in the latter having five or six stamens, with a calyx and corolla of the same texture; and from *Iridaceæ*, by two of the stamens being either deformed or abortive; and from *Marantaceæ*, by the single stamen being placed opposite to the labellum or anterior division of the inner series of the corolla, and proceeding from the base of the posterior outer division. Cardamoms are the seeds of several plants of this order, which are, however, principally valued for the aromatic stimulating properties of the root or rhizoma; such are found in ginger (*Zingiber officinale*), galangale (*Alpinia racemosa* and *galanga*), and zedoary (*Curcuma zedoaria* and *zerumbet*). Turmeric, a substance half dye and half condiment, is the powder of the rhizoma of *Curcuma longa*.

ZI'RCON. A mineral chiefly composed of zirconia and silica, found in the sand of the rivers of Ceylon, and occasionally imbedded in primitive rocks. It is of various colours, and when transparent is sometimes used in jewellery.

ZIRCO'NIUM. The metallic base of *zirconia*, an earth discovered in 1789 by Klaproth in the jargon or zircon of Ceylon. Zirconium has only been obtained in the form of a black powder, which when heated in the air burns into the oxide. The salts of zirconia are distinguished from those of alumina and glucina by being precipitated by all the pure alkalies, and by being insoluble when they are added in excess.

ZOA'NTHUS. (Gr. ζωον, *an animal*, and ανθος, *a flower*.) The name of a genus of Polypes, comprehending those which possess the complex structure of the *Actiniæ*, but consist of different individuals adhering to a common fleshy basis.

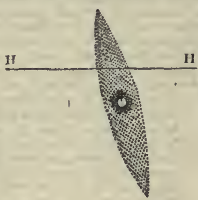
ZO'CLE, or ZOCCOLO. (It. zoccolo, *a wooden shoe*.) In Architecture, the same as *socle*; which see.

ZO'DIAC. (Gr. ζωδιον, dim. of ζωον, *animal*; because the constellations of the ecliptic are for the most part represented in celestial charts by the figures of animals.) An imaginary zone or belt in the heavens, extending to about 8° or 9° on each side of the ecliptic, which divides it in the middle. No use is made of the zodiac in astronomy; the name only indicates that region of the heavens within which the apparent motions of the sun, moon, and all the greater planets are confined. Three of the new planets, Juno, Ceres, and Pallas, have inclinations which exceed the limits of the ancient zodiac, and are therefore sometimes called *extra-zodiacal* planets; but Vesta is also sometimes included in the same description. *See* PLANET.

The zodiac is divided into twelve equal parts, called *signs*; which are designated by the names of the constellations with the places of which the signs anciently corresponded. They are Aries, Taurus, Gemini, Cancer, Leo, Virgo, Libra, Scorpio, Sagittarius, Capricornus, Aquarius, and Pisces. The signs are counted from the vernal equinox, one of the points in which the equator intersects the ecliptic; whence, in consequence of the regression of the equinoctial points, their position with respect to the constellations or fixed stars is greatly different from what it was in remote ages. Some time prior to Hipparchus, the first points of the constellations Aries and Libra corresponded to the vernal and autumnal equinoxes; those of Cancer and Capricorn to the summer and winter solstices: at present, the difference is about 30°. The vernal equinox now happens in the constellation Pisces, the summer solstice in Gemini, the autumnal equinox in Virgo, and the winter solstice in Sagittarius; but the vernal equinox always corresponds to the first point of the sign Aries, the summer solstice to the first of Cancer, and so on. On this account it is necessary to distinguish between the *signs* of the zodiac, which follow the motions of the equinoctial points, and the *constellations* of the zodiac, which are immoveable in the celestial sphere.

It has been supposed that the constellations of the zodiac were invented in Egypt in a very remote age, and that they had a reference to the divisions of the seasons and the agriculture of that country at the time of their invention. If we go back to a period about 2500 before Christ, the constellations Aquarius and Pisces, at the season of the overflow of the Nile, would be diametrically opposite to the sun, and would consequently rise at sunset. Virgo, usually represented as a woman with an ear of corn in her hand, would be the constellation rising at sunset in the time of the harvest in Egypt. Such conjectures, however, it is easy to conceive, are at best extremely uncertain. Representations of the zodiac have been found in several Egyptian temples, and also in other eastern countries, which have given rise to much discussion. (See Dupuis, *Mémoire sur l'Origine du Zodiaque*; Biot, *Récherches sur l'Astronomie Egyptienne*; Montucla, *Histoire des Math.* tom. i.; Bailly, *Histoire de l'Astr. Ancienne*.)

ZODIACAL LIGHT. In Astronomy, a faint nebulous aurora which accompanies the sun. This curious phenomenon was observed by Kepler, who supposed it to be the solar atmosphere; but it was first accurately described by Dominic Cassini, who gave it the name by which it is now known. It is visible immediately before sunrise or after sunset, in the place where the sun is about to appear or has just quitted in the horizon. It has a flat lenticular form, as represented in the annexed figure, extending from the horizon H H obliquely upwards, and following the course of the ecliptic, or rather of the sun's equator. For this reason it is scarcely visible in our latitudes, excepting in those seasons when the plane of the sun's equator is most nearly perpendicular to the horizon. The most favourable times for observing it are in the months of April or May, in the evening, or at the opposite season of the year before sunrise. At other times, the plane of the solar equator being more oblique, and the luminous pyramid inclined in the same degree, it rises so little above the horizon that its light is effaced by the atmosphere of the earth. The apparent angular distance of its vertex form the sun varies, according to circumstances, from 40° to 90° or 100°, and the breadth of its base perpendicular to its axis from 8° to 30°. It is extremely faint and ill-defined, at least in this climate; though it is better seen in tropical countries.



Numerous opinions have been entertained respecting the nature and cause of this singular phenomenon. Cassini thought it might proceed from the blended light of an innumerable multitude of little planets circulating about the sun, as the milky way owes its appearance to the light of agglomerated myriads of stars. Euler endeavoured to prove that it proceeds from the same causes as the tails of comets. Kepler had ascribed its appearance to the solar atmosphere; and the same hypothesis was adopted by Mairan and others, till it was shown by Laplace to be untenable for the following reasons:— In the first place, the solar atmosphere cannot extend beyond the distance at which the centrifugal force would be balanced by the attraction; but this point lies far within the orbit of Mercury, the greatest elongation of which is 28°, whereas the zodiacal light has been observed to extend to 100° from the sun. In the second place, in order that the spheroid of the solar atmosphere may be in equilibrium, the ratio of the equatorial to the polar axis cannot exceed that of 3 to 2; whence its form would not correspond with the lenticular appearance of the zodiacal light. Sir John Herschel remarks, that "it may be conjectured to be no other than the denser part of that medium, which, as we have reason to believe, resists the motion of comets; loaded, perhaps, with the actual materials of the tails of millions of those bodies, of which they have been stripped in their successive perihelion passages, and which may be slowly subsiding into the sun."—*Astronomy*, *Cab. Cyc.* p. 407. (Biot, *Astronomie Physique*; Mairan, *Traité Physique et Historique de l'Aurore Boreale*; Euler, *Mém. de Berlin*, 1746; Lalande, *Astronomie*, tom. i.; Hooke, *Opera Posth.*)

ZO'HAR. (Heb. *splendour*.) A Jewish book, highly esteemed by the rabbis, and supposed to be of great, though altogether unascertained, antiquity. It consists of cabalistical commentaries on Scripture, especially the

books of Moses. It has been translated into Latin (ed. 1680).

ZOI'SITE. A variety of epidote, named after its discoverer Baron von Zois.

ZONE (Gr. ζωνη, *a girdle* or *belt*), in Astronomy, denotes a portion of the celestial sphere included between two parallel circles. In Geography, the terrestrial zones are the five broad spaces or belts into which the surface of the earth is divided by the two tropics and the two polar circles. The space included between the tropics is called the *torrid zone;* its breadth is equal to 47°, or twice the sun's greatest declination, and it is divided into two equal parts by the equator. That included between the tropic of Cancer and the arctic circle is called the *north temperate zone;* and that between the tropic of Capricorn and the antarctic circle the *south temperate zone.* The breadth of each of these is 43°. The space between the arctic circle and the north pole is the *north frigid zone;* and that between the antarctic circle and the south pole is the *south frigid zone. See* GEOGRAPHY, EARTH.

ZOO'GRAPHY. (Gr. ζωον, and γραφω, *I write.*) The description of animals.

ZOO'LATRY. (Gr. ζωον, *an animal*, and λατρευω, *I worship.*) The worship of animals; which was the characteristic of the ancient Egyptian religion most remarked upon by foreigners.

ZOO'LOGY. (Gr. ζωον, *an animal;* λογος, *a discourse.*) The science of animals. It teaches their nature and properties, their classification, and their order of succession upon and their distribution over the earth.

A knowledge of the nature of animals, as it implies that of their organization, and of the functions and interdependencies of their component parts, constitutes the two great branches of zoology, called *Zootomy*, or comparative anatomy, and *Physiology*. The doctrine of the succession of species of animals upon the earth, as it relates principally to such as no longer exist, is included in a third branch of the science of animals, called *Palæontology*, with which is closely connected that which treats of the geographical distribution of existing species. The term *Zoology* is practically restricted to the science of the outward characters, habits, properties, and classification of animals.

As the forms of living animals, the parts they play in the theatre of nature, their good and evil relations to man, cannot be profitably treated of in the space assigned to this article, it will be limited to the exposition of the principles of the classification of animals, and of the characters and relative value of those groups which have not been already treated of in the present work.

A classification is essentially based on the ideas of likeness, unlikeness, and proportion in its subjects. When it is purposed to define, in a classification of animals, their different degrees of resemblance, a natural system is aimed at. When a classification is restricted to the enunciation of a few likenesses which may be most readily detected and most easily retained in the memory, it becomes an artificial system. A likeness extends as far as a character is common; and the more extended or common the property or structure on which such character is founded, the more important and essential it becomes as an element of the classification.

Zoologists having ascertained as many of the characters common to all animals as served to form their complex idea of an animal, have, in the next place, endeavoured to discover the difference, which, added to the idea or definition of the animal, would form the most extended species of that genus, logically speaking.

Such a difference or character is not to be detected by a superficial examination. Aristotle thought he had found it in the blood, recognizing as blood only the red-coloured nutrient fluid, like that which flows in the arteries and veins of man. His primary division of animals was therefore into Sanguineous and Exsanguineous animals; the *Enaima* and the *Anaima*. The Enaima were the beasts, birds, reptiles, and fishes; and the Anaima, or bloodless animals, included all the lower species.

Nothing, perhaps, can show more forcibly the nature and amount of observation required to frame a good classification, and the value of the information concentrated in its exposition, than the great and long-continued deference paid to this early step in the classificatory branch of zoology, and the minute and extended researches required for the elimination of its erroneous element. First, it was found that many of the Exsanguineous animals of Aristotle did actually possess blood, differing only in colour from that of the so-called Sanguineous species. This discovery, however, led only to a nominal improvement in the primary division of animals; the Enaima being "red-blooded," and the Anaima "white-blooded" animals. It was reserved for Cuvier, in the course of his minute dissections of the lower animals, to discover that an extensive class of worms had red blood circulating in a closed system of arteries and veins; and this discovery first materially affected the value of the character adopted by Aristotle for the primary groups of the animal kingdom.

Now, if scientific classification were really based on the idea of likeness alone, and the grouping together of individuals into kinds in forming a natural system were regulated by a consideration of their resemblances only, then the modification of the Aristotelian system involved in Cuvier's discovery would be merely an extension of the group Enaima at the expense of the group Anaima; and the Anellides, or red-blooded worms, must have been united with birds, fishes, and other Sanguineous animals. But the zoologist, in the formation of a natural system, has to be governed at every step by the idea of difference as well as by that of likeness. Coincident with the discovery above mentioned was the perception that if the Anellides resembled beasts in the colour of their blood, they differed from them in most other essential points; and thus the circulating fluid was rejected as a ground for the primary groups of the animal kingdom, and other characters were eagerly sought for.

Lamarck conceived that he had discovered the best substitute for the Aristotelian primary character in the vertebral column; this structure being present in all the Enaima of Aristotle, and absent in all the Anaima. He proposed, therefore, the name of *Vertebrata* for the one class, and *Invertebrata* for the other. The defect of this primary division of the animal kingdom was soon perceived to arise from the neglect of a third fundamental idea in a classificatory science, viz. that of proportion, or relative value, in the primary groups; and in the attempt to remedy this defect the important discovery was made, that the vertebral column was a modification of structure subordinately related to a particular condition of an organic system of much higher importance in the animal body than the skeleton, viz. the nervous system. A knowledge of the anatomy of this system hence became essential to the zoologist; and the result of a long series of minute and elaborate dissections was the detection of at least three modifications of the nervous system of equal importance with that in regard to which a skull and vertebral column are dependent and subordinate. Hence arose the proposition by Cuvier to divide the animal kingdom primarily into four provinces or subkingdoms: viz. *Vertebrata, Mollusca, Articulata*, and *Radiata;* or, as they have been termed, in accordance with the modifications of the nervous system respectively characterizing them, *Myelencephala, Heterogangliata, Homogangliata*, and *Acrita*.

All previous primary divisions of the animal kingdom*, having been proposed in ignorance of the true characters by which such groups exist in nature, are now abandoned by the common consent of naturalists, and nothing would be gained by quoting them in this place. Herein the Linnæan method is inferior to the Aristotelian system: the class *Vermes* of the *Systema Naturæ*, as it included the *Ostracoderma* and *Malakia* of Aristotle, afterwards the *Mollusca* of Cuvier, with the true *Vermes*, was a retrograde step in this branch of zoological science.

The subkingdom *Vertebrata*, or *Myelencephala*, is subdivided into classes, according to the modifications of the respiratory and circulating organs. These modifications are essentially four in number, which may be thus expressed:—

1. Lungs suspended freely in a thoracic cavity; subdivided into minute air-cells. Heart divided into four cavities; pulmonic and systemic circulations distinct.

2. Lungs adherent to the walls of a thoracic cavity, communicating with large air-cells in other cavities of the body. Heart with four cavities; pulmonic and systemic circulations distinct.

3. Lungs suspended freely in, or attached to the parietes of a thoracic-abdominal cavity; not divided into minute air-cells. Heart with four or three cavities; pulmonic and systemic blood mixed in the general circulation.

4. Gills for respiration, with or without lungs. Heart with two cavities, transmitting all the blood to the breathing organs.

The first condition of the respiratory and circulating organs coexists with a viviparous generation, and lacteal organs for the nourishment of the new-born young; whence the class was termed *Zootoca* † by Aristotle, and *Mammalia* by Linnæus; and the latter term is retained, because it expresses a character which is truly peculiar to the class. The total or partial clothing of hair, and the other organic coexistences which proclaim the naturalness of the group in question, are mentioned under the term MAMMALIA.

The second condition of the respiratory and circulating organs characterizes the class of Birds. It is associated in this class with an oviparous generation, a covering of feathers, and those other modifications of the vertebrate type of structure which are detailed under the

* If we except some of the schemes of classification of the animal kingdom by John Hunter, found among his manuscripts after his death. (See Preface to Palmer's edition of his *Animal Economy.*)

† The term *Zootoca* has been degraded by a modern naturalist to designate a subgenus of lizards, distinguished by their viviparous generation.

head of Aves. This is the most natural and circumscribed of all the groups of animals of corresponding value. Both mammals and birds differ from all other classes of animals in being warm-blooded; whence they have been combined to form a group called *Hematherms*.

The condition of the circulating and breathing organs which characterizes the third class of vertebrate animals, called Reptiles, is associated with cold blood, and a covering of scales, bony plates, or a naked skin. The generation is oviparous or ovoviviparous: the other characters are given under the head Reptilia.

Fishes, besides breathing by gills, and having a heart composed of a single auricle and ventricle, have the skin defended by scales, or by bony plates, or are naked. They are likewise oviparous, or ovoviviparous; and, with a few exceptions, as the tunny, the temperature of their blood corresponds with that of the surrounding medium. They are exclusively aquatic; and their general characters and classification are given under the heads Pisces and Ichthyology.

The subkingdom *Mollusca*, or *Heterogangliata*, is characterized by a ring of nervous matter surrounding the gullet, whence the nerves radiate, often unsymmetrically, to different parts of the body. There is a ganglion or little brain below the gullet, and sometimes also above that tube: the nerves of the body are generally connected with one or more detached ganglions. The form of the body corresponds with the disposition of the nervous system, and is often unsymmetrical; it is generally soft, covered with a mucous skin, and destitute of jointed limbs. In one class (*Cephalopoda*), in which the supra-œsophageal nervous mass is large, it is protected by a cartilaginous cranium; but this is absent in other Mollusca, and a vertebral column exists in none. Many species have for their skeleton a calcareous plate or plates, called *shells*, secreted by the skin. (*See* Conchology.) The animal functions are feebly enjoyed in the *Heterogangliate* subkingdom. Distinct organs of hearing and smell have as yet been found only in the highest class (*Cephalopoda*); the eyes are reduced to mere rudiments in the group next in subordination (*Gasteropoda*); and the head is altogether wanting in the three lower classes, thence collectively called *Acephala*. The machinery of the organic functions, on the other hand, is largely and completely developed. Every mollusk has a heart, and a closed system of arteries and veins: in the higher Cephalopods the circulating system is physiologically as perfect as in the highest Vertebrates, and the heart is anatomically more complicated. An organ of respiration is never wanting; but it presents this character, that whereas in the *Vertebrata* it communicates with the mouth, in the *Mollusca* it is connected with the opposite termination of the alimentary canal. The *Mollusca* are either Diœcious or Hermaphrodite.

The primary division of *Mollusca* is, according to the presence or absence of a head, into the *Encephala* and *Acephala*.

The Encephalous Mollusks are divided, according to their locomotive organs, into the classes *Cephalopoda*, *Gasteropoda*, and *Pteropoda;* the Acephalous Mollusks, according to their respiratory organs, into *Lamellibranchiata*, *Palliobranchiata*, and *Heterobranchiata:* the two latter classes are more commonly called *Brachiopoda* and *Tunicata*. See those names of classes, and Malacology.

The third primary division of the animal kingdom, viz. the *Articulata*, is as well characterized, Cuvier states, as that of the *Vertebrata*. "The skeleton is not internal, as in the latter; neither is it annihilated, as in the *Mollusca*. The articulated rings which encircle the body, and frequently the limbs, supply the place of it; and as they are usually hard, they furnish to the powers of motion all requisite points of support; so that we have here as many kinds of locomotion as among the *Vertebrata*. This external position of the hard parts, and internal one of the muscles, reduce each articulation to the form of a sheath, and allow it but two kinds of motion, unless the limbs be united by flexible membranes, or fit into one another; and then their motions are more various, but have not the same force.

"The system of organs in which the *Articulata* resemble each other the most is that of the nerves. Their brain, which is placed above the œsophagus, and furnishes nerves to the parts adhering to the head, is very small. Two cords, which embrace the œsophagus, are extended along the abdomen, and united at certain distances by double knots or ganglia, whence arise the nerves of the body and limbs. Each of these ganglia seems to fulfil the functions of a brain to the surrounding parts, and to preserve their sensibility for a certain length of time when the animal has been divided. If to this we add that the jaws of these animals, when they have any, are always lateral, and move from without inwardly, and not from above downwards, and that no distinct organ of smell has hitherto been discovered in them, we shall have expressed all that can be said of them in general." The existence, however, of the organs of hearing, the presence, number, and form of those of sight, the kind of respiration, the condition of the organs of circulation, and the colour of the blood, present great differences, which characterize the subdivisions or classes of the Articulate or Homogangliate subkingdom.

These classes are, *Crustacea*, *Arachnida*, *Insecta*, *Anellata*, and *Cirripedia*. See those words.

The first three are combined by Latreille into a large group, called *Condylopoda*, in reference to their possessing articulated members; but these are likewise possessed by the *Cirripedia*, which, although placed by Cuvier in the Molluscous subkingdom, are proved by their nervous system and metamorphoses to be essentially *Articulata*, nearly allied to the Crustaceans.

The Radiated, or fourth primary division of animals in the system of Cuvier, is so called because the low-organized animals composing it agree, Cuvier says, in having their parts arranged round an axis, and on one or several radii, or on one or several lines extending from one pole to the other. "Even the *Entozoa* have at least two tendinous lines, or two nervous threads, proceeding from a collar round the mouth; and several of them have four suckers situated round a proboscidiform elevation! The nervous system, when traces of it have been visible, is also arranged in radii." This cannot, however, be affirmed with propriety of the nerves of the *Entozoa* or *Rotifera;* but these classes agree with all the other *Radiata* (*Holothuria* excepted) in the absence of distinct respiratory organs. It has been proposed to divide the Radiated animals, or Zoophytes of Cuvier, into two subkingdoms: the *Nematoneura*, presenting conspicuous nervous filaments; and the *Acrita*, in which such filaments are rarely distinguishable. The *Nematoneura* are more definitely and readily characterized by having the alimentary canal in the form of a distinct tube, with proper parietes, floating in an abdominal cavity, and provided with a separate inlet and outlet; while in the *Acrita* the digestive cavity is excavated in the parenchyma of the body, is devoid of distinct parietes, and has no anal outlet. The *Nematoneura* never propagate by germination or spontaneous fission, but these modes of reproduction are common in the *Acrita*. The latter division has been termed *Oozoa*, from their analogy to the ova or germs of the higher classes; but I have elsewhere observed * that as the changes of the embryo succeed each other with a rapidity proportionate to its proximity with the commencement of its development, so, also, in each class of *Acrita*, there are genera which closely approximate or merge into some one or other of the higher or Nematoneurous classes, and their characters are consequently less definite and fixed. If, therefore, guided by their natural affinities, we arrange the *Radiata* into their primary groups, it will be found that one part of each of these groups presents the characters of the *Nematoneura*, and another those of the *Acrita*. This will be exemplified in the disposition of the Radiated classes in the following table of the primary groups and classes of the animal kingdom.

Kingdom Animalia.

Subkingdom *Vertebrata*.

Class Mammalia.
Aves.
Reptilia.
Pisces.

Subkingdom *Articulata*.	Subkingdom *Mollusca*.
Class Crustacea.	Class Cephalopoda.
Arachnida.	Gasteropoda.
Insecta.	Pteropoda.
Anellata.	Lamellibranchiata.
Cirripedia.	Brachiopoda.
	Tunicata.

Subkingdom Radiata.

Nematoneura.	*Acrita*.

Class Radiaria, Lamarck.

Echinoderma, Cuv.	Acalepha, Cuv.

Class Entozoa, Rudolphi.

Cœlelmintha, Owen.	Sterelmintha, Owen.

Class Polypi, Cuvier.

Ciliobrachiata, Farre.	Nudibrachiata†, Farre.

Class Infusoria, Cuvier.

Rotifera, Ehrenb.	Polygastria, Ehrenb.

ZOO'NOMY. (Gr. ζωον, and νομος.) The branch of science treating of the laws of animal life.

ZOO'PHAGANS. (Gr. ζωον, and φαγω, *I devour*.) The term applied to the order of Unguiculate Mammals

* *Cycl. of Anat. and Physiol.*, art. "Acrita."

† This may be again subdivided into the *Anthozoa* and *Nudibrachiata* proper, which lead to the doubtful class of *Spongiæ*.

which live on animal food, and corresponding to the French term *Carnassiers;* also the corresponding group of the Marsupial Quadrupeds.

ZOO'PHORUS. (Gr. ζωον, *an animal*, and φερω, *I bear.*) In Architecture, the same as frieze; which see.

ZO'OPHYTES, *Zoophyta.* (Gr. ζωον, and φυτον, *a plant.*) The name given by Cuvier to his fourth and last primary division or subkingdom of animals. By Linné it was applied in a more restricted sense to an order of *Vermes*, comprehending those beings which he supposed to participate of the natures of both animal and plant. Mr. Hatchett's dissertation upon these subjects, in the *Philosophical Transactions* for 1800, contains nearly all the chemical information which we have respecting them. In respect to their composition they may be arranged into four classes: — 1. Those which consist almost entirely of carbonate of lime and gelatine. They are perfectly soluble, with effervescence, in muriatic acid, and the solution yields slight traces only of animal matter: when heated red-hot they evolve but little smoke or odour, and leave quicklime. Common white coral (*Madrepora virginea*) is an instance of this variety. 2. Those which, like the former, have carbonate as their hardening principle, but which when steeped in muriatic acid are less rapidly acted on, and leave membranous or cartilaginous films, and which, when heated, exhale smoke and the odour of burned bone; these, therefore, consist of carbonate of lime, gelatine, and albumen. Such are the *Madrepora zamea* and the *Madrepora fascicularis.* The *Isis hippuris* is a curious variety of this class, in which separate portions of var. 1. are united by cartilaginous joints. 3. This class includes the *Gorgonia nobilis*, or red coral, the *Tubipora musica*, and some other varieties; the earthy part of which is not merely carbonate of lime, but contains a portion of phosphate of lime, whilst the animal part resembles class 2. 4. This class includes the various sponges. Some of these consist almost exclusively of what may be called animal matter, that is, of a peculiarly organized albumen, with a trace of gelatine; others are hardened by abundant siliceous or calcareous spiculæ. Mr. Hatchett has pointed out the resemblance which exists among the three first classes to porcellaneous shell, mother-of-pearl shell, and the crustaceous coverings of the crab and lobsters.

ZOO'TOMY. (Gr. ζωον, and τεμνω, *I dissect.*) The branch of anatomical science which relates to the structure of the lower animals. *See* ANATOMY, COMPARATIVE.

ZOTHE'CA (Gr.) In ancient Architecture, a small apartment or alcove, capable of being separated from or added to a larger one by means of curtains.

ZU'MIC ACID. (Gr. ζυμη, *leaven.*) A compound formed in sour bread, and in vegetable substances which have undergone acetous fermentation.

ZUMO'LOGY. (Gr. ζυμη, and λογος, *a discourse.*) The doctrine of fermentation.

ZUMO'METER, or ZUMOSI'METER. (Gr. ζυμη, and μετρον, *a measure.*) An instrument intended to show the degree to which fermentation has proceeded in different fermenting liquors. *See* SACCHAROMETER.

ZU'RLITE. A name given to a recently discovered Vesuvian mineral.

ZYGODA'CTYLES. (Gr. ζυγον, *a yoke;* δακτυλος, *a finger.*) The name given by M. Temminck to an order of Climbing Birds, including those which have the toes arranged in pairs, two before and two behind; corresponding to the *Scansores* of Cuvier.

ZYGŒ'NA. (Gr. Ζυγαίνα; the name of a fish in Aristotle.) A genus of Cartilaginous fishes of the Squaloid or Shark tribe, remarkably characterized by the extreme breadth and flatness of the head, the sides of which extend outwards at right angles with and far beyond the body, just as the head of a hammer is placed on the handle: the eyes are placed at the lateral margins of the head. The term *Zygæna* has also been applied by Tchsenheimer to a genus of *Lepidoptera.*

ZYGO'MA. (Gr. ζυγον, *a yoke;* because it transmits the tendon of the temporal muscle like a yoke.) The cavity under the *zygomatic* process of the temporal bone. Hence, also, the term *zygomatic muscles.*

ZYGOPHYLLA'CEÆ. (Zygophillum, one of the genera.) A natural order of arborescent, shrubby, or herbaceous Exogens, inhabiting the hotter parts of the world. Are nearly allied to *Oxalidaceæ*, from which they differ in many characters; with *Simarubaceæ* they accord in the stamens springing from the back of an hypogynous scale; and are distinguished from *Rutaceæ* in the leaves being constantly opposite, with lateral or intermediate stipules, and in being generally compound, and always destitute of pellucid dots. The ligneous plants of this order are remarkable for their hardness. Guaiacum, or *Lignum Vitæ*, is one of them.

LONGMAN, BROWN, GREEN, AND LONGMANS.
1852.

SUPPLEMENT.

ABSI'NTHINE. (Gr. *α, priv.*; *ψινθος, sweetness.*) A peculiar bitter principle extracted from wormwood (*Artemisia Absinthium*).

ACE'TAL. (Lat. acetum, *vinegar.*) A colourless inflammable liquid, obtained by the action of spongy platinum upon the vapour of alcohol: it is convertible by slow combustion into *acetic acid*.

ACETO'METER (Lat. acetum and Gr. *μετρον, measure.*) An instrument in the form of an hydrometer, for determining the strength of vinegar and other forms of acetic acid: it was invented by Messrs. J. and P. Taylor, and is described in the *Quarterly Journal of Science and the Arts*, vol. vi.

ACE'TONE. (Lat. acetum.) When acetate of lime, baryta, or lead, is subjected to dry distillation, a limpid colourless liquid is obtained, to which the above name has been given: it has a penetrating aromatic odour, and is highly inflammable: its ultimate components are 3 atoms of carbon, 3 of hydrogen, and 1 of oxygen.

A'CETYLE. The hypothetical radical of the acetic compounds: it is composed of 4 atoms of carbon and 3 of hydrogen. Its symbol therefore is $C_4 H_3$, and that of the acetic acid $C_4 H_3 O_3$.

ACHILLEI'NE. A peculiar bitter principle procured from the *Achillea millefolia*.

ACH'MITE. (Gr. *αχμη, the point of a sword.* Named from the pointed form of its crystals). A mineral found near Kongsberg in Norway: it is a double silicate of soda and iron.

ACIDI'METER. (Lat. acidus, *acid*, Gr. *μετρον, measure.*) An instrument for determining the strength of an acid by its saturating power: it usually consists of a glass tube graduated into 100 equal parts, and containing an alkaline liquor of known strength, the proportion of which, requisite to saturate a given quantity of any acid, is the equivalent of that acid. *See* ALKALIMETER.

A'CINI. (Gr. *ακινος, a grape.*) A number of vesicles arranged in clusters usually round the ends or by the sides of the smallest branches of the ducts of aggregated glands. Each acinus seems to be formed by the fusion of the walls of several vesicles which combine to form one cavity lined or filled with secreting cells. The various modes of grouping of the *acini* afford characters for the different aggregated or conglomerate glands.

ACRO'LEINE. (Gr. *ακρος, extreme; ελαιον, oil.*) An acrid volatile product, formed during the destructive distillation of the fat oils: it appears to arise from the decomposition of glycerine, inasmuch as it is not obtained from the pure fat acids.

ACTI'NOGRAPH (*ακτιν, a sunbeam; γραφω, I write*). An instrument for the purpose of registering the variations of chemical influence in the solar rays, the intensity of which has been found to bear no direct relation to the quantity of light, but to vary at different periods of the day and year. The instrument, as contrived by Mr. Hunt, and described to the British Association, "consists of a fixed cylinder, on which is placed a prepared photographic paper. This is covered by another metal cylinder which revolves once in twenty-four hours. Through this there is a triangular opening divided by fifty bars, through which the paper is exposed to the sunshine. As the time during which the smallest part of the opening allows the paper to be exposed is one hundred times less than the time during which it is exposed by the largest opening, different effects are produced on the paper, and consequently a register for every hour of the day may be numerically kept of the actinic radiation associated with light." — *British Association Reports* for 1845 and 1846.

ACTINO'METER (Gr. *ακτιν, a sunbeam*, and *μετρον, measure*), an instrument invented by Sir John Herschel for measuring the force of solar radiation. It consists of a hollow cylinder of glass soldered at one end to a thermometer tube terminating at the upper end in a hollow ball drawn out to a point, and broken off so as to leave the end open. The other end of the cylinder is closed by a silver, or silver-plated, cap cemented on it, through which a screw, working in a collar of leather, passes into the interior of the cylinder, and gives the means of increasing or diminishing the hollow capacity of the cylinder to a small extent at pleasure. The cylinder is filled with a deep-blue fluid (the ammonio-sulphate of copper); a graduated scale is applied to the stem, or thermometer tube, and the instrument is defended from currents of air by being enclosed in a case having the interiors of three of its sides blackened, and the fourth, or face, composed of a thick plate of glass.

Before using the instrument for observation any air-bubbles in the cylinder must be carefully expelled. This is easily effected by means of the screw and the ball at the top of the stem, which serves as a reservoir and contains a small portion of superfluous liquid. When the ball and stem are both filled and no air bubble is left, the fluid is brought down to the zero of the scale by turning the screw.

The general object is to determine the expansion of the liquid produced by the exposure of a given area of the cylinder to the direct rays of the sun during a given interval of time. But as the expansion of the liquid depends, not only on the heating power of the sun, but also on the rapidity with which the heat received is radiated away, and on every other circumstance exerting a thermometrical influence, it is necessary to eliminate those influences. For this purpose the observations are made with the instrument alternately exposed to and screened from the solar rays for intervals of one minute.

On exposure to the sun, the liquid in the stem rises rapidly, and the difference of the readings of the scale at the beginning and end of the interval of exposure shows the combined effect of all the heating and cooling influences. The instrument is then placed in the shade during an equal interval. If during this second interval the liquid remains stationary, then it may be inferred that the rise in the first interval was due to the solar action alone. If the liquid *falls* during the shade observation, then it is manifest that the solar action is opposed or counteracted by the cooling influences, and the number of divisions through which the liquid falls must be *added* to the number through which it rose in the interval of exposure, in order to have the measure of the solar action. But if the liquid continues to *rise* during the shade observation, then it is plain that the action of the solar rays is assisted by other heating influences, and the number of divisions through which the liquid rises in the second interval must be *subtracted* from the number through which it rose during the first.

The observations are made in triplets: that is to say, the instrument is held in the sun's rays one minute, then one minute in the shade, and again one minute in the sun, an interval of 20 or 30 seconds being interposed at each change for the purpose of noting the readings. The difference of the readings at the beginning and end

of each minute interval is taken, and the difference in respect of the second interval is added to or subtracted from the mean of the two differences in respect of the first and third. A complete actinometer observation, however, cannot consist of less than three sun observations and two shade observations intermediate; but the more there are taken the better.

It will be readily seen that the results obtained, as above described, are only relative; some positive determination must therefore be had recourse to before the indications given by any two instruments are comparable. This is a matter of much difficulty. No doubt it is possible to determine for every instrument both the area of the section of the sunbeam which falls on the bulb, and is effective in raising the temperature, and also the absolute quantity of liquid in the capillary tube, corresponding to any length on the scale; or, which comes to the same thing, to determine the value of the parts of the scale in water grains, or some other absolute measure; but even this would not be sufficient, for, in so delicate an experiment, the slightest difference in the thickness or composition of the glass would produce discrepancies, and no two plates of glass are ever found to be precisely the same in respect of the proportion of calorific rays they stop or absorb. Hence, the only means of discovering the relation between the results given by two instruments is to make a series of experiments with both together, and under precisely the same circumstances. Sir John Herschel proposes to adopt as the *actine*, or unit, that intensity of solar radiation which, at a vertical incidence, and supposing it to be wholly absorbed, would suffice to melt one-millionth part of a *metre* in thickness from the surface of a sheet of ice horizontally exposed to its action in one minute of mean solar time.

In the Philosophical Transactions for 1842 Professor Forbes, of Edinburgh, has given an account of some interesting experiments with the Actinometer, made by him on the Faulhorn (in Switzerland), for the purpose of ascertaining the difference of solar radiation at the bottom and top of the mountain, and thence the proportional quantity of calorific rays absorbed in passing through a stratum of the atmosphere of a given thickness. This is one of the most useful purposes to which the instrument can be applied. It may also be used for measuring the defalcation of heat in an eclipse of the sun.

The Actinometer was first described in the *Edinburgh Journal of Science*, vol. iii. for 1825. For a full description of the instrument, and of the method of using it, see the *Report of the President and Council of the Royal Society on the Objects of scientific Inquiry in Physics and Meteorology*, 1840.

AD′JUTAGE, or AJUTAGE. (French.) In Hydraulics the name given to a short tube or pipe applied to a vessel containing a liquid for the purpose of facilitating the discharge. *See* HYDRAULICS, in DICT.

ADRIANO′PLE RED. A term applied by dyers to the red obtained from madder: it is also called *Turkey red*.

AE′RIAL IMAGES. In Optics, the name given to images of objects produced by reflection or refraction when they appear suspended in the air. For example, a spectator standing before a concave mirror, at a somewhat greater distance from it than its radius of curvature, sees an inverted image of himself, hanging as it were between himself and the mirror. For examples of aerial images produced by refraction, see FATA MORGANA, MIRAGE, in DICT.

ÆS′CULINE. A peculiar substance contained in the bark of the horse-chestnut tree (*Æsculus hippocastanum*): it appears in the form of a white crystalline powder, and when dissolved in very minute quantities in water, communicates a blue opalescence to it.

Æ′THOGEN. (Gr. *αιθων*, *brilliant*, *γιγνομαι*, *I become*.) A compound of nitrogen with boron, remarkable for the intense luminosity which it exhibits in the flame of the blowpipe.

ÆTI′TES. (Gr. *αιτος*, *an eagle*.) A mineralogical term applied to globular masses of clay iron-stone. The name is derived from its being supposed to form one of the component parts of an eagle's nest.

AF′FERENT. The term, in Anatomy, applied to those lymphatic vessels which enter the lymphatic glands, subdivide, and form tortuous plexuses therein, whence other vessels proceed, converge, and unite into two or more efferent vessels which are larger than the afferent ones, and proceed towards the main trunk called "thoracic duct." The term *afferent* has also been applied to those nerves which convey impressions to the central axis, and which Hartley called "sensory" nerves, in contradistinction to the efferent or "motory" nerves.

AG′GREGATED GLANDS. Those secreting organs in which a number of compound vesicles or *acini* are arranged in groups, forming lobules. (*See* CONGLOMERATE.) Such are the so-called mucous glands of the mouth, trachea, and vagina; the tonsils, salivary, pancreatic, and mammary glands; the lachrymal and Brunnian glands; Cowper's glands and prostate.

AG′MINATE GLANDS. (Lat. agmen.) The glands of Peyer, in the small intestines, where they are aggregated in groups, are so called: these groups are of various sizes, and usually of an oval form.

A′LCOHOL. The following is Fownes' table of the specific gravities of mixtures of alcohol and water.

Sp. Gr. at 60°.	Per centage of real Alcohol.	Sp. Gr. at 60°.	Per centage of real Alcohol.	Sp. Gr. at 60°.	Per centage of real Alcohol.

ALCOHO′LMETER. An instrument by which the quantity of alcohol contained in wines and other spirituous liquors is determined by reference to their respective boiling points at given pressures.

AL′CORNINE. A crystallisable substance contained in the alcornoque bark of America.

AL′DEHYDE. (From *alcohol dehydrogenatus*.) A chemical term applied to a pungent volatile liquid, obtained by distilling alcohol with oxide of manganese and sulphuric acid. Alcohol is a compound of 4 atoms of carbon, 6 of hydrogen, and 2 of oxygen; whereas aldehyde consists of 4 of carbon, 4 of hydrogen, and 2 of oxygen.

ALKA′RSINE. A compound of carbon, hydrogen, oxygen, and arsenic; it was formerly called *Cadet's fuming liquor of arsenic:* it is the *oxide of kakodyle* of modern chemistry. *See* KAKODYLE.

ALLANTO′INE. The substance originally termed *Allantoic acid*. It has been produced artificially by the action of peroxide of lead on uric acid: its formula is $C_4\,H_3\,O_3\,N_2$.

ALLO′PATHY. (Gr. *αλλος*, *different*, and *παθος*, *disease*.) A term recently invented to describe the ordinary system of medical practice in opposition to *Homœopathy*, which see.

ALLOPHA′NIC ACID. (Gr. *αλλος*, *different*, and *φαινομαι*, *I appear*.) An acid body discovered by Wöhler and Liebig, and formed by passing the vapour of cyanic acid into alcohol: its chemical formula is $C_4\,H_3\,O_5\,N_2$.

ALLO′TROPY. (Gr. *αλλοτροπος*, *of a different character*.) A term used by Berzelius to designate the property belonging to certain substances of exhibiting variable characters at different temperatures, especially as relates to *colour*, *texture*, *solubility*, &c.: thus sulphur is usually yellow and brittle; but if fused at a high temperature, and poured into water, it becomes brown and viscid. The characters of phosphorus may also be remarkably changed by temperature, though its nature, as well as that of sulphur, remains the same.

ALLO′XAN. One of the products of the action of nitric acid on uric acid: it is a colourless crystalline substance, the aqueous solution of which tinges the cuticle purple: its chemical formula is $C_8\,H_4\,O_{10}\,N_2$.

AL′LYLE. (Lat. allium, *garlic*.) A hydro-carbon ($C_6\,H_5$) supposed to constitute the basis of the volatile oil of garlic.

ALTE′RNATE GENERATION. In Physiology, that modification of generation in which the young do not resemble the parent but the grand-parent; so that the successive series of individuals seem to represent two species alternately reproduced. The *salpa*, a floating gelatinous molluscous animal, is an example: it may be found as a solitary individual, pregnant with numer-

ous minute salpæ, of a more simple structure, which continue after birth to be united together in the form of a long chain floating on the sea. In each individual of this chain there is generally developed an egg, from which is hatched a solitary salpa, of the form and organisation of the parent of the chain of aggregate salpæ: thus the species is represented by an alternation of simple and aggregate salpæ. *See* PARTHENOGENESIS.

AMANI'TA MUSCARIA. (*Fly Mushroom.*) One of the most poisonous of the fungi of this country: it renders water in which it is boiled so poisonous that animals are killed by it, whilst the boiled fungus itself is nearly harmless. The liquid procured from it is used as a *fly-poison*, whence the name of the mushroom is derived. It is known by its rich orange-red colour.

AMI'DOGEN. (The generator of *amides.*) A compound of 1 atom of nitrogen and 2 atoms of hydrogen: this compound has not been isolated, but may be traced in combination with other substances, constituting compounds called *amides:* thus *potassiamide* is a compound of the metal potassium with amidogen; and, in reference to the same view, ammonia (which see) is an amide of hydrogen. Amidogen is thus represented by the symbol $N\,H_2$, and ammonia as $= N\,H_2 + H$, or $N\,H_3$.

AMPHIO'XUS. (Gr. *αμφι, both*, and *οξυς, sharp.*) The name of a genus of fishes, so called because the animal is sharp at both ends. It has not, in fact, any proper head, brain, or heart; and is recognised as a vertebrate animal only by its gelatinous dorsal chord, which supports a medullary spinal chord or nervous axis, and gives attachment to segmental partitions.

AMPU'LLA. (Lat.) In Anatomy, that end of each of the three semicircular canals of the internal organ of hearing which is more dilated than the other.

AMY'GDALINE. (Gr. *αμυγδαλον, an almond.*) A crystalline principle contained in the bitter almond, which, under the influence of *emulsine* and water, yields hydrocyanic acid, and the volatile oil of bitter almonds. By the action of certain bases amygdaline yields ammonia, and amygdalic acid. The composition of amygdaline is $C_{40}\,H_{27}\,O_{22}$.

AMY'LE or AMYLENE. (Gr. *αμυλον, starch.*) This term implies in chemistry the hydrocarbon which is the basis of the so-called *Amylic alcohol*, or hydrated oxide of amyle. Amyle contains 10 atoms of carbon and 11 of hydrogen, and is represented, therefore, by the symbol $C_{10}\,H_{11}$. The volatile oil of potatoes, or the *Fousel oil* of the Germans, includes this compound.

ANACA'RDIC ACID. An acrid fatty substance, found in the fruit of the *Anacardium occidentale*, or Cashew nut.

A'NALOGUE. (Gr. *ανα* and *λογος, method.*) In Comparative Anatomy, an organ which resembles another in its functional relations; as the wing of a bird is analogous to the wing of the flying lizard (*Draco volans*) and to the wing of an insect, though it be not in its structural relations the corresponding organ of the body.

ANAMO'RPHOSIS. (Gr.) In Natural History, expresses the change of form which may be traced throughout the species or higher members of a natural group of animals or plants, either in the actual series, or, as they have succeeded each other in the course of time on this planet; which change is usually ascensive, or indicative of a progression towards a higher series of species. It has been conjectured that the succeeding or supplanting species may be actually the species supplanted, but changed, *i. e.* otherwise and commonly more highly developed, but of this there is no proof; and the term "anamorphosis" must be understood as expressive of an *ideal* change, in contradistinction to the real or bodily change observed in the development of the individual, and which is called "metamorphosis."

ANAPO'PHYSIS. (Gr. *ανα, backward; αποφυσις, a process.*) That process of a vertebra which, arising in the dorsal region from above the diapophysis or transverse process, recedes to the side of the centrum, as the vertebræ approach the sacrum, and projects more or less backwards. It usually supports and strengthens the joint of the anterior zygapophysis of the succeeding vertebra. It is well developed in the hare and most rodents.

A'NATASE. (Gr. *ανατασις, extension.*) A mineralogical name of the *oxide of titanium.*

ANCHUSINE. The colouring principle of alkanet root (*Anchusa tinctoria*).

ANEMO'METER. Dr. Lind's Anemometer, described in the DICTIONARY OF SCIENCE, gives the means of determining at any particular instant the force of the wind by its pressure against a column of water directly opposed to it. For meterological purposes it is, however, very important that instruments should be *self-registering*, because the changes proposed to be measured often take place very suddenly, and may therefore escape notice altogether when observations are taken at intervals. The anemometer now generally introduced into the principal observatories was contrived by Mr. Osler of Birmingham, and registers the direction as well as the force of the wind at every successive instant. It is described as follows in the *Report of the President and Council of the Royal Society on the Objects of Scientific Inquiry in Physics and Meteorology*, 1840.

"In this instrument the direction of the wind is obtained by means of the vane attached to the rod, or rather tube, that carries it, and consequently causes the latter to move with itself. At the lower extremity of this tube is a small pinion working in a rack, which slides backwards and forwards as the wind moves the vane; and to this rack a pencil is attached, which marks the direction of the wind on a paper ruled with the cardinal points, and so adjusted as to progress at the rate of one inch per hour by means of a clock; the force is at the same time ascertained by a plate one foot square, placed at right angles to the vane, supported by two light bars running on friction rollers, and communicating with three spiral springs in such a way that the plate cannot be affected by the wind's pressure without instantly acting on the springs, and communicating the quantum of its action by a wire passing down the centre of the tube, to another pencil below, which thus registers its degree of force."

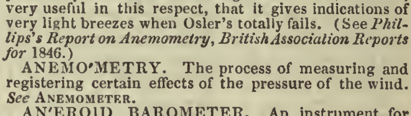
Another self-registering anemometer, proposed by the Rev. Dr. Whewell, is described in the same Report. "In it a small set of windmill vanes, something like the ventilators of windows, are presented to the wind by a common vane, in whatever direction it may blow. The current, as it passes, sets these vanes in rapid motion, and a train of wheels and pinions reduces the motion, which is thence communicated to a pencil traversing vertically, and pressing against an upright cylinder, which forms the support of the instrument: 1000 revolutions of the fly only cause the pencil to descend 1-20th of an inch. The surface of the cylinder is covered with white paper, and the pencil, as the vane wavers, keeps tracing a thick irregular line like the shadings on the coast of a map. The middle of the line may be easily traced, and it gives the mean direction of the wind, while the length of the line is proportional to the velocity of the wind, and the length of time during which it blows in each direction." This instrument consequently records both the direction and integral effect of the wind. Being more complex in its construction than Osler's, it is practically more liable to derangement. It is, however, very useful in this respect, that it gives indications of very light breezes when Osler's totally fails. (See *Phillips's Report on Anemometry, British Association Reports for* 1846.)

ANEMO'METRY. The process of measuring and registering certain effects of the pressure of the wind. *See* ANEMOMETER.

AN'EROID BAROMETER. An instrument for indicating the variations of atmospheric pressure, recently brought into use, and said to be the invention of M. Vidi, of Paris, for whom a patent was taken out in this country by M. Fontainemoreau in 1844.

In the ordinary barometer the pressure of the atmosphere is measured by the height of the column of mercury which it supports; in the aneroid the differences of pressure are measured by the effect produced on a metallic spring, no fluid being employed. Hence the composition of the terms from the Greek *α, without, υγρος, watery*, and *ειδος, form.*

The instrument may be described as consisting of three essential parts: first, an air-tight box or vase formed of thin metallic plates, so that the sides yield to the pressure, and collapse when the air is withdrawn from the interior; secondly, a spiral spring resisting the compression of the sides of the box; and thirdly, a system of levers connected with the box and spring, and giving motion to an index by which the amount of pressure is exhibited on a scale. The arrangement is represented in the annexed diagram, in which A represents the vacuum-vase, B B the main lever, C the fulcrum or support, and S the spring; the direction of the forces being indicated by the arrows. If, at a certain pressure, the lever has the direction indicated in the figure, then, supposing an increase of pressure to take place, the upper side of the box will be pressed downwards, carrying the lever, with which it is shown to be in connexion, along with it, and consequently compressing the spring against which it acts. The lever, it will be observed, is of the second order, and, as usually constructed, the distance of the spring from the fulcrum is to that of the box from the fulcrum in the ratio of six to one.



The box is of a cylindrical form, about $2\frac{3}{4}$ inches in diameter, and 5-16ths of an inch deep, partially exhausted of air, and hermetically sealed. It is composed of thin corrugated copper plates. The spring is formed of steel wire, about 1-20th of an inch in thickness, and the helix or coil is about an inch in height, and 5-8ths of an inch in diameter. A system of levers is employed to multiply the movement of the main lever, and to the ultimate lever is attached a piece of fine watch-chain pressing round a small roller, on the axis of which the index is placed, which exhibits the variations of pressure on a graduated dial. The index is kept in its place, and the chain in a state of tension, by means of a delicate spiral spring attached to the same axis. The whole is placed within a cylindrical box, about five inches in diameter, and the general form of the instrument resembles that of a watch.

The principal difficulty to be overcome, in the construction of the aneroid, is to eliminate the influence of changes of temperature; and the manner in which this is done, or, perhaps it should be said, *attempted* to be done, is sufficiently ingenious. It has been stated above that the air-tight box is only partially exhausted of air; indeed, it would scarcely be possible to effect a perfect vacuum. A small portion, however, is purposely allowed to remain, and elastic fluids, as is well known, expand about 1-480th part of their volume by an increase of temperature corresponding to a degree of Fahrenheit's thermometer. Now the range of temperature in our climate may be considered to be about 50 degrees, and consequently the expansion of unconfined air will vary to more than one-tenth of its volume. But as the capacity of the vase remains sensibly the same (for the small increase arising from expansion of the metal of which the box is formed may be disregarded), the portion of air confined within it cannot vary in volume; its elastic force is therefore increased with the increase of temperature, and the action of this force being in opposition to the external pressure on the sides of the box, the effect on the lever is the same as would be produced by an increase of the elastic force of the spring. But the effect of an increase of temperature on the spring itself is to diminish its elastic force. Hence it is easy to see that, in order to effect a perfect compensation, the parts of the instrument must be so adjusted to each other that, upon an increase of temperature taking place, the loss of elastic force sustained by the spring shall be just equal (allowing for the leverage) to that which is gained by the air confined within the vase, and the lever consequently remain in equilibrio. It is manifest that a perfect adjustment must be attended with great practical difficulty, if indeed it be possible.

From comparisons that have been made, it appears that, within a certain range of barometric pressure (and a variation corresponding to two or three inches of mercury is all that is necessary to provide against), the indications of the aneroid agree sufficiently well (for ordinary purposes) with those of the mercurial barometer, the greatest differences of reading through the ordinary range of the barometer and thermometer having been found, in the case of certain instruments, not to exceed six or seven hundredths of an inch. It possesses great advantages in its small bulk, its portability, and also its extreme sensibility, which is such that the variation of pressure corresponding to an ascent or descent of a few feet is distinctly indicated. On the other hand, it is liable to move by jerks; the spring can hardly be expected to preserve the same elasticity for any considerable time; and it has been found that the zero point has been altered by a journey. For philosophical purposes it can never supersede the mercurial barometer; but there are cases in which it may be used with great advantage: for example, by sailors employed in the coast trade, or the fisheries, as it may be carried even in an open boat.

Though the aneroid has been brought forward as a new invention, Mr. Weld, in a communication to the Athenæum (December 30, 1848), has shown that the principle was developed so long ago as 1798 by M. Conté, who describes an instrument similarly constructed, and resembling a watch in appearance, in the *Bulletin des Sciences Naturelles*, tom. i. No. xiii. p. 106. (See *Dent on the Aneroid Barometer; Frodsham's Few Remarks upon the Construction and Principles of the Aneroid*, &c.; *Belville's Manual of the Barometer; Mechanics' Magazine*, No. 1307.)

A'NGLEME'TER. This name has been specially given to an instrument used by geologists for measuring the dip of strata, the angles of joint-planes, &c. (*British Association Reports*, 1847.)

ANHARMO'NIC RATIO. In Geometry, if four points A, B, C, D, be taken in a straight line in any order, the ratio which is compounded of the ratio of A B to B C and of C D to D A, or (A B : B C) × (C D : D A) has been styled by Chasles *anharmonic ratio*. In the particular case in which this compounded ratio is one of equality, or 1 : 1, we have A B : B C = A D : C D; and when this property holds the line A D is said to be *harmonically* divided in B and C. The term *harmonical* applied in this sense, first occurs, we believe, in Lahire's Conic Sections. The characteristic property of the anharmonic ratio is the following:— If from any point out of the given straight line four straight lines a, b, c, d, be drawn through the four points respectively, and if sin $(a\,b)$ denote the sine of the angle included between a and b (and so with the others), then the double or anharmonic ratio is equal to [sin $(a\,b)$: sin $(b\,c)$] × (A B : B C) × (C D : D A) × [sin $(c\,d)$: sin $(d\,a)$]. These angles being entirely independent of the position of the straight line in which the four points A, B, C, D are taken, it follows that if any straight line whatever be drawn to intersect the four straight lines a, b, c, d respectively in the points A′, B′, C′, D′, then the anharmonic ratio (A′ B′ : B′ C′) × (C′ D′ : D′ A′) will be the same as (A B : B C) × (C D : D A). From this general property some very remarkable relations of geometrical figures have been deduced. (Steiner, *Systematische Entwickelung der Abhangigkeit geometrischer Gestalten von einander;* Berlin, 1832; Chasles, *Aperçu Historique des Méthodes en Géométrie* (*Mémoires de Bruxelles*), 1837.)

A'NILINE. (Anil, the Indigo plant.) A colourless oil-like liquid of a strong odour and hot aromatic flavour, remarkable for its tendency to form crystallisable compounds with the acids, so that it was originally termed *crystalline;* it is a product of the distillation of certain organic substances, and among others it has been derived from *indigo*. It is a compound of carbon, hydrogen, and nitrogen, $= C_{12}\,H_7\,N$.

ANO'RTHOSCOPE. (Gr. ανορθος, and σκοπεω, *I view*.) The name given by M. Plateau, of Brussels, to an instrument invented by him, and intended to produce a peculiar kind of anamorphoses by means of two discs rotating rapidly one before the other, the hind one of which is transparent, and bears distorted figures, while the front one is opaque, and pierced with a small number of narrow slits. As in other toys of a similar kind, the *Phenakistoscope*, for example, the effect depends on the persistence of impressions on the retina. The instrument is described at length in the *London, Edinburgh, and Dublin Philosophical Magazine*, Third Series, No. 245. — June, 1850.

ANTAGONI'STICS. In Anatomy, those muscles are so termed which are opposed to others in their action, as the extensors to the flexors, the pronators to the supinators, the abductors to the adductors, &c.

ANTH'ELIA. (Gr. αντι, *opposite;* ἥλιος, *the sun.*) Luminous coloured rings, or glories, observed under certain conditions round the shadow of the spectator's own head. The conditions of the phenomenon are two; first, that the sun be near the horizon, and secondly, that the shadow be projected on a surface covered with dew drops, as a field of grass or stubble, or on a dense cloud or fog-bank, distant about 50 or 60 yards. Generally the luminous appearance is very faint, and only one or two rings can be traced; but sometimes, in favourable circumstances, it is strikingly vivid, and two or three small concentric circles appear, surrounded by a much larger one, of whitish light, the head of the observer's shadow being at the common centre. Such brilliant Anthelia were observed by Bouguer and his companions on the clouds of the Andes (*Figure de la Terre*, p. 43.), and by Scoresby on the fog-banks in the Arctic seas. Scoresby gives the following dimensions of the rings as measured by him on one occasion: radius of the first or innermost ring 2°; of the second $4^{\circ}\,45'$; of the third $6^{\circ}\,30'$; and of the outermost $38^{\circ}\,50'$. The cause of interior rings is thus explained by Fraunhofer. Light falling directly from the sun on the anterior side of an aqueous globule undergoes a refraction, and a portion of this refracted and consequently coloured light on falling on the interior surface of the opposite side of the globule is reflected back to the eye of the spectator. The large surrounding circle is supposed to be formed by a double reflection, as in the case of the ordinary rainbow. *See* HALO, in DICT.

ANTI'ARINE. The poisonous principle contained in the milky juice of the *Antiaris Toxicaria*, a large forest tree growing in Java. This poison acts upon the brain and spinal marrow, and paralyses the heart.

ANTIGU'GGLER. A siphon, so inserted into casks or carboys as to admit air over the liquor contained in them, and to allow of its being poured out without agitation.

A'NTIPERISTA'LTIC. (Gr. αντι, and περιστελλω, *I wrap up.*) That movement of the intestinal tube which is retrograde or contrary to the proper course impressed upon the contents by the ordinary vermicular or peristaltic action.

A'PIINE. A gelatinous substance (distinguished by affording a blood-red colour with solution of sulphate of iron), obtained from parsley (*Apium petroselinum*).

APLANA'TIC LENS. (Gr. α, *without;* πλανη, *de-*

viation.) In Optics, a lens such that rays parallel to its axis, or rays diverging from a point in its axis, after passing through it and suffering refraction at its surfaces, converge to a single point, or the true focus. In order, therefore, to be aplanatic, the lens must not only have the true geometrical figure necessary to destroy aberration, but must also be constructed of different media, so as correct the effects of the unequal refrangibility of the different rays, that is to say, it must be achromatic. Neither of these conditions can be accurately fulfilled in practice; the object aimed at is therefore to give the lens such a form that, with a given index of refraction, the aberration shall be the least possible. *See* ABERRATION, ACHROMATISM, in DICT.

APOPHY'LLITE. (Gr. ἀπο, and φυλλον, a leaf: from its lamellar structure). In Mineralogy, a lamellar zeolite.

A'POTHEME. (Gr. ἀποτιθημι, I deposit.) A term applied by the old chemists to some of the varieties of *extractive matter*.

A'QUA VITÆ. (in Fr. *Eau de vie*.) The name absurdly given to brandy and other intoxicating liquors.

AQUÆDU'CTUS. In Anatomy, the term is applied to certain canals leading from the labyrinth or internal ear to the outside of its bony capsule or os petrosum: one of these, which extends from the hinder part of the vestibule to the posterior margin of the petrosal, is called "aquæductus vestibuli;" a second canal leading from the cochlea to the jugular fossa of the petrosal is called "aquæductus cochleaæ:" the function of the "aqueducts" is unknown.

A'QUEOUS HUMOUR. A thin watery fluid holding in solution a small quantity of chloride of sodium and extractive matter, situated in a space behind the cornea of the eye-ball, which is divided into an anterior and posterior chamber by a musculo-membranous partition called "iris," perforated by the aperture called "pupil:" the chief use of the aqueous humour is to maintain the convexity of the cornea and support and facilitate the movements of the iris.

ARCH. In Anatomy, a structure commonly composed of bone or other hard material disposed in a bow-like form, and constituting the chief part of the primary segment of the skeleton: that which rests upon the body of the vertebra (projects backward in man), and spans across the neural axis or trunk of the nervous system, is called the "neural arch;" that which is suspended in an inverted position (extends forward in man), and incloses the hæmal axis (heart and vascular trunks), is called the "hæmal arch." Those in the segments composing the head are called, with their surrounding soft parts in the embryo, "visceral arches." Curved portions of the great arterial and intestinal tubes are called "arches," as the "arch of the aorta," the "arch of the colon."

A'RCHETYPE. (Gr. ἀρχη, *beginning*, and τυπος, *a type*.) In Anatomy, is that ideal original or fundamental pattern on which a natural group of animals or system of organs has been constructed, and to modifications of which the various forms of such animals or organs may be referred. The archetypal figure has been most clearly recognised in the study of the modifications of the skeleton of the vertebrate animals.

A'RCOGRAPH. (Lat. arcus, *a bow; γραφω, I write.*) A drawing instrument for describing arcs of circles, or other curves, without centres.

ARDENT SPIRIT. *See* ALCOHOL.

A'REA. (Lat.) In Embryology, certain definite spaces which successively arise in the germinal membrane are so called: thus the opaque spot produced by an accumulation of cells and cell-nuclei is called "area germinativa," or germinal area; the clear space which subsequently appears in its centre is called "area pellucida;" and the outer part of this space, where the blood-vessels are first formed, is called "area vasculosa."

A'REOLAR TISSUE. In Anatomy, a term synonymous with CELLULAR TISSUE, which see.

ARGAND LAMP. The application of a circular wick to oil lamps, so contrived as to allow of a current of air both inside and outside, was originally patented by a person of the name of Argand: the contrivance constitutes an important epoch in the history of the improvement of lamps; by it the amount of light derivable from a given quantity of oil was enormously increased. The same principle is also applied to gas burners. *See* LAMP.

A'RMATURE. A piece of soft iron applied to a loadstone, or connecting the poles of a horse-shoe magnet.

A'RNICINE. A bitter principle contained in the flowers of the *Arnica montana*.

A'RRAGONITE. A peculiar variety of carbonate of lime originally found in Arragon in Spain: it is harder than the common variety, and is prismatic instead of rhomboidal. Some specimens contain about 3 per cent. of carbonate of strontia.

ARTE'SIAN WELLS. Numerous works of this kind have been executed of late years. One of the most remarkable of them is that of Grenelle, a suburb at the south-west of Paris, where there was formerly a great scarcity of water. The strata which were penetrated were, 1. the tertiary strata above the chalk; 2. chalk; 3. green sand and clay; 4. oolite or Jura limestone. The sheet of water flows in a stratum of gravel under the limestone. On account of the great depth of the boring the work was attended with much difficulty, and retarded by various accidents. At length, in February, 1841, after eight years of exertion, the engineer (M. Mulot) had the satisfaction of seeing the water he was in search of burst forth from a depth of about 600 English yards, and the jet yielded no less than 4,000,000 litres, or in round numbers 880,000 imperial gallons in the 24 hours. The temperature is 81° of Fahrenheit, corresponding to an increase of 1° for each 20·4 yards of descent. The bore is protected by a metal tube divided into four unequal lengths, and successively decreasing in diameter. The dimensions are as follows: — From the surface of the ground to the commencement of the first tube, 2·5 yards; length of first tube, 162 yards; of second tube, 227 yards; of third, 75 yards; of fourth, 124 yards; from extremity of last tube to bottom of bore, 7·5 yards; total, 598 yards. The diameter of the first or highest tube is about a foot, and of the lowest about six inches, English. The expense was about 12,000*l.* sterling. For a description of the boring apparatus, and methods of conducting such works usually followed in this country, see Ure's *Dictionary of Arts, Manufactures, and Mines;* and for details respecting some Artesian wells in England, the *Reports of the British Association.*

ASAFŒTIDA. *See* ASSAFŒTIDA.

A'SBOLINE. (Gr. ἀσβολη, *soot.*) A resinous pitchy matter obtained from wood-soot.

ASSOCIATION. In Physiology, a name given to that combination of motions which arises from the voluntary impulse to one motion exciting other motions contrary to or independently of the will; as, for example, whenever the eye is voluntarily turned inwards the iris contracts: these are termed associate or consensual movements.

ASTA'TIC NEEDLE. A term applied to the magnetic needle when it is withdrawn from the action of the earth's magnetism, and has no longer the *statical* position in which it is in equilibrio with the influence of this force. A needle is rendered astatic by placing the axis about which it is moveable in the direction in which terrestrial magnetism acts, because it cannot then receive any motion from this force, and will rest in any position. The same effect will be accomplished by neutralising the action of the earth by means of an equal and opposite magnetic action. (*Brewster's Treatise on Magnetism.*)

ASTI'GMATISM. (Gr. α, *without;* στιγμα, *a mark.*) In Optics, the name given to a peculiar defect in the eye, which consists in its refracting the rays of light differently in different planes. The defect may be detected by looking at a small pin-hole in a card, held up against the sky or any bright object, and moved to different distances from the eye. In the case of ordinary eyes the image of the hole remains circular at all distances, but to an eye having the peculiar defect in question the image of the hole, as the card is moved away from the eye, becomes elongated in a particular direction, and at a certain distance passes into a straight line. On moving the card still farther from the eye it becomes elongated in a direction perpendicular to the former, and again at a certain distance (the second limit of distinct vision) it passes into a straight line. This imperfection may be corrected by means of a cylindrical, or spherico-cylindrical, lens, the distances of the card from the eye when the two focal lines are formed, giving the means of calculating the required curvature of the cylindrical surface. (See *Transactions of the Cambridge Philosophical Society for* 1829, *Reports of the British Association for* 1849.)

ASTRÆ'A. One of the recently discovered small planets circulating between the orbits of Mars and Jupiter. Astræa was discovered on the 8th of December, 1845, by Hencke of Driessen, in Prussia, who had for several years previously been engaged in astronomical observations directed to the discovery of such a body. The announcement of his success excited great interest among astronomers, no other addition having been made to the planetary system since the discovery of Vesta by Olbers in 1807; but nine others belonging to the same group have since been added to the number. Astræa appears as a small star of the ninth magnitude. Its mean distance from the sun is 2·577 times that of the earth, and it completes its revolution in 1511·095 mean solar days. Unlike the four others previously discovered in the same region, the inclination of its orbit was found to be only 5° 19′ 22·7″, which is less than the inclination of Mercury, and consequently the term *ultra-zodiacal* is no longer applicable to the whole group. This distinction also belongs to three of the others since detected, viz. Flora, Iris, and Metis. Hebe, also

discovered by Hencke, has an inclination of nearly 15°. *See* PLANET.

ASTRO'METER (Gr. *αστρον, a star; μετρον, measure*), the name given by Sir John Herschel to an instrument invented and employed by him for comparing the intensities of light of the stars one with another by the intervention of the moon, or the planet Jupiter, or some other *natural* standard, no invariable standard of artificial light having yet been discovered. It is necessary that the intermediate standard of comparison be brighter than any of the stars to be compared, so as to allow of being equalised with them by a reduction of its light optically effected, and at the same time either invariable, or at least variable in such a manner that its changes can be calculated and reduced to numerical estimation. Jupiter being brighter than any of the stars, subject to no phases, and variable in its light only by the variation of its distance from the sun, may be considered as best fulfilling all the conditions. "The process," says Sir John, "consists in deflecting the light of the moon by total internal reflexion at the base of a prism, so as to emerge in a direction exactly coincident with that of the undeflected light of one of the stars to be compared. It is then received upon a lens of short focus, by which the image of the moon is formed, which, viewed at a considerable distance by an observer placed in or near the axis of the lens, will appear to him as a star. This artificial star is then to be approached to or removed from the eye until its light is judged to be exactly equal to that of the real star, which, lying in nearly the same direction from the observer, will be seen side by side with the artificial one by the same eye, or with both eyes at once, without the aid of a telescope, in the ordinary mode of natural vision. The distance of the eye from the focus of the lens being then measured, the prism and lens are to be placed so as to form another similar artificial star in a direction nearly coincident with that of the other star under comparison; and another equalisation being made and distance measured, it is obvious that the intensities of the lights of the two stars, or at least their effects on the retina under the circumstances of comparison, will be to each other in the inverse ratio of the distances so measured respectively." (*Results of Astronomical Observations*, &c., p. 353; also *Outlines of Astronomy*, Art. 783.)

Sir John remarks that the use of a prism to deflect the light of a standard luminary by total reflexion at its base, is common to the astrometer described by him and an instrument which had been previously described by Steinheil in a paper printed in the Memoirs of the Göttingen Academy in 1836, though he had no knowledge of the existence of Steinheil's memoir until his return to Europe from the Cape (where he had used the astrometer) in 1838.

It may be noticed that the name *Astrometer* was given by Bouguer to the Heliometer, or object-glass micrometer. It was also given by Jeaurat to an instrument for finding the rising and setting of the stars and their position, which he has described in the *Memoirs* of the Academy of Sciences of Paris. An improved instrument for the same purpose is described in the *Edinburgh Encyclopædia*, art. SCIENCE.

ASTRO'NOMY. During the few years that have elapsed since the publication of the DICTIONARY, the progress of this science has been very remarkable. A brief outline of the principal discoveries and improvements which have been made in it in the decade 1840—1850 is, therefore, necessary, in order to bring down its history to the present date.

Among the recent discoveries in astronomy, the most prominent, and in certain respects the most remarkable ever made in the science, is that of the new planet, to which the name of Neptune has been given, beyond the orbit of Uranus. In all previous instances of the discovery of a new planet, the discovery was accidental, in so far as the existence of the body was not foreknown, or even suspected, until its true nature became revealed by the observation of its relative motion. In the present case, not only had the existence of the planet been made known through the effects of its attraction, but the precise spot which it occupied in the heavens had been indicated by the results of a profound theoretical investigation, and the planet was immediately recognised on directing a telescope upon the spot so indicated. The researches which led to this notable result were directed by the following considerations.

For several years it had been remarked that the motions of the planet Uranus were not in accordance with theory. On comparing the observations with the tables of Bouvard, it appeared that the true longitudes of Uranus began to be in advance of the computed longitudes from about the year 1795, and more notably from 1804, the difference continuing gradually to increase till about 1822, when the excess attained its maximum. After that year the difference began to diminish rapidly, and in 1830 the tabular and true longitudes agreed. But the planet still continued to fall behind, as if hindered or retarded by some opposing force. The attractions of the other known planets afforded no explanation of these irregularities; and in searching for a cause, the idea of disturbance from a more remote planet did not fail to present itself, and in fact afforded the only probable explanation of the phenomena. It was no easy matter, however, to test this hypothesis; for, unless the place of the supposed planet could be assigned within moderate limits, so as to direct the observations, any attempt to find it must be undertaken at random, and insufficient to prove its non-existence as a visible object. The problem, therefore, which presented itself for solution (and it had never before occurred in physical astronomy) was this: Given the disturbances to find the orbit and the place in that orbit of the disturbing planet. By a singular coincidence, though not without example in the history of discovery, the problem was undertaken about the same time by two distinguished mathematicians, Mr. Adams in England, and M. Leverrier in France, neither having the slightest knowledge of the other's attempt; and both arrived at a correct conclusion. Mr. Adams's results, however, though communicated to two or three astronomers, were not published or generally known until some time after the actual discovery of the planet, and, as it happened, did not contribute in any way to that discovery. Those of M. Leverrier were given to the Academy of Sciences at Paris, and published in the *Comptes Rendus*; and by their means the planet was found by Dr. Galle, of Berlin, on the very day on which his attention was directed to them, within less than a degree of its predicted place. This memorable discovery took place on the 23rd of September, 1846, and was hailed by every astronomer of Europe as the most signal triumph of theory which had ever been achieved.

Soon after the planet had been found and regularly observed, it was perceived that, notwithstanding the agreement between its actual and predicted position, the elements of its orbit differed very considerably from those which had been assigned by the two mathematicians. In order to render the computations possible, it had been necessary to assume a certain mean distance of the hypothetical planet from the sun; and both M. Leverrier and Mr. Adams had assumed, as a first approximation, the law of Bode (*see* PLANET), which, though purely empirical, had a great probability in its favour, in consequence of its being observed to hold good in the case of the other planets. According to this law, the mean distance of the planet from the sun should be double that of Uranus, or 38·34 radii of the earth's orbit, in which case the periodic time would be 237·4 years. M. Leverrier had concluded the distance to be 36·15, and Mr. Adams 37·25, radii of the terrestrial orbit; the former corresponding to a period of 217·4 years, and the latter to one of 227·3 years. On computing the real orbit from the observed motions of the planet, the mean distance was found to be only 30·036 radii, and the period 164·6 years, differing widely from both predictions, and still more from the law of Bode, which fails entirely in this single instance. On considering all the circumstances of the case, the disagreement between the elements of the real and theoretical planet will not appear in any way remarkable; the latter, in fact, representing the perturbations which were to be accounted for with all the accuracy that could possibly be expected in such a research.

Neptune is attended by at least one satellite, probably two, and is suspected to resemble Saturn, in having also a ring. Its position in the ecliptic, since the date of its discovery, has been unfavourable to its being distinctly seen.

The next most remarkable feature in the recent progress of astronomy is the discovery of six new planets belonging to the group which circulate between the orbits of Mars and Jupiter. It has been stated, under the term PLANET, that the first of these small bodies, or asteroids, as they have been called, was discovered by Piazzi, at Naples, on the first day of the present century; and the discovery was regarded with great interest by the astronomers of that time, more especially as it had been surmised that a planet probably existed whose orbit, lying between those of Mars and Jupiter, would preserve the continuity of Bode's law of the distances; and the orbit of the new planet was found to be in conformity with that law. The discovery of a second, in the following year, was entirely unexpected, but it led to a more careful observation of the small stars in and near the zodiac than had previously been attempted, in the hope of detecting others. The result was the discovery of a third, in 1804, and of a fourth in 1807; but for nearly forty years the number was not increased. About the end of 1845, however, a fifth, belonging to the same group, was discovered by M. Hencke, of Driessen, in Prussia, and since that time ten more have been found, so that at the present time (January, 1852) no fewer than fifteen small bodies are known, all circulating at nearly the same mean distance from the sun, and consequently

in nearly the same period of time. Their names, with those of their discoverers, and the dates of their respective discoveries, are as under: —

Ceres,	discovered by	Piazzi	1801, Jan. 1.
Pallas	-	Olbers	1802, March 28.
Juno	-	Harding	1804, Sept. 2.
Vesta	-	Olbers	1807, March 29.
Astræa	-	Hencke	1845, Dec. 8.
Hebe	-	Hencke	1847, July 1.
Iris	-	Hind	1847, August 13.
Flora	-	Hind	1847, Oct. 18.
Metis	-	Graham	1848, April 25.
Hygeia	-	De Gasparis	1849, April 12.
Parthenope	-	De Gasparis	1850, May 11.
Victoria	-	Hind	1850, Sept. 13.
Egeria	-	De Gasparis	1850, Nov. 2.
Irene	-	Hind	1851, May 19.
Eunomia	-	De Gasparis	1851, July 29.

In reference to the eleven recently discovered planets it is proper to remark, that although none of them was previously known to exist, their discovery was in every instance the result of a "careful and minute examination and mapping down of the smaller stars in and near the zodiac, undertaken with that express object." The singular circumstance of so many planets moving in orbits of nearly the same dimensions, and all so insignificant (in comparison of the other planets) in size, gives considerable probability to the hypothesis proposed by Olbers on the discovery of Pallas, that a large planet originally occupied that region of space, and was shattered into fragments by an internal convulsion. But the hypothesis of Laplace, that they have their origin in a ring or zone of nebulous matter, thrown off from the sun's atmosphere in the gradual process of cooling, and broken up into small masses, no one being of sufficient magnitude to attract the others to its centre (as has happened in the case of all the other planets), will equally account for the phenomena. But whatever hypothesis may be formed respecting their origin, the number of them already known makes it extremely probable that many more exist, though by reason of their excessive smallness they may long, or for ever, elude observation. Those already known appear in the telescope as stars of the ninth or tenth magnitude, but such is their minuteness, that it is impossible, with the existing means of observation, to measure their apparent diameters, and thence to deduce their real dimensions, with any degree of accuracy.

Another recent discovery, affording evidence at the same time both of the excellence of the instrumental means now applied to astronomy and of the attention bestowed on the careful and accurate examination of the heavens, is that of an eighth satellite of Saturn; and it is not a little remarkable that the discovery was made both in England and America at the same time — even on the same day. In England the body was first observed by Mr. Lassell, of Liverpool, with a two-foot reflecting telescope, on the 18th of September, 1848, and taken for a faint star. On the 19th it seemed to have changed its place, following the motion of Saturn, and was accordingly suspected to be a satellite; and on the 21st, when it was next observed, its true nature was satisfactorily made out. The same object was observed in America by Mr. G. P. Bond at the Cambridge Observatory, Massachusetts, on the 16th of September, and then supposed to be a small star. On the 18th it was again noticed, but still without suspicion of its nature. On the 19th it was suspected to be in motion, and its position was therefore accurately determined. On the 20th it could not be seen, but on the 21st it was proved by its relative motion to be an attendant of Saturn The new satellite is very faint, and can only be seen in a powerful telescope. Reckoning from the outermost satellite inwards towards the planet, it is the second in the order of distance.

Cometary Astronomy has also been cultivated of late years with great assiduity, and in a manner which promises to lead to important results. Formerly the computation of an orbit was a task which not many observers were competent to undertake. At present the methods of performing such computations are far more generally known; and, indeed, no sooner does a comet make its appearance than elements of its orbit proceed from many quarters with a sort of rivalry. The first approximate calculations are carefully corrected by means of subsequent observations till the path of the body is determined with great accuracy, and in this manner the means are prepared of identifying it if it should make its appearance at any future time. Only a small number have yet been satisfactorily proved to move in elliptic orbits, and consequently to return at definite intervals; by far the greater numbers move in orbits which cannot be distinguished from parabolas, and after passing their perihelia shoot off to indefinite distances, and may possibly enter within the sphere of attraction of other systems. Their physical constitution still remains a profound mystery. One of the most remarkable on record appeared in 1843. It was visible within four degrees of the sun and in full day. No other comet has been known to approach so near to the sun. At the perihelion its distance from the luminous surface of the sun was computed to be less than a seventh part of the sun's radius, and the whole segment of its orbit cut off by the plane of the ecliptic was passed through in the short space of two hours, its actual velocity being then no less than 366 miles per second. It has been supposed to be identical with a comet which appeared in 1668.

In sidereal astronomy, a great accession to our knowledge has been recently made through the publication of the results of Sir John F. W. Herschel's observations at the Cape of Good Hope. This distinguished astronomer, after devoting some years to the examination and description of the nebulæ and double stars in the northern hemisphere, with the view of completing the work begun by his father Sir William Herschel (who may be regarded as the founder of this interesting branch of astronomy), conceived the idea of extending his survey to the southern hemisphere, in order to place on record a description of the principal nebulæ and double stars over the whole heavens, as observed with the same telescope and by the same observer, whereby the astronomers of future time would be enabled to detect changes in their physical appearances or relative positions, should any such take place. For this purpose he removed his Observatory to the Cape of Good Hope, where he passed four years (1834—1838), assiduously employed in carrying out the objects of his great undertaking; and after completing the still more laborious task of reducing his observations, the results were given to the world in 1847. Though the main purpose of his voyage was the observation of nebulæ and double stars, of which objects he has given reduced catalogues, accompanied with minute description and interesting remarks; the work also embraces a great variety of observations and disquisitions on other matters connected with astronomy, — the constitution of the galaxy, the Magellanic clouds, Halley's comet, the satellites of Saturn, the solar spots, &c. It is right to add, that this noble enterprise, which has conferred so much honour on his country, and been productive of so much benefit to astronomy, was undertaken and carried through by Sir John Herschel at his own private charges. He held no public appointment, and received no public assistance; and for the means of rendering his labours available to astronomers by the publication of the results, he professes his obligations to the Duke of Northumberland.

Among the circumstances which have most contributed to the general advance of astronomy in late years, one is the increased dimensions now given to telescopes, in consequence of which the objects of observation are not only greatly multiplied, but the observations are made with far greater distinctness and precision. Refracting object-glasses, of a foot or upwards in diameter, can now scarcely be considered as rare. But greatly exceeding these in optical power is the reflecting telescope made and erected by the Earl of Rosse, at his lordship's seat, in Ireland. The mirror of this gigantic instrument is six feet in diameter, and weighs about four tons. For a short account of the ingenious contrivances and apparatus made use of for the casting, grinding, polishing, and placing in its position this enormous mass of metal, we would refer to article *Telescope*, in this Supplement; they are all due to Lord Rosse himself, and could only have been produced by the combined exercise of extraordinary ingenuity, patience, and mechanical skill. Nor has the performance of the instrument disappointed the expectations that were formed of it. Nebulæ which, in other telescopes, gave no indication of resolvability, are by this easily resolved into stars; and in fact it already seems probable that it will be the means of upsetting the whole nebular theory. The appearance of some of the nebulæ or clusters in this telescope is extremely remarkable. Some are observed of a spiral form, perfectly regular; others exhibit streaks, sometimes straight, and sometimes curved; and generally they give evidence of systematic arrangement. Telescopes on the same principle have also been brought to great perfection by Mr. Lassell, and though of far inferior dimensions to those of Lord Rosse, have already rendered good service to astronomy in the discovery of a satellite of Neptune, two new satellites of Saturn, and two of Uranus.

Concurrently with the increase of optical powers, the art of observing, and the science of reducing the observations, have undergone corresponding improvements. The probable errors are consequently now confined within much narrower limits, and the consequence is, that astronomers are enabled to recognise and measure minute changes in the places of stars which formerly eluded observation. It is to this extreme practical accuracy that we are indebted for the present perfection of the planetary theories, and that astronomers look for the solution of many problems still beyond their reach; such

as the parallaxes and proper motions of the stars, and their systematic connexion with one another and with our own sun. Already the point in the heavens towards which the sun, with all his planets, appears to be moving, has been indicated with considerable probability; and a German astronomer (Mädler) has ventured to assign a star in the Pleiades as the centre about which not only the sun, but the whole stratum of stars among which it is placed, is revolving.

The measurement of two additional arcs of the terrestrial meridian in India by Colonel Everest, under the auspices of the East India Company, is a work of sufficient importance, in an astronomical point of view, to deserve notice in this rapid retrospect. Under the term *Degree of Latitude*, in the *Dictionary*, a short reference has been made to the principal geodetical operations for determining the magnitude and form of our globe,— an element of great importance in physical astronomy, and by which the magnitudes of all the planets are estimated, — and among these operations some which had been effected in India occupied a prominent place. With instruments of a much superior kind to any which had previously been used in that country, and with all the appliances of modern science, Colonel Everest has added two arcs of meridian to the former measurements, one of 6° 3′ 56″, and the other of 5° 23′ 37″; which, taken in connexion with Lambton's operations, gives a continuous meridianal arc of 21° 21′ 13″, extending from Cape Comorin to the foot of the Himalayas. The details of the measurement were published in 1847. It may also be noticed, that the trigonometrical measurement of the British arc, of 10° 7′ 55″, from Dunnose, in the Isle of Wight, to Balta, in Shetland, is understood to be completed, and, it may be hoped, the details will shortly be given to the public. For the purpose of verification, a new base was measured in 1849, on Salisbury Plain, with the same apparatus as was used in measuring the Irish base; and it may be presumed, that all the distances will be given in terms of this new measurement, the results being much more trustworthy than those which were obtained by the older methods. Another interesting operation of the same kind, extending to about 4½°, and including a repetition of Lacaille's arc, has been completed at the Cape of Good Hope, but the results are not yet published.

Physical astronomy has now been carried to a state of such perfection, and the disturbing forces resulting from the reciprocal attractions of the different planets on each other so completely represented by mathematical formulæ, that the improvements which remain to be made must consist chiefly in giving greater accuracy to the numerical coefficients, which depend on data furnished by observation. For this purpose, the most important work which has been executed in recent times is the reduction of the planetary and lunar observations made at Greenwich, from 1750 to 1830, under the superintendence of the Astronomer Royal; a work of immense labour and utility, which puts the theoretical astronomer in possession of the results, in their most available shape, for perfecting the elements of the solar system, by means of the longest, and probably the most accurate, series of continuous observations which the world can furnish.

ATA′CAMITE. The native muriate of copper of the desert of Atacama in South America.

ATHAMA′NTINE. A crystallisable substance contained in the root of the *Athamanta oreoselinum*.

ATHA′NOR. A term applied by the alchemists to a furnace so constructed as to supply itself with fuel.

ATHE′RMANOUS. (Gr. α, *priv.* and θερμος, *heat.*) Transparent or translucent substances which resist the passage of radiant heat.

ATMOSPHE′RIC TIDES. Diurnal oscillations of the atmosphere, produced by the attractions of the sun and moon, and similar to the tides of the ocean. The attractions of the sun and moon tend continually to cause a variation in the figure of the atmosphere relatively to the meridian of any place, and consequently to produce a change in the amount of barometric pressure; but the change is so small in comparison to those produced by many of the other causes which disturb the equilibrium of the atmosphere, that a long series of accurate observations is necessary to render it sensible, even within the tropics where the influence of solar and lunar attraction is greatest, and the other causes of atmospheric disturbance act with least effect. In the *Philosophical Transactions* for 1847, Colonel Sabine gives an account of a series of observations of the barometer made at St. Helena, *hourly*, during a period of three years, for the purpose of determining the moon's influence. The result of the first year's observations, which were reduced at St. Helena, showed an average excess of barometric pressure of ·0014 parts of an inch at the hour when the moon is on the meridian (above or below the pole), and an average defect of ·00115 when six hours distant from the meridian, making together an average difference of ·00255 in. when the moon is on the meridian, and when 90° from it. The observations of the other two years were reduced at Woolwich, under the superintendence of Colonel Sabine, and the result was still more decided, the average difference exceeding ·00365 in., or nearly four-thousandths of an inch. These differences are, no doubt, exceedingly minute; but as the observations were made with great care, and on being broken up into periods of six months were still found to give consistent results, it may be reasonably presumed that they represent with considerable accuracy the amount of the lunar influence on the atmosphere. The effect of the sun's attraction being not only much smaller than that of the moon, but also masked in the diurnal barometric oscillation by the much greater and variable influence of the solar heat, probably cannot be satisfactorily determined.

ATOLL, or LAGOON ISLAND. In Physical Geography, the name given to a particular kind of coral island. The Atoll consists of a chaplet or ring of coral, enclosing a lagoon or portion of the ocean in its centre. The average breadth of the part of the ring which rises above the surface of the sea is nearly a quarter of a mile, and it seldom rises higher than from six to ten or twelve feet above the surface. On the outer side the ring gradually shelves down to the distance of 100 or 200 yards from its edge, so that the sea deepens to about 25 fathoms, beyond which the sides plunge almost perpendicularly into the unfathomable depths of the ocean. On the lagoon side, where the water is calm, the bounding ring or reef shelves into it by a succession of ledges, also of living coral, but of a different species from those which build the exterior wall, and the foundation of the whole ring. The size varies from two to ninety miles in diameter. The lagoon islands are widely spread, but chiefly in the Pacific Ocean. Most frequently they occur in elongated archipelagos, extending in groups over a large surface; the Carolina Islands, for example, extend to 1000 miles. Sometimes the lagoons have islands within them: Otaheite, the largest of the Society group, is a remarkable instance of this formation. The lagoon which encompasses it is thirty fathoms deep, and hemmed in from the ocean by a coral band of the usual kind, at a distance varying from half a mile to three miles. (*Somerville's Physical Geography*.)

AU′GITE. (Gr. αυγη, *splendor*.) A crystalline mineral common in volcanic and basaltic rocks. It is the *pyroxene* of Hauy.

AU′RIC ACID. (Lat. aurum, *gold*.) A term now frequently applied by chemists to the *peroxide of gold*.

AU′RIPIGME′NTUM. (Lat.) Yellow sulphuret of arsenic.

AU′ROCYA′NIDES. Compounds of the cyanide of gold with basic oxides. The aurocyanide of potassium is used in the art of electro-gilding.

AUTO′MALITE. (Gr. αυτομαλος, *a deserter*.) Named from the presence of zinc in a mineral not resembling a metallic ore.) A crystalline mineral consisting chiefly of oxide of zinc and alumina. It is the zinc-spinelle of some mineralogists.

AUTOMA′TIC. In Physiology, applied to those muscular actions which are not dependent on the will or other act of the mind: such are the successive contractions of the hollow viscera of organic life, *e. g.* the heart, the intestines, the ureters, urinary bladder, the uterus; the involuntary movements of respiration; the motions of the muscles of the eye during sleep; the persistent contraction of the sphincters.

AVA′NTURINE. (Deriv. unknown.) A beautifully iridescent variety of rock crystal.

AXIS-CYLINDER. In Anatomy, the name applied to the central substance of the primitive nerve-fibre.

A′ZOLI′TMINE. A dark red substance forming a great part of the colouring material of litmus: its chemical formula is, according to Kane, $C_{18} H_{10} O_8 N$.

AZOTI′SED PRINCIPLES. (Gr. α, *without*, and ζωη, *life*.) In Anatomy, the two chief classes of substances of animal bodies, — viz. the gelatinous and albuminous. In Chemistry, the term is chiefly applied to substances containing nitrogen, and used as aliments: many of them are common to animals and vegetables.

B.

BA′BLAH. An astringent dye-stuff imported from the East Indies and from Senegal: it has been used for dyeing drabs, as a substitute for more expensive materials. It is the shell of the fruit of the *Mimosa cineraria*.

BACK. A reservoir or cistern. The *liquor back* in a brewery is the water reservoir.

BAGA′SSE. (Fr.) The sugar-cane in its dry crushed state, as used for fuel in the colonial sugar-houses.

BALEE′N. (Fr. baleine.) The term in common use among whale fishers for whalebone.

BALSA. (Spanish.) A species of float or raft, chiefly used on the coasts of South America, for landing goods

through a heavy surf. The balsa is formed of two seal skins sewed up so as to form two large bags, which are covered with pitch to render them perfectly air-tight, and secured by ligatures. The bags or bladders thus prepared are inflated with air passed through a flexible tube, which is left of sufficient length to reach the mouth of the conductor, who is thus enabled to replenish them with air, should any have escaped. The two bags are fastened together at one end, which forms the prow of the vessel, the other ends being kept about four feet apart by means of a small plank; and the raft is completed with small sticks covered over with matting, having thus the shape of a wedge or triangle. It is propelled by a double-bladed paddle, and the conductor, on approaching the shore, contrives to keep the balsa on the top of the highest wave till it is thrown on the beach to the greatest extent the surf reaches, where it is immediately secured. The balsa will carry three passengers besides the person who conducts it, and by this means cargoes are landed from merchant vessels where the violence of the surf prevents ordinary boats from passing through it without great danger. Floats of a still ruder kind, usually formed of the hides of bullocks simply stretched on a frame, are used for crossing rivers in South America, and go by the name of balsa. (*Penny Magazine*, vol. iii. p. 150.)

BANDA'NNA. A style of calico-printing in which white spots are produced upon a red ground. The term is of Indian origin, and the art has been extensively adopted and improved upon in this country. (See a detailed account of Messrs. Monteith's manufactory at Glasgow, in Brande's *Quarterly Journal of Science and the Arts*, June, 1823, and in Ure's *Dictionary of Arts*, &c.)

BARBA'DOES NUTS. The fruit of the *Jatropha Curcas*, a native of South America and Asia. They are sometimes called *physic nuts*, and are virulently purgative.

BARBA'DOES TAR. Petroleum. A bituminous liquid of the consistence of tar: it oozes from the soil along with water, from which it is skimmed off and preserved in earthen jars. By distillation it yields *naphtha*. It is used in medicine as an internal remedy in certain chronic pulmonary affections, in obstinate diseases of the skin, and against tape-worm. As an external agent it is sometimes applied to ill-conditioned ulcers, and to chilblains. These stimulating bituminous oils have been recommended as effectual in cholera: the dose is from 30 drops upwards.

BARM. The yeast which collects upon the surface of fermenting beer. The term is of Welsh origin.

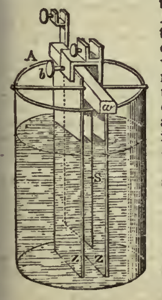
BA'ROSE'LENITE. A mineralogical name applied to *sulphate of baryta*, or heavy spar.

BASTARD SUGAR. *Bastards* is a term applied by the sugar refiners to an impure sugar chiefly produced by the action of heat and various substances used in the refining, and which cannot be remuneratively purified. They are also called *pieces*.

BAT'TERY, ELECTRICAL. A series of Leyden jars so arranged that they may all be discharged at once. *See* ELECTRICITY, in DICT.

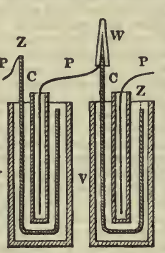
BATTERY, GALVANIC. Several forms of this apparatus have already been described (*see* VOLTAIC ELECTRICITY); many others have lately been invented, two of which, namely, SMEE'S BATTERY, and GROVE'S BATTERY, deserve particular notice. In Smee's battery, of which a detailed description will be found in his *Elements of Electro-metallurgy*, the positive or generating plates are composed of amalgamated zinc, and the negative plates of platinised silver, which, on account of its rough surface, favours the escape of the hydrogen gas evolved upon it, the adhesion of which to platinum or silver in their ordinary state is a serious impediment to the action of the battery.

One form of Smee's battery "consists of a piece of silver S, on the top of which is fixed a beam of wood *w* to prevent contact with the silver. A binding screw is soldered on to the silver to connect it to any required object. A strip of zinc Z, varying, at the fancy of the operator, from one half to the entire width of the silver, is placed on each side of the wood, and both are held in their place by a binding-screw *b*, sufficiently wide to embrace the zincs and wood. These batteries vary from the size of a tumbler to a ten or twelve gallon vessel."



A single cell of this battery is represented in the annexed cut. A is an earthenware or glass vessel containing dilute sulphuric acid (composed of 1 part of oil of vitriol to 6 or 7 of water). *w* is a bar of wood to which the platinum, or platinised silver plate is attached. Z Z are two plates of amalgamated zinc, connected and secured to the bar by a binding screw; and a separate binding screw is soldered to the platinised plate; these are for the convenience of making connections by wires. When a series of these cells are required they are connected together in the usual way.

Grove's battery, called also *the nitric acid battery*, is an extremely valuable instrument both to the lecturer and experimentalist; it combines great power both of quantity and intensity; it is free from the inconveniences of local action, and, therefore, so far, a *constant battery*; it occupies little space, and is upon the whole more economical than any other form of battery possessing the same advantages. The sections of two cells of this battery are represented in the annexed cut. The outer vessel V is a flat cell of glazed porcelain, containing within it another similarly shaped, but smaller and thinner cell C, of *porous* earthenware. A flat plate of amalgamated zinc Z is bent so as to receive the porous cell; a plate of thick platinum foil P being contained within the latter cell, and long enough to extend to the projecting end of the zinc plate of the next cell, perfect contact being there preserved by the cleft piece of wood W. The inner porous cell is charged with strong nitric acid; the outer porcelain cell is filled with a mixture of 1 part of oil of vitriol and 6 of water. The zinc being amalgamated, there is in this apparatus, as in Daniell's, and Smee's, no chemical action till the electrical current passes, and then the evolved hydrogen is suppressed by the nitric acid, which it converts, by deoxydizement, into nitrous acid. Twenty of these cells form a very powerful combination. Many years ago Mr. Cooper proposed to substitute coke for platinum in these batteries, and a similar plan has been more recently adopted by Bunsen, but so much inconvenience has attended the use of this material that it has not been generally adopted.



BE'BEARINE. A bitter basic principle contained in the bebearu plant or *Greenheart* of British Guiana.

BEISTINGS, or *Colostrum*. The first milk yielded by the cow immediately upon the birth of the calf.

BELU'GA. The species of whale (*Delphinus leucas*, Pallas) which, from its colour, is commonly called by the whalers "white-fish." It is confined to northern latitudes.

BENGAL STRIPES. Cotton cloth woven with coloured stripes. Ginghams.

BENJAMIN. *See* BENZOIN, in DICT.

BENZO'LE. A compound of carbon and hydrogen, originally discovered by Faraday amongst the products of the destructive distillation of whale oil. The same compound was produced by Mitscherlich from *Benzoic acid*. It consists of 12 atoms of carbon, combined with 6 of hydrogen, its formula being $C_{12} H_6$. It has a peculiar aromatic odour: it boils at 176°, and concretes into a crystalline solid at 32°, a property which enables it to be separated from other hydrocarbons, which remain liquid at low temperatures. Benzole has lately acquired much interest from having been discovered by Mansfield (*Journal of the Chemical Society of London*) amongst the products of the distillation of coal tar: it promises to form a valuable article for the manufacture of varnishes, and as a source of light.

BERLIN BLUE. *See* PRUSSIAN BLUE.

BERM (Fr.) in Fortification, a narrow level space, two or three feet wide along the exterior slope of a parapet to prevent the mass of earth and other materials of which it is composed from falling into the ditch.

BERRIES OF AVIGNON. (*Graines d'Avignon.*) The fruit of the *Rhamnus infectorius*, generally known under the name of *Persian Berries*. They are grown in Provence, Languedoc, and Dauphiné, and another variety comes from Persia. They contain a peculiar principle which has been termed *Rhamnine*, and which acquires a yellow colour by exposure to air.

BEZO'AR MINERAL. Peroxide of antimony. It is also called *diaphoretic antimony*.

BICU'SPID. (Lat. bis, cuspis, *a point*.) In Anatomy, when a part has two cusps, or pointed portions, as the bicuspid valve between the left auricle and ventricle.

BIO'LOGY. (Gr. *βιος, life; λογος, discourse*.) A branch of statistics having for its object the determination of the average duration of human life from the comparison of recorded observations. The term, MORTALITY, or *doctrine of* MORTALITY, is more generally applied to the same inquiry.

BITTER APPLE. The fruit of the *Cucumis colocynthis*.

BLACK ASH. Impure carbonate of soda.

BLACK DROP. A preparation of opium, known also under the name of *Lancaster*, or *Quakers' black drops*. It is said to be a solution of opium in verjuice.

BLAS. A term applied by Van Helmont to certain supposed emanations of the heavenly bodies.

BLISTERED STEEL. *See* STEEL.

BLOCK MACHINERY. A system or assemblage of machines for manufacturing the shells and sheaves of blocks required for ship tackle. The term is specially applied to the ingenious machinery invented by Sir M. I. Brunel, and set up in the woodmills in the dockyard at Portsmouth between 1802 and 1808, and also at Chatham about 1807, for the supply of the royal navy. By these machines every operation connected with the construction of blocks, from the cutting up of the timber to the polishing of the iron pinion which the sheave turns, is performed with astonishing celerity and precision; and when it is known that a single ship of war of 74 guns requires about 1430 blocks for her equipment, the advantage and even the necessity of abridging the labour of construction by appropriate machinery will be understood. Although it would scarcely be possible, without entering into long details and the aid of drawings to give any idea of the peculiar mechanism employed, the principal operations may be easily indicated. In the first place the rough timber (which is generally elm) is squared by an upright saw; it is then cross cut into pieces of the proper length by a circular saw. These pieces are then brought under the *boring machine*, when one centre bit bores a hole for the centre pin of the sheave, and another bores another hole at right angles to the former at one extremity of the mortise (or two or more such holes are bored when the block is to hold two or more sheaves) to admit the first stroke of the chisel. The next operation is performed by the *mortising machine*, which consists of a set of cutting chisels attached to a moveable frame, and making from 100 to 130 perpendicular strokes in a minute, the block being placed on a carriage which at every ascent of the chisels advances forward a little until the proper length has been mortised out. The block is then removed from the mortising machine, and the four corners are taken off by a circular saw, after which it is placed under the *shaping machine*, when, by tens at a time, the proper curvature is given by means of a tool moving in a direction curved towards the line of the axis. Lastly, the *scoring machine* scoops out a groove round the longer diameter of the block to receive the hempen or iron strap which goes round the block, and by which it is suspended when in use, and the *shell* is thus completed. The *sheaves* of the block are made of lignum vitæ, a log of which wood is first cut into plates of the proper thickness by a circular saw. The plates are then carried to the *crown saw*, which at once bores the centre hole through which the pin is to pass, and gives an exact circular form. They are next brought to the *coaking machine*, for the purpose of having grooves cut in them, on both sides, for the insertion of the *coak* or bush, which is of gun metal and of a peculiar shape (to prevent them from turning in the sheaves) the section being bounded by three semicircles, the diameters of which form the sides of an equilateral triangle. This part of the machinery is exceedingly curious, and so accurately is the operation performed that the coaks are fixed in the sheaves by the tap of a hammer. The two coaks (one on each side of the sheave) are secured by copper rivets passing through them and the sheave—an operation also performed by the machine. The sheave is then completed by turning a groove round its periphery for the rope to run in, and by smoothing its sides, both operations being performed on the same lathe. The iron pin only now remains, and this is also turned and polished by engines for the purpose. The whole of the machinery is put in motion by straps passing over drumheads, and is driven by a single steam engine. It is found that by means of this machinery ten men can with ease finish in one year from 130,000 to 140,000 blocks of different sizes.

BLOWING MACHINES. Instruments for producing a current or blast of air, chiefly for the purpose of exciting the combustion of fuel, and producing a great heat. The common bellows is an instrument of this kind, but for certain processes of metallurgy, as in smelting and refining ores, the intermittent blast produced by the single bellows is prejudicial, and even in the double form of the machine, as used generally by blacksmiths, the defect is not altogether remedied. Various contrivances have been had recourse to for the purpose of producing a continuous and equable blast, though depending generally on the principle of forcing air into large cylinders or air-chests, by means of a force air-pump, and allowing it to escape by eduction pipes under a regulated pressure. For the regulation of the pressure the air may be forced into a vessel inverted in a reservoir of water; but as the air is chilled by its contact with the water, the water regulator is found to be objectionable for large blast furnaces, and a weight is employed. Machines on this principle, frequently on a large scale, are in use at every foundry and great engine manufactory; and they have this advantage, that a number of forges may be supplied from the same air-chest. (See Ure's *Dictionary of Arts, Manufactures, and Mines*, Art. *Metallurgy*.)

BLUE PILL. The *pilula hydrargyri* of the Pharmacopœia. It consists of mercury triturated with conserve of roses and the powder of liquorice root till the globules disappear, and a homogeneous bluish-grey pill-mass is obtained: it contains one-third of its weight of mercury.

BLUE STONE. *Blue vitriol.* Sulphate of copper.

BO'CCIUS LIGHT. A form of gas-burner invented by Boccius, in which two concentric metal cylinders are so placed over the flame, and within the usual lamp glass, as to modify the combustion and increase the proportion of light.

BOLO'GNA PHIALS. Small flasks or phials of unannealed glass which fly into pieces when their surface is scratched by a hard body, as by dropping into them a fragment of flint; whereas a bullet may be dropped into them without injury.

BONE BLACK. The black carbonaceous substance obtained by heating bones to redness in a retort or other close vessel. When deprived by the action of hydrochloric acid of the phosphate of lime with which it is blended, it yields one of the most valuable forms of *animal charcoal*, and is highly prized by chemists as a decolouring and deodorising material.

BORNEO CAMPHOR. The camphor of the *Driabalanops aromatica*, or camphor tree of Sumatra.

BOUGIE. (French.) A slender flexible tube, intended for introduction into the urethra, œsophagus, or rectum, when those passages are obstructed by stricture or other disease.

BOULDERS. In geology, detached masses or fragments of rocks detached from their native locality, and scattered about upon the actual surface of the earth. They are also called "erratics" and "greyheads."

BOXINGS. A term applied by millers to an inferior or second flour.

BOYLE'S FUMING LIQUOR. This term was applied to the *hydrosulphuret of ammonia*, originally obtained by distilling a mixture of sulphur, sal ammoniac, and quick lime. When recently prepared it exhales dense fumes on exposure to air.

BOYLE'S HELL. A piece of chemical apparatus contrived by Boyle, resembling a flattened flask with a very long neck. It was principally used for the preparation of oxide of mercury (*precipitatum per se*).

BRAZING. The soldering of metals with an alloy of brass and zinc, to which small portions of tin are occasionally added.

BREAST-WHEEL. In hydraulics, the name given to a water-wheel so placed as to be struck by the stream of water nearly on a level with the axle, the lower quadrant of the circumference on the side opposed to the stream being placed in a *race* or channel concentric with the wheel, through which the water is conducted in its descent from the higher to the lower level, and in falling on the float boards within the channel acts both by its momentum and weight.

BRIGHT'S DISEASE. A morbid condition of the kidney, occasioning the secretion of urine loaded with albumen: the disease has hence been termed *Albuminuria:* it was originally described by Dr. Richard Bright.

BRITANNIA METAL. An alloy of tin with a little copper and antimony, used for tea-pots and similar purposes.

BRONZE POWDER. Copper or brass reduced to the state of a fine powder.

BRONZING LIQUID. A solution containing chloride of antimony and sulphate of copper, used for bronzing iron gun-barrels. Brass is sometimes bronzed by washing it over with a solution of chloride of platinum.

BRUNNER'S GLANDS. These glands, so called after their discoverer, are minutely lobulated bodies, situated beneath the mucous membrane in the submucous tissue of the duodenum: they are provided with permanent gland-ducts, which pass through the mucous membrane and open on the internal surface of that intestine. They resemble the pancreas in intimate structure.

BRYO'ZOA. (Gr. *βρυον, moss; ζωον, animal.*) An order of compound polypes, including the *Flustra* or sea-mat, which encrusts foreign bodies like moss. The organisation of the individual polypes resembles that of the Ascidian molluscs.

BUDE LIGHT. This term has been applied to various forms of oil and gas burners contrived by Mr. Gurney, of Bude, in Cornwall. The original proposal was to maintain the combustion by means of a supply of

oxygen gas to the burner, by which, with oil, or naphthalised gas, an intense light may be commanded, but at an inconvenience and expenditure quite incompatible with its economical adoption. Large gas burners with variously formed reflectors and refractors have since been erected in different parts of London under the name of *Bude Lights*, but they have nothing in common with the original proposal.

BUFF LEATHER. A leather prepared by imbuing the prepared skin with an aluminous compound, and afterwards some oily matter, such as yolk of egg.

BUFFERS. Elastic cushions attached to railway carriages for the purpose of breaking the shock when one carriage is pushed against another. They are usually formed of horsehair covered with leather; but may consist of strong iron springs, or of vulcanised caoutchouc.

BUFFY-COAT. When the coagulation of blood is retarded so as to allow the red particles to sink, and the lighter white corpuscles to rise towards the surface, the supernatant opaline plasma coagulates without the red particles, but includes the white ones, and forms a light-coloured clot of fibrine and white corpuscles resting upon the main body of the coagulum which has included the red corpuscles, and constitutes what is called the "buffy-coat." It is indicative of inflammatory disease, during which the coagulation of the blood is retarded beyond the ordinary time.

BULBUS ARTERIOSUS. In Embryology, the third cavity developed upon the primitive arterial trunk; the first being the auricle, the second the ventricle. The trunks of the aorta and pulmonary artery are developed out of the bulbus arteriosus in the warm-blooded vertebrata. In Comparative Anatomy the muscular basis of the branchial artery in fishes is so called, which may be regarded as a retention of the embryonic structure by arrested development.

BUMBE'LO. A glass flask or mattrass of flattened ovoid shape, in which camphor is sublimed.

BURSÆ MUCOSÆ. In Anatomy, synovial serous sacs, either subcutaneous or situated beneath tendons that glide over bones.

BUTY'RIC ACID. One of the fatty acids contained in butter: it is also formed in certain cases in which sugar undergoes fermentation in contact with curd, and hence termed *butyric fermentation*. This acid is a volatile, colourless, and very mobile liquid, of a pungent sour odour, resembling that of a mixture of acetic acid and rancid butter; its taste is first pungent and sour, then sweetish and ethereal. The chemical formula of this acid is $C_8 H_7 O_3 + H O$; that is, the anhydrous butyric acid consists of 8 atoms of carbon, 7 of hydrogen, and 3 of oxygen; which in the ordinary acid are combined with an atom of water: in the *butyrates* this atom of water is replaced by an atom of base.

C.

CA'CODYLE. *See* KAKODYLE.

CACO'THELINE. A substance formed by the action of nitric acid upon brucia.

CALO'RIFA'CIENT. (Lat. calor, *heat;* facio, *I make.*) The term is applied in Physiology to those non-azotised materials of food, in the form of fat, starch, sugar, gum, which are believed to be employed in the production of heat.

CA'LOTYPE, or KALOTYPE. (Gr. καλος, and τυπος.) A term applied to the photogenic drawings obtained by the action of light upon certain salts of silver. See PHOTOGRAPHY.

CA'LYX. In Anatomy, is applied to that branch of the pelvis of the kidney which receives the apex of the cone or bundle of the uriniferous tubules: in man there are several "calyces" in the kidney.

CAM or CAMB. In Machinery, a contrivance for converting a uniform rotatory motion into a varied rectilinear motion. The end of a rod which is free to move only in the direction of its length is held in contact, by the action of a spring, or weight, with the edge of an irregularly shaped mass which revolves uniformly upon an axis. A varied motion is thus communicated to the rod, which carries with it the machinery by which the motion is to be applied. This contrivance is much used in the machinery for lace-making. *See* ROSE ENGINE, in DICT.

CAM WOOD. The wood of *Baphia nitida:* the tree which yields it grows in Sierra Leone and the interior of Africa. It is used in dyeing instead of Brazil wood, and gives a finer and more durable red.

CANNA STARCH. The fecula of the *Canna coccinea*, sold in the shops under the name of *Tous les mois.* It is imported from St. Kitt's, and is a good substitute for arrow-root. Its granules are comparatively large, and form an excellent microscopic object.

CA'PRIC ACID. One of the volatile acids of butter obtained by saponifying it with soda, adding excess of sulphuric acid, and distilling: it passes over mixed with butyric acid, and with two other acids, namely, the *caproic* and the *caprylic* acid. Capric acid has a mixed odour of acetic acid and the smell of a goat. The odour of caproic acid is less goaty, and that of caprylic acid strongly resembles perspiration. A curious relation exists between the formulæ of these several acids, the carbon and hydrogen successively increasing by the addition of 4 equivalents, as shown in the following table:—

Butyric acid - -	$C_8\ H_7\ O_3$, HO
Caproic - - -	$C_{12}\ H_{11}\ O_3$, HO
Caprylic - - -	$C_{16}\ H_{15}\ O_3$, HO
Capric - - -	$C_{20}\ H_{19}\ O_3$, HO.

CA'PSICINE. An acrid soft resin found in the fruit or seed pods of the *Capsicum annuum;* it appears to be the acrid principle of Cayenne pepper.

CA'PSULAR LIGAMENTS. Those ligaments which surround moveable articulations, and retain the synovia, as in a bag.

CA'PSULE. (Dimin. of *Capsa*, a box or case.) In Anatomy, a membranous sac investing an organ; as the capsule of the liver, the spleen, &c.: those flask-shaped sacculi from which the uriniferous tubes commence are called "capsules of Malpighi:" they surround the capillary glomerules or plexuses, called "corpuscles of Malpighi."

CARAGHE'EN MOSS. The *Chondrus crispus:* called also Irish moss. It is very common on rocks and stones on the sea coast: it appears to contain a peculiar mucilage, which has been called *Caragenine.* It is a popular remedy for pulmonary complaints, and is sometimes used in soups and jellies.

CA'RAITES. A sect among the Jews who adhere closely to the text and letter of the Scriptures, rejecting the rabbinical interpretations and the Cabbala.

CA'RAMEL. *See* CAROMEL.

CA'RAPACE. The upper shield or plate of the armour or shell of the tortoise and crab.

CA'RBAMIDE. A compound of carbonic oxide and amidogen, contained, according to Regnault, in chlorocarbonate of ammonia: its chemical formula is CO, NH_2.

CARBO'LIC ACID. A substance obtained by the distillation of coal tar: it crystallises in prismatic needles, which fuse at 95° and boil at 270°: it has a penetrating odour and burning taste, and in many respects resembles kreasote: its specific gravity is 1·06. It appears to be identical with the substance called *hydrate of Phenyle.* Its formula is $C_{12}\ H_5\ O$, HO.

CARI'NTHINE. In Mineralogy, a sub-species of *Augite* from Carinthia.

CARMI'NIC ACID. This, according to De la Rue, is the colouring principle of *cochineal.* Its formula is $C_{28}\ H_{14}\ O_6$. When in powder it is of a brilliant crimson. It appears to be the substance described by Pelletier and by Preisser under the names *Coccinelline* and *Carmeine.*

CAROLI'TIC COLUMNS. Architecture. Columns with foliated shafts.

CA'ROTINE. A deep red crystallisable substance contained in carrots.

CARPO'LOGY. (Gr. καρπος, *fruit*, and λογος, *discourse.*) That branch of botany which treats of the structure of fruits.

CAR'PUS. In Anatomy, the segment of the skeleton of the upper or fore-limb, answering to the wrist: it consists of eight small bones in the human subject.

CA'RTHAMINE. The colouring matter of the *safflower.*

CA'RYOPHY'LLINE. (Gr. καρυα, *a walnut tree*, and φυλλον, *a leaf.*) A crystalline substance (called also *Clove camphor*) deposited by a strong alcoholic tincture of *Cloves.* In composition it resembles common camphor: $C_{10}\ H_8\ O$.

CA'SCALHO. The name given to the alluvial deposit in which the diamond is found in Brazil.

CASE HARDENING. The superficial conversion of iron into steel.

CA'SEINE. *See* CASEUM.

CASKET. A small rope used to fasten the sail to the rope in furling.

CASSELL YELLOW. A compound of oxide and chloride of lead: it is also known in commerce under the name of *patent yellow* and *Turner's yellow.*

CA'STOR OIL. The expressed oil of the seed of the *Ricinus communis*, or *Palma Christi.* It is a mild aperient.

CATA'LYSIS. (Gr. κατα, and λυω, *I dissolve.*) That process in which a substance excites by its mere presence (and without itself undergoing change) some chemical action in the substances with which it is in contact.

CATECHU'IC ACID. A substance in the form of white silky filaments contained in *Catechu.* Its formula is $C_{14}\ H_6\ O_6$. It has also been termed *Catechine* and *Tanningenic acid.*

CAT SILVER. A species of mica.

CAUDA EQUINA. (Lat.) In Anatomy, the roots of the terminal spinal nerves which are contained in the neural canal of the vertebræ, and surround the "filum terminale" of the myelon.

CAU'DATE. (Lat. cauda, *a tail.*) In *Anatomy*, when the apex of a pyramidal part or organ is prolonged into a long slender point: certain microscopic bodies found in ganglia are termed especially "caudate" nerve-corpuscles. In *Zoology*, an animal provided with a tail.

CAUK or CAWK. The term applied by miners to massive sulphate of baryta or heavy spar.

CAU'SALTY. A miner's term for the light parts of ores which are carried away by washing.

CAU'ZERANITE. A crystallised mineral found at Cauzeran in the Pyrenees, of a black or dark blue colour: it is a silicate of lime and alumina, with potassa and soda.

CAVA VENA. *See* VENA CAVA.

CA'VENDISH EXPERIMENT. An important mechanical experiment for the purpose of ascertaining the mean density of the earth; the method employed being a comparison of the force of terrestrial attraction with that of the attraction of leaden masses of known magnitude and density, determined by means of the balance of torsion.

The idea of rendering sensible and measuring the attractive force of a dense body upon another body in its immediate vicinity by means of the torsion balance, appears to have been suggested by the Rev. John Michell; but the experiment was first actually made by the celebrated Henry Cavendish, whose report is published in the *Philosophical Transactions* for 1798. It was subsequently repeated by Reich, Professor of Physics at Freiberg in Saxony, who published his results in 1838; and again by the late Francis Baily with far greater precision, and by a far more varied and extensive series of observations, the details of which are given in a paper of great value published in the *Memoirs of the Royal Astronomical Society*, vol. xiv. 1843.

In the mode of proceeding adopted by Cavendish, and followed by Baily, the data for determining the earth's mean density were obtained in the following manner:— A slender deal rod of six feet in length, having a leaden ball of about two inches in diameter attached to each of its ends, is suspended horizontally from a beam by a fine metallic wire, about 40 inches in length. This forms the torsion balance. Immediately under the balance is placed a strong horizontal plank about 8 feet in length, supported by and turning upon an axle, the central line of which is in the same vertical with the suspension wire. On this plank, near its extremities, are placed two equal spheres of lead (12 inches in diameter, and each weighing about 380lbs.), cast with great care, in order that the density may be uniform throughout the mass, and accurately turned. The apparatus is so arranged that the centres of the two balls at the extremities of the arm of the torsion balance, and the centres of the two leaden spheres, or *masses*, are in the same horizontal plane, and equally distant from the vertical axis of motion. Suppose now the torsion balance to be at rest in a certain direction, and the plank which supports the masses to be at right angles to the direction of the balance; in this position the attraction of the two masses will have no tendency to give motion to the balance. But let the beam be turned round till the two masses approach near to the balls, then the attraction of each mass, acting most powerfully on the nearest ball, tends to bring the masses and balls still closer together. A motion is thus given to the arm of the torsion balance, and in consequence of the elasticity of the suspension wire, the balance performs a series of isochronous oscillations, and ultimately comes to rest in a position in which the attraction of the two masses on the balls is exactly counterbalanced by the torsion of the wire.

The force developed by the leaden masses being exceedingly minute, not more than a 50-millionth part of their weight, a very small disturbing force will prevent the success of the experiment, and accordingly many precautions are requisite. In Baily's experiments the torsion rod was enclosed in a mahogany case, gilt in the inside, wrapt round with thick flannel, and covered over with gilt paper, to prevent the radiation of heat, and consequent derangement from the currents of air thereby produced. The balls were also gilt and burnished, and the whole apparatus was surrounded by a close wooden frame or case, having glazed openings, through which the motions of the torsion rod were observed by means of a telescope from a distant part of the room.

In order to deduce the mean density of the earth from the data furnished by the experiments, it is necessary to find expressions for the torsion developed in the wire, and for the attractive force of the masses on the balls, in that position of the arm of the balance at which it comes to rest under the action of the two forces, which th counterbalance each other. The theory is as follows.

Let F denote the force (measured by the weight grains) which, being applied horizontally and perpe dicularly to the arm of the balance at the unit of distan (one inch) from the suspension wire, causes the arm pass through a unit of angular space, or describe an a equal to the radius. Also, let F′ denote the torsi actually developed by the attraction of the masses, the distance of the suspension wire from the centre the ball, and θ the angle of deviation of the arm fro its first position. By the nature of the lever, the for required to produce a given effect is inversely as t distance of its point of application from the fulcru which is here the suspension wire; and according to t law determined by Coulomb, the force of torsion is rectly proportional to the angle of torsion; therefore

$$F' = F\frac{\theta}{a}.$$

The measure of this force F′ is deduced from the tir in which the oscillations of the balance are perform The general formula (see TORSION, in DICT.) for t torsion force is,

$$F = \frac{\pi^2}{n^2} \times \text{moment of inertia},$$

where $\pi = 3{\cdot}14159$, and n is the number of seconds in t time of an oscillation. In the present case the whole the matter in each ball may be regarded as accumulat at its centre, and the matter in the rod may be neglecte hence in respect of each ball the moment of inertia expressed by the mass (m) multiplied into the square the distance of its centre (a) from the suspension wi that is, by a^2m, consequently the inertia in respect both balls is $2a^2m$, and the above formula becomes

$$F = \frac{2\pi^2}{n^2} a^2 m.$$

Let w denote the weight in grains of each ball, g t accelerating force of gravity, and l the length of t seconds' pendulum; then $w = gm$, and $g = \pi^2 l$, whence substitution $F = \frac{2a^2w}{ln^2}$, and consequently, since $F' = F\frac{\theta}{a}$

$$F' = \frac{2aw\theta}{ln^2}.$$

Having obtained an expression for the torsion for we have next to find the force of the attraction of t leaden masses. In respect of each mass let g' denote t force of attraction, r the radius, v the volume, and d t density; and in respect of the earth (assumed to be sphere) let the same elements be respectively denot by g, R, V, and D; also, let k denote the distance of t centre of the mass from the centre of the ball at t middle of the oscillation, and assume f to be the c efficient of gravity. Now, because the attraction o sphere on a point without it is directly as its mass, that as its volume multiplied into its density, and invers as the square of the distance of the attracted point fr its centre, we have $g' = \frac{fvd}{k^2}$, and $g = \frac{fVD}{R^2}$; when $\frac{g'}{g} = \frac{vdR^2}{VDk^2}$. But $\frac{v}{V} = \frac{r^3}{R^3}$, therefore $\frac{g'}{g} = \frac{r^3d}{RDk^2}$; con quently, since the attraction of the earth upon the b is the same thing as the weight of the ball, or $g = w$, have $g' = \frac{r^3dw}{RDk^2}$, and therefore

$$\text{attraction of both masses} = \frac{2r^3dw}{RDk^2}.$$

By the conditions of the problem this attraction equal to, or balances, the torsion force F′; therefo putting the two expressions equal to each other, we ha $\frac{a\theta}{ln^2} = \frac{r^3d}{RDk^2}$; whence, finally,

$$D = \frac{r^3ld}{aRk^2} \cdot \frac{n^2}{\theta}.$$

In this expression for D, the mean density of earth, all the quantities are supposed known excepti n and θ, and the object of the experiment is to determ their values. The angle θ is determined by observi the number of divisions, on a known scale, passed over an index or pointer attached to the extremity of the a of the balance, so that if β denote the value of one divis of the scale in parts of an inch, λ the distance in inc between the suspension wire and the extremity of index, and h the number of divisions passed over by index when the arm of the balance moves from its sition of rest *before* the mass is approximated to ball, to its position of rest *after* the approximation, t $\theta = \frac{h\beta}{\lambda}$.

Cavendish gives the numerical values of the consta which enter into the expression for D as follows: r= $l = 39{\cdot}14$, $a = 36{\cdot}65$, $k = 8{\cdot}85$, $R = 250800000$, all in inch

and d (the density of the leaden mass as compared with water)=10·64. He also had $\beta=\frac{1}{20}$, $\lambda=38{\cdot}3$, whence $\theta=1\div766$; and the substitution of these numbers in the formula gives $D=\frac{n^2}{10683h}$. There are, however, several corrections to be made, on account of the attraction of the matter in the plank and mahogany case, and other parts of the apparatus, as also for the inertia of the arm of the balance, and for the variation of the masses on the balls according to the position of the arm, for the details of which we must refer to the memoir of Baily already cited. It may be noticed that the motion of the arm is very slow, the average time of a complete vibration in Cavendish's experiments having been from six to seven minutes.

The result obtained by Cavendish gave the mean density of the earth, as deduced from 17 sets of experiments, equal to 5·45, that of water being unity. Reich, from 57 experiments, found it to be 5·44. Baily's experiments were far more numerous and varied than those of his two predecessors. The torsion rod was suspended in different ways: by a single copper wire, as had been practised by Cavendish and Reich; and by double lines, as proposed by Gauss; and in the latter case the substances used were silk fibres, brass wire, and iron wire. In order to ascertain whether the results would be affected in any way by varying the substance of the attracted body, the experiment was made not only with leaden balls attached to the ends of the torsion balance, but also with balls of platina, zinc, glass, ivory, and hollow brass, and with a torsion rod of brass without balls. The actual number of experiments recorded in the memoir is no fewer than 2153; and nearly as many more, which had been made before the anomalies of the balance had been entirely got rid of, were rejected. The mean result from all the recorded experiments, without exception, gave the mean density of the earth equal to 5·675, with a probable error of ·0038.

CE'LANDINE, the poisonous irritant principle of the *Chelidonium majus*.

CELE'STINE. (Lat cœlum.) The blue variety of sulphate of strontia.

CELL. In Anatomy, a primary microscopic vesicle, of larger average size than the nucleus, composed of membranous cell-walls, with usually liquid contents, round or oval, and sometimes flattened like a scale. With a few exceptions—*e. g.* the mammalian blood discs and old cells of the epidermal or adipose systems — the primary cell contains a nucleus.

CENTRAL SUN. In sidereal astronomy, the name given to the body about which the sun, and all the stars in the great cluster or nebula to which the sun belongs, is assumed to be revolving. M. Mädler, of Dorpat, has recently published a paper under this title, in which he attempts to assign the real motions of the stars, and consequently the position of the central point, in reference to a dynamical theory. He thinks there is no reason for supposing that there exists anywhere a star of such magnitude as to dominate the motions of others as the sun does the motions of the planets; but if we suppose the stars of our stellar cluster to be pretty uniformly distributed, and the form of the limit of the cluster to be nearly spherical, or a surface compressed between two planes, as is supposed to be the case of the milky way, then, whatever the law of attraction may be, the stars near the centre will move with much smaller linear velocity than the distant one; and this difference of real velocity will give rise to apparent motions by comparison of which the relative distances from the centre may be assigned. Applying these considerations to the apparent motions actually observed, and assuming the direction of the sun's motion in the heavens to be that which has been determined by Argelander and others, Mädler shows that a point somewhere in the group of the Pleiades, and probably not far from the star *η Tauri*, possesses the characteristics of the central point. Having thus obtained, approximately, the position of the central body, Mädler proceeds to discuss its probable distance from our sun, and the velocity of the sun's orbital motion about the centre. Assuming the star 61 *Cygni* to be at the same distance from the central body as the sun is, and the distance of 61 *Cygni* from the sun to be known from the parallax found by Bessel, he finds from these assumptions, and from the observed proper motions of 61 *Cygni* and *η Tauri*, that the parallax of *η Tauri* is 0′′·0061, or that its distance is thirty-four millions of times as great as the distance of the earth from the sun. The proper motion of *η Tauri* gives for the periodic time of our sun round the centre 18,200,000 years; and the velocity of our sun in its orbit round the central sun is about thirty English miles in a second of time. (*Monthly Notices of the Royal Astronomical Society*, vol. vii. No. 12. February, 1847.)

CERAU'NIA. (Gr. *κεραυνος*, *lightning*.) Thunderstones of the old mineralogists.

CERE'BRIC ACID. (Lat. cerebrum, *the brain.*) A fatty acid, containing nitrogen and phosphorus, forming one of the components of brain.

CE'RINE. (Lat. cera, *wax.*) A name given by some chemists to that portion of bees' wax which is soluble in boiling alcohol: the insoluble portion has been termed Myricine.

CE'ROSINE. (Lat. cera, *wax.*) A waxy substance which exudes from the sugar-cane.

CERVI'DÆ. *See* Deer, in Dict.

CHALCOLITE. (Gr. *χαλκος*, *copper*, and *λιθος*, *a stone.*) A green crystalline mineral found in several of the Cornish mines, and supposed to contain copper, till it was shown by R. Phillips to be a *hydrated phosphate of uranium.*

CHA'LILITE. A mineral found in the Donegore mountains in the county of Antrim. It is a hydrated silicate of alumina, lime, and oxide of iron: its name is derived from its *flinty* appearance — *χαλιξ*, *a flint.*

CHA'MOISITE. A mineral from Chamoisin in the Valais; it is of a dark greenish grey colour, and appears to be a hydrated silicate of protoxide of iron.

CHA'RTISTS, the name assumed by a certain political party in England, composed chiefly of the working classes, who have embodied their principles in a document called the "People's Charter," the leading points of which are universal suffrage, vote by ballot, annual parliaments, electoral districts, abolition of property qualification, and payment of members of parliament.

CHARY'BDIS. *See* Scylla, in Dict.

CHA'SCHISCH. The term applied by the Indians to the inspissated juice of the Cannabis sativa, or Indian hemp: it has been used as a substitute for opium. It is also known under the name of *Churrus*. It is a powerful narcotic poison.

CHE'LMSFORDITE. A crystallised greyish-white mineral composed of silicate of alumina and silicate of lime. It appears to have the same composition as Meionite and Scapolite.

CHEILO'GNATHA. (Gr. *χειλος*, *a lip; γναθος*, *a jaw.*) An order of myriapods or centipedes, of which the lower lip is formed by the tongue and two mandibles.

CHEILO'PODA. (Gr. *χειλος*, and *πους*, *a foot.*) A family of myriapods, in which a pair of feet form the lower lip.

CHEROPHY'LLA. The poisonous principle of the *Cherophyllum silvestre*, or Wild chervil.

CHIA'STOLITE. Hollow-spar. A mineral found imbedded in clay-slate: it occurs in the slate of Cumberland, and of Antrim in Ireland: in rhomboidal prisms, exteriorly greyish-white, and interiorly black. Some of the sections of the crystals have the form of an X, hence the term from *χιαζω*, to mark with that letter.

CHINA INK. A finely divided carbon, probably lamp-black of some kind, mixed with gelatine, and formed into cakes or sticks. It is sometimes stated to be the desiccated ink of the cuttle-fish.

CHINO'LEINE, or CHINO'ILINE. An oily liquid obtained by distilling quinine with caustic potassa.

CHINO'NE. A substance obtained by distilling certain salts containing kinic (cinchonic) acid, as for instance the kinate of lime, with oxide of manganese and sulphuric acid. Chinone sublimes in the form of golden-coloured crystals, soluble in water, very volatile, and of a very peculiar and distinctive odour. Their formula is said to be $C_{25}\ H_8\ O_8$.

CHI'TINE. (Gr. *χιτων*, *a coat of mail.*) The hard insoluble matter forming the shells and elytra of insects.

CHLORACE'TIC ACID. A crystalline acid obtained by the action of the solar rays upon a mixture of chlorine with the vapour of acetic acid. Its formula is $C_4\ Cl_3\ O_3$, $H\ O$; in it, therefore, the hydrogen of the acetic acid is replaced by chlorine.

CHLORHYDRIC ACID. *See* Hydrochloric.

CHLO'RIC ACID. A compound of 1 atom of chlorine with 5 of oxygen, represented therefore by the formula $Cl\ O_5$. Its most important salt is the chlorate of potassa, formerly called oxymuriate of potash.

CHLO'ROFORM. (Gr. *χλωρος*, *pale*, and Lat. formica, *an ant.*) A compound represented by the formula $C_2\ H\ Cl_3$, and obtained by distilling a mixture of chloride of lime with diluted alcohol. It is a heavy liquid, its sp. gr. being 1·48; it boils at 140°. Its name has reference to the constitution of *formic acid*, which is represented by $C_2\ H\ O_3$, and is therefore the teroxide of a hydrocarbon $= C_2\ H$, to which the term *formyle* has been applied; so that, in reference to this view of its composition, chloroform has also been denominated *terchloride* of formyle. When the vapour of pure chloroform is respired it soon induces insensibility, in the same way as ether vapour; and hence has been similarly used, in the performance of surgical operations and in child-birth. Much prudence and caution are requisite in its administration.

CHLORO'PAL. A mineral of a greenish yellow colour, associated with the opal of Hungary. It is a hydrated silicate of iron.

CHLO'ROUS POLE. The voltaic pole or electrode at which chlorine is evolved in cases of the electrolysis of chloric compounds.

CHOLE'IC and CHOLIC ACID. Choleic acid is a fatty acid, which, in combination with soda, constitutes a principal ingredient in *bile*. By the protracted action of caustic potassa it evolves ammonia, and is converted into *Cholic* acid. The elements of choleic acid are carbon, hydrogen, oxygen, nitrogen, and sulphur, the following being its formula: $C_{44}\ H_{40}\ O_9\ N\ S$.

CHO'NDRINE. (Gr. χονδρος, *cartilage.*) That form of gelatine which is obtained from cartilage, and which differs from ordinary gelatine in being precipitable by acetic and the mineral acids, and by sulphate of alumina and potash, persulphate of iron, and acetate of lead.

CHO'NDRODITE. (Gr. χονδρος, *a grain.*) A mineral found in Finland, and also in N. America. It is yellow, and of a vitreous fracture: it is a *fluosilicate of magnesia.*

CHO'RDA DORSALIS. *See* NOTOCHORD.

CHO'RDA TYMPANI. (Lat.) A branch of the facial nerve or portio dura, which crosses the tympanum, and supplies the lingualis and some other muscular fibres of the tongue.

CHOR'DÆ VOCA'LES. (Lat.) In Anatomy, are the ligaments which extend from the thyroid to the cricoid cartilages, and bound the glottis. They contain much elastic tissue, and can be made to vibrate under various degrees of tension by the action of the muscles upon the cartilaginous parts of the larynx to which they are attached: they are the proper organs of voice.

CHO'ROGRAPH. (Gr. χωρος, *a region;* γραφω, *I describe.*) The name given by the late Professor Wallace, of Edinburgh, to an instrument contrived by him for the mechanical construction of this geodetical problem, viz. "To determine the position of a station, having given the angles made by lines drawn from it to three other stations in the same plane, whose positions are known." The problem, which is important by reason of its frequent application in maritime surveying, was reduced by Professor Wallace to another very simple one, viz. "To construct two similar triangles on two given straight lines, having given their angles." The triangles may be constructed by any of the ordinary methods; but inasmuch as they are similar, the construction is much facilitated in practice by means of the *chorograph*, a particular kind of protractor, having two moveable indices or arms. "The circle from which the two arms project is of brass, and is divided into 180 equal parts, each serving as the measure of an angle of two degrees at the centre, or one at the circumference. Each of the equal parts is subdivided into half degrees. [By means of a vernier the degrees are subdivided into single minutes.] The graduations on the scale are numbered quite round from 0 to 180° both ways. One of the three arms has a fixed position on the circle, and is placed against zero and 180°; the others turn on a common centre. There is a steel pin terminating in a point at the extremity of each arm, at equal distances from its centre, and perpendicular to its plane. By the graduated circle the moveable arms may be placed in such positions that lines joining the steel points at the extremities of the arms may form a triangle similar to any given triangle." (*Geometrical Theorems and Analytical Formulæ, &c.* By W. Wallace, L. L. D. Edinburgh, 1839.)

CHROMA'TIC THERMOMETER. When the edge of a rectangular plate of glass is applied to a piece of heated metal, or other substance having a temperature different from that of the glass, and exposed to a beam of polarized light, coloured fringes are developed; and as the particular tints depend on the difference between the temperature of the glass (which is supposed to be known) and that of the substance to which it is applied, the colour of the central fringe affords a means of inferring the temperature of the substance. Hence the term *Chromatic Thermometer*. The phenomena in question were discovered and first studied by Sir David Brewster.

CHROME-ALUM. The potassa-sulphate of chromium; a salt isomorphous with alum, in which alumina is replaced by oxide of chromium.

CHROME YELLOW. The yellow chromate of lead.

CHRO'MULE. (Gr. χρωμα, *colour.*) The green colouring matter of the leaves of plants; more commonly and properly termed chlorophylle.

CHRYSA'MMIC ACID. (Gr. χρυσος, *gold;* αμμος, *sand.*) A substance in the form of a brilliant golden-coloured powder, obtained by the action of nitric acid on aloes.

CHRY'SENE. (Gr χρυσος, *gold.*) One of the numerous products of the destructive distillation of woods.

CHRYSOLE'PIC ACID. (Gr. χρυσος, and λεπος, *a scale.*) A peculiar acid formed along with chrysammic acid by digesting aloes in nitric acid.

CHUCK. In Mechanics, the name given to that part of the turning-machine by which the *work* is connected with the lathe. There are various kinds of chucks, as the *screw*-chuck, the hollow-chuck, the drill chuck, &c., for ordinary turning; the excentric chuck, the geometric chuck, for ornamental turning.

CHYLE-CORPUSCLES. Cells developed in chyl of a subspherical form, greyish-white colour, abou $\frac{1}{2500}$ of an inch in diameter: often tuberculated on thei surfaces. When found in the blood they are calle "white corpuscles."

CHYMISTRY. *See* CHEMISTRY. Those who deriv the word from χυω, *I melt* or *dissolve*, adopt the forme mode of spelling.

CINCHO'NIC ACID, or *Kinic Acid.* An acid foun in combination with the alkaloids in the varieties o Peruvian Bark, or *Cinchona:* it is crystallisable, an represented by the formula $C_{14}\ H_{11}\ O_{11}$, H O.

CINNA'MIC ACID. When the essential oil of cin namon is exposed to air, it gradually absorbs oxyge and deposits crystals of cinnamic acid $= C_{18}\ H_7\ O_8$, H O It much resembles *benzoic acid*, into which it is con verted when mixed with bichromate of potassa and sul phuric acid. This acid is found, together with benzoi acid, in Peruvian and in Tolu balsam, from the latte of which it is readily obtained.

CIN'NAMYLE. The supposed *radical* of oil of cin namon and of cinnamic acid, and of which oil of cinna mon is the *hydruret*. The formula of Cinnamyle $C_{18}\ H_7\ O_2$, and that of oil of cinnamon, $C_{18}\ H_7\ O_2 + H$

CIRCI'NNUS. The Compasses: — a constellatio of four stars near the South Pole.

CIRCULATION OF THE BLOOD. *See* BLOOD

CIRROCU'MULUS. The *sonder cloud.* (Lat. cirru *a curled lock of hair*, and cumulus, *a heap.*) A cloud in termediate between the Cirrus and Cumulus. *Se* CLOUD.

CIRRO'STRATUS. (Lat. cirrus, and stratus, *a be or covering.*) The *wane cloud*, intermediate between th Cirrus and Stratus. The *mackereled sky* of a summe evening, which is regarded as foreboding rain, is a mod fication of this cloud. *See* CLOUD.

CIRRUS. The *curl-cloud*, or *mare's-tail.*

CITRACO'NIC ACID. One of the acids resultin from the action of heat on citric and on itaconic acid.

CITRI'BIC ACID, CITRICIC ACID, CITRIDI ACID. Acids derived from the *Citric acid*, and iden tical with the *Citraconic, Itaconic*, and *Aconitic* acids.

CI'TRINE OINTMENT. An ointment containin nitrate of mercury; it has a lemon yellow colour. Th *unguentum hydrargyri nitratis* of the Pharmacopœia.

CLEA'VAGE. In Mineralogy, the direction which the structure of a crystal enables it to be spli the resulting smooth surfaces are called *cleavage plane*

CLEA'VELANDITE. A variety of felspar: it h also been called *Albite.*

CLEDGE. A miner's term, applied to thin strata clay or fuller's earth.

CLEPSA'MMIA. (Gr. κλεπτω, *I hide*, and αμμ *sand.*) An antient instrument for measuring time by th running of sand, like the modern hour-glass.

CLEW LINES. CLEW GARNETS. Tackle which the sails of a ship are trussed up to the yard.

CLI'CHY WHITE. A pure carbonate of lead, white-lead, manufactured at Clichy in France.

CLOT. In Physiology, the coagulum of blood.

CLU'TCHES, or GLANDS. In machinery, couplin which have no coupling boxes are denominated *clutch* or *glands*. A coupling of this kind consists of tw crosses, one fixed to the end of each of the shafts to b connected. One of the crosses, having its end bent fo ward, lays hold of, or *clutches*, the other, and by doi so turns round the other shaft. Instead of cross piec two round cast-iron plates are sometimes used, ea having a part cut out, and a corresponding projectio The projection of the one plate is inserted in the ope ing of the other, and thus serves to engage the shaf (*Buchanan on Mill Work.*)

COA'GULUM. (Lat.) The part of the blood whi changes from the fluid to the solid state, when dra from the body and left at rest, or subjected to heat certain chemical reagents. It consists of the fibri with the blood-discs.

COA'GULABLE LYMPH. A term given in so surgical works to the fibrine of the blood, which is t only part that has the power of spontaneously coagulati

CO'CHLEA. (Lat. *shell.*) In Anatomy, a port of the internal ear, which in mammals is shaped like t common snail-shell, with its base resting on the bott of the internal meatus, and perforated to receive so filaments of the acoustic nerve. It is traversed by a co cal column, called "modiolus," around which a "spi canal" makes two turns and a half. This canal divided into two ramps or "scalæ," by a partition of b called the "lamina spiralis." At the base of the coch one scala communicates with the vestibule, the oth with the tympanum; they communicate with each ot at the apex of the cochlea.

COCI′NIC ACID. When the solid fatty matter of cocoa-nut oil is saponified, the crystalline fatty acid into which it is converted has been called *cocinic* or *cocostearic* acid.

COCOA. The fruit of the *Theobroma Cacao*, which is about the size of a kidney-bean, and inclosed in a thin shell.

COD LIVER OIL. This oil, expressed from the liver of the cod-fish, has lately acquired much reputation for its remedial powers. It has been used in the dose of a table-spoonful three or four times a day, in pulmonary phthisis, in various scrofulous affections, in chronic gout and rheumatism, and in some obstinate skin diseases. It is supposed to contain iodine or bromine, to which its efficacy has been ascribed: but, on the other hand, it is asserted that it cures those forms of scrofula and other diseases which do not yield to the usual forms of iodine.

COGS. In mill work the term *cogs* is given to the teeth of wheels when they are not of the same piece with the body of the wheel, but are each of a particular piece.

COIN WEIGHING MACHINE. A machine for this purpose was constructed by Mr. Napier for the Bank of England in 1844, and has since been more extensively applied at the Mint.

It consists of a square brass box, on the top of which is placed a hopper to hold the sovereigns to be weighed, and in front of it are two small apertures fitted with receivers, one for the sovereigns of full weight, and the other for light sovereigns. The balance for weighing the sovereigns is placed inside the box near the upper plate vibrating upon a knife edge, and receiving the sovereigns upon a small platform at one end of the beam and above it. The platform is kept in its place by means of a small pendulum, on which, at about an inch below the platform, there is an oblong perforation, about half an inch in length, technically called a *slot*, in which a small ivory rod works freely up and down, without touching the sides.

Between the slot and the platform a pair of forceps is placed. From a knife-edge at the other end of the beam a small round polished plate is suspended, to which a pendulum is fixed, and at its lower part the scale is placed to receive the weight. Above the small round plate, under the top of the box, is fixed an agate with a blunt point. When the machine is in motion the small ivory rod is depressed; this, on touching the bottom of the slot, or opening in the pendulum in which it works, brings down the beam on that side, and raises it of course on the other, the weight side, until the small round plate on that side touches the agate point. The beam is then in a horizontal position. As soon as this is effected the forceps catch hold of the pendulum between the platform and the slot, and hold it firmly. The balance is then in a condition to receive the sovereign, which is shifted from the bottom of the pile in the hopper, and brought by means of a slide along a channel, just large enough for a sovereign of the proper standard gold to pass, but not large enough to admit a counterfeit, and deposited upon the platform. The forceps then let go their hold, the ivory rod is gently raised, and, if the sovereign happens to be light, that end of the beam rises, and the other end leaves the agate point; but, if the sovereign be of full weight, the beam remains stationary, and the small plate on the weight end is in contact with the agate point.

When the sovereign is weighed, the operation of its removal is very ingenious, and is as follows:—Two bolts are placed at right angles to each other, and on each side of the platform or scale there is a part cut away to admit of the bolts striking so far into the area of the platform as to remove anything that would nearly fill it. These bolts are made to strike at different elevations, the lower one striking (as to time) a little before the other. If the sovereign be of full weight the scale remains down, and the lower bolt knocks it off into the full-weight box. If the sovereign, on the other hand, be light, it rises up, and the first bolt strikes under and misses it, and the higher bolt then strikes and knocks it off into the light box. The machine weighs about thirty-three sovereigns in one minute. The weights used are of glass, and are adjusted to within the ten-thousandth part of a grain.

COLCHI′CIA. An alkaloid obtained from, and probably constituting the active principle of the *Colchicum autumnale*. It was formerly confounded with *Veratria*.

COLD-BLOODED. In Zoology, those animals are so called which have a range of temperature from a little above the freezing-point to 90° Fahr. and upwards, and which follow the changes of the surrounding medium through that range. Almost all invertebrate animals, and fishes and reptiles, amongst vertebrates, are "cold-blooded" in this sense.

COLISEUM. *See* AMPHITHEATRE.

COLLA′TERAL CIRCULATION. In Physiology, the passage of the blood from one part to another of the same system of vessels by collateral communicating channels: it is much more frequent in the veins than in the arteries.

COLLO′DION.* (Gr. κολλα, *glue*.) A term applied, in consequence of its adhesive properties, to a solution of gun-cotton in ether.

COLOBO′MA. (Gr. κολοβοω, *I contract*.) The adhesion of the eyelids. Congenital fissures of the upper eyelid.

COLOGNE EARTH. A deep brown pigment, or species of umber. It is supposed to be of vegetable origin.

COLUMN. In Anatomy, the term is applied to longitudinal portions or tracts of the myelon, of which there are three in each lateral moiety, called from their situation in the upright posture of man, "anterior," "middle," and "posterior," columns.

COLU′MNÆ CARNEÆ. (Lat.) In Anatomy, the fleshy prominences from the inner surface of the ventricles of the heart. Some are conical, with free apices giving attachment to the threads "chordæ tendineæ" attached to the valves; others extend from one part of the walls of the ventricle to another, and are sometimes called "trabeculæ."

COMBU′STION-HEAT. A term given by Liebig to the animal heat generated by the union of the oxygen absorbed into the blood from the atmosphere with the carbon and hydrogen taken into the system as food.

COMBUSTION, SPONTANEOUS. *See* IGNITION, in DICT.

COME′NIC ACID. When a solution of *meconic* acid in water, or in dilute sulphuric acid, is long boiled, or when dry meconic acid is heated to 400°, it is converted into a modified bibasic acid, water and carbonic acid being at the same time evolved. The formula of comenic acid is $C_{12}\ H_2\ O_8 + 2\ H\ O$.

COMMUNISM. *See* RIGHT OF PROPERTY and SAINT SIMONIANS, in DICT.

COMPASS OF THE VOICE. In Physiology is the number of notes of the musical scale comprehended in the voice of a singer: it usually extends from two to three octaves.

COMPENSATION PENDULUM. *See* PENDULUM.

COMPOST, vulgarly called COMPO. *See* CEMENT.

COMPLEMENTARY COLOURS. In Optics, two colours are said to be complementary to each other which are such that the blending together of the two gives rise to the perception of whiteness. According to the Newtonian theory, a beam of white light is resolved by the prism into rays of seven primary colours: if, therefore, the rays of one colour be intercepted, the composition of the remainder will give the complementary colour. Or, adopting the simpler supposition of Mayer, that all colours are produced by the mixture of three primitive colours—*red*, *yellow*, and *blue*—in certain proportions, then, on intercepting the red rays in a beam of white light, the remaining yellow and blue rays will give the colour arising from the mixture of yellow and blue, namely green, so that red and green are complementary colours. In like manner as a mixture of red and yellow gives orange, and a mixture of red and blue gives violet, orange is the colour complementary to blue, and violet to yellow. *See* CHROMATICS, in DICT.

CONDUCTION OF IMPRESSIONS. In Physiology, is the propagation of that state or action of a nerve-fibre, which is produced by the application of a stimulus, through the whole length of the fibre; it takes place with immeasurable rapidity, in the same way as electricity is said to be conducted along a wire.

CONSE′NSUAL MOVEMENTS. In Physiology, when one motion gives rise to the production of other motions contrary to or independent of the will, they are so called: as, e. g., the contraction of the iris when the eye is voluntarily directed inwards.

CONTRACTI′LITY. In Physiology, is the power which certain tissues have, during life, of shortening themselves in a peculiar manner: it is usually observed in muscular and some kinds of fibro-cellular tissue; but is also exercised by series of cells, as in the *Hydra* polype.

CONVOLU′TIONS. (Lat.) In Anatomy, the winding folds of the superficial layer of the brain; and also the coils and turns of the intestinal tube.

COPYRIGHT, INTERNATIONAL. A literary treaty of vital importance to the interests of authors, translators, composers, painters, sculptors, or engravers, was agreed to between France and England in 1851. The French enactment contains fourteen separate articles, and by the fourteenth it is stipulated that, after its legislative sanction by the British parliament, a day shall be fixed on which the following important privileges shall be granted to all works published subsequent to its date. The authors of literature or of art of either nation are to exercise the same rights with respect to their productions in the country in which they were not originally published as are granted to authors of similar works when first produced in that country. Authors of either nation will be entitled in both coun-

tries to the protection of the laws which are or may hereafter be in force in England or France for the suppression of piracy. Translators, under certain conditions, are to enjoy the same privileges as original authors. Nevertheless it is only in the case in which an author chooses to reserve to himself the exclusive right of translating his own original work that the law prohibits independent translations of the same work. To reserve to himself this exclusive right of translation for five years in either country, the author must have registered and deposited his original work within three months from the day of its publication in the other country; he must have declared in the title-page his intention of reserving this right; the translation must appear in part at least within three years from the date of the deposit, and when eventually published in either country must be legally registered.

These stipulations apply also to all species of original dramatic works and musical compositions. Nevertheless, the prohibitions against translations are not intended to apply to imitations or adaptations of works suitable to the theatres of either country. All pirated works, whether printed in France, England, or elsewhere, are to be considered as contraband, to be seized and destroyed, and the persons introducing or selling them to be liable to prosecution. The question of piracy is in all cases to be determined by the legal courts of the country in which the act has been committed. The treaty, which is only to be applicable to works which shall be published after the day upon which it shall come into operation, is to remain in force for ten years from that day, and to continue to exist until a year's notice of cessation shall have been given.

CO'RIUM. (Lat.) In Anatomy, is the basis of the skin, or "true skin," and consists of a vascular and fibro-cellular tissue, of interlaced dense, but elastic, filaments. It rests on the subcutaneous cellular tissue, and is covered by the cuticle or "scarf-skin."

CORPUS CALLO'SUM. (Lat.) In Anatomy, the great commissure, or band of transverse fibres, connecting the hemispheres of the cerebrum.

CORPUS LU'TEUM. (Lat.) In Anatomy, a yellowish mass which is formed in a Graafian vesicle subsequent to the escape of an ovum. It is largest, most conspicuous, and lasting, after the escape of an impregnated ovum in the human subject.

COU'PLING. In Machinery, this term is applied to any contrivance for connecting or disconnecting the different parts of a machine, and particularly for effecting the longitudinal connexion of shafts. *Hook's Joint* (Dict. of Science) is one of the most ingenious of the contrivances of this kind. (See Buchanan's *Practical Essays on Mill Work, &c., with Additions*, by Tredgold and Rennie.)

COU'NTERPOISE. In Mechanics, a mass of metal connected with an instrument or machine, either for the purpose of giving steadiness, or diminishing the pressure on some particular point, as, for example, the pressure of the pivots of a transit-instrument on its supports.

CRAB. A machine for raising weights, consisting of a horizontal barrel, usually turned by a winch handle, and having a rope wound round it, which, when the weight is to be raised to a greater height than the machine, passes over a pulley fixed on the scaffolding. *See* Windlass.

CRE'ATINE. *See* Kreatine.

CRE'NIC ACID, or KRENIC ACID. (Gr. *κρηνη, a fountain.*) A term applied by Berzelius to a species of extractive matter occurring in spring-water.

CRI'SPITE. A mineralogical name of the *titanite.*

CROCO'NIC ACID. (Gr. *κροκος, saffron.*) A yellow substance resulting from the action of potassium on carbonic oxide. It is difficulty soluble, and of a sour astringent taste. Its composition is $C_5\ O_4$, H O.

CRO'NSTEDITE. A hydrated silicate of iron from Pritzbram, in Bohemia. It was originally regarded as a species of tourmaline.

CROSS FLOOKANS. A name applied by the miners of Cornwall to veins of stony matter running North and South.

CROWN GLASS. The glass usually employed for windows: it differs from *flint glass* in containing no oxide of lead.

CRU'OR. (Lat.) In Anatomy, the substance contained in the red discs or corpuscles of the blood.

CRU'RA. (Lat. *crus*, the leg.) In Anatomy, are the bundles of nervous fibres which expand into the hemispheres of the cerebrum (crura cerebri), or of the cerebellum (crura cerebelli).

CUBE ORE. A hydrated arseniate of iron, crystallising in cubes.

CUBE SPAR. A synonym of the *anhydrite* or anhydrous sulphate of lime.

CU'BIZITE. A mineralogical synonym of the *cubic zeolite* or *analcime.*

CURVOGRAPH. *See* Arcograph.

CYCADEOI'DEA. A name given by Buckland to a genus of fossil dicotyledonous plants: the genus *Mantellia* of Brongniart.

CY'CADITES. A genus of dicotyledonous fossil plants.

CYCLOGRAPH. *See* Arcograph.

CY'PRINE. A variety of the green garnet, or *grossularia.*

CYSTINE. A term applied by some chemists to the *cystic oxide*, a constituent of certain urinary calculi.

CY'TISINE. A purgative bitter principle, extracted from the *Cytisus alpinus.*

CY'TOBLAST. (Gr. *κυω, I hold; βλαστη, a sprout or growth.*) In Physiology, the nucleus, cellule, or centre of assimilative force, from which the organic cell is developed.

CY'TOBLASTE'MA. (See above.) The structureless substance in which the elementary nuclei, cellules, or cytoblasts, are imbedded.

D.

DA'NAIDE. In *Hydronamics*, a machine put in motion by the power obtained from a fall of water applied in a particular manner. A cylindrical trough of tin-plate is fixed to a vertical axis of iron, which passes through the middle of a hole in the bottom of the cylinder, the diameter of the hole being somewhat greater than that of the axis, so as to allow the water to escape. A drum of tin-plate, close above and below, is also fixed upon the axis, and placed within the trough; its diameter being so much less than that of the trough that a clear cylindrical space of about an inch and a half in thickness is left between the outer circumference of the drum and the inner circumference of the trough; and the bottom of the drum is also about an inch and a half from the bottom of the trough. This space between the two bottoms is divided into compartments, by diaphragms radiating from the axis to the circumference of the drum. Into the space between the two cylinders water is made to fall from a reservoir above, through one or more pipes, the ends of which are bent into a horizontal direction, so that the water escapes in the direction of a tangent to a horizontal section of the cylinders, and, impinging on the interior surface of the trough, communicates a circular motion to the machine. The water between the cylinders thus acquires a centrifugal force, in consequence of which it presses against the interior surface of the trough and the diaphragms on the bottom; while, on the other hand, the action of gravity constantly tends to make it run out at the hole in the bottom. The moving power is measured by the weight of water escaping from the supply pipes multiplied into the height of the reservoir, and the useful effect by the same product diminished by half the force which the water retains when it issues from the hole in the bottom of the cylinder. (*Encyc. Brit.* art. *Hydrodynamics.*)

DA'TISCINE. A name given by Braconnot to a substance having the appearance of grape sugar, which he extracted from the *Datisca Cannabina.*

DAU'RITE. A variety of Tourmalin.

DA'VIDSONITE. A mineral discovered by Dr. Davidson in the granite quarry of Rubislaw, near Aberdeen: it is a *Silicate of Alumina.*

DECI'DUA. (Lat.) In Anatomy, a product or an alteration of the mucous membrane of the uterus, preparatory to the reception of the impregnated ovum, which is discharged at parturition. When the ovum enters the womb it becomes imbedded in the decidua, which yields and is protruded inwards, and becoming more and more inverted as the ovum grows, it is called the "decidua reflexa," while the other part of the membrane is called the "decidua vera."

DECLINO'METER. An apparatus for measuring the declination of the magnetic needle, or the force of terrestrial magnetism in the plane of the horizon. *See* Magnetometer.

DEGREES OF LATITUDE AND LONGITUDE. The most important operation executed of late years in connexion with the measurement of terrestrial degrees, of which the results have been published, is the prolongation of the great meridional arc of India, described by Colonel Everest in his Account of the Measurement of two Sections of the Meridional Arc of India, bounded by the parallels 18° 3′ 15″, 24° 7′ 11″, and 29° 30′ 48″, published in 1847. Of these two sections, the southern one, extending from Damargida to Kalianpur, had been previously measured, and the result is referred to under the article Degree (Dict. of Science); but on account of the state of the instruments the result was not considered as altogether satisfactory; and accordingly, when a new measuring apparatus and astronomical instruments of a better description had been provided for the purpose of extend

ing the arc to the northward, the Directors of the East India Company sanctioned the repetition of the whole operation. The northern section, from Kalianpur to Kaliana, embraces an arc of rather more than 5° 23′. Adding both sections to the arcs formerly measured by Colonel Lambton, the result is the "Great Meridional Arc of India," extending from Punnæ, near Cape Comorin (lat. 8° 9′ 31″) to Kaliana, near the base of the Himalayas (lat. 29° 30′ 48″), and including 21° 21′ 17″ of the meridian—the longest continuous line which has been measured on the surface of the earth.

Colonel Everest's measurement was executed with extraordinary care, and with instruments sufficient to ensure the utmost attainable accuracy. Three base lines, each exceeding seven miles in length, were measured with a compensating apparatus similar to that invented and used by General Colby for the measurement of the base of the trigonometrical survey of Ireland. The terrestrial angles were observed with theodolites of three feet in diameter, and the two celestial arcs were determined by observations of stars made simultaneously at both extremities of each arc with altitude and azimuth circles, having vertical circles also of three feet in diameter. The final results were as follows: the amplitude of the celestial arc corresponding to the northern section, Kaliana to Kalianpur, was found by the mean of all the observations to be 5° 23′ 37″·051; and that of the southern, Kalianpur to Damargida, 6° 3′ 55″·973. The terrestrial distances on the meridian, computed from the mean of the two bases (near the extremities of each section), and reduced to the level of the sea, were 1961157·117 feet, and 2202926·196 feet respectively. Hence the length of the meridional degree, as found from the northern section, is 363606 feet, or 68·865 miles, at the middle latitude 26° 49′, and as found from the southern section is 363187 feet, or 68·785 miles, at the mean latitude 21° 5′. The comparison of the two arcs, without reference to other measures, gives an ellipticity to the terrestrial spheroid of 1÷192, considerably greater than the ellipticity deduced from the results (properly combined) of all the principal operations of the same kind executed in different countries, namely 1÷300, and consequently indicating some irregularity either in the curvature of the earth at that locality, or in the density of the superficial strata, giving rise to local attraction at the terminal stations.

The long-protracted operations connected with the trigonometrical survey of the British Islands are now, it is understood, approaching completion, and one of the results will be the prolongation of the arc of meridian, which was measured about the beginning of the century between Dunnose in the Isle of Wight and Burleigh Moor in Yorkshire, to Balta in Shetland, the amplitude or difference of latitude of the extreme stations being 10° 7′ 55″·28. The astronomical observations made at the extreme and several intermediate stations were published in 1842; and as the principal triangles of the southern sections have been observed anew, and the distances have been computed from the base measured in Ireland, the result will be entirely independent of the previous work. A base of verification was measured on Salisbury Plain in the summer of 1849, and it is understood that the calculations are now completed and ready for publication.

Degrees of the meridian have now been measured under so many latitudes in the northern hemisphere that it is not probable the general elements of the terrestrial spheroid, as already determined, will be much disturbed by any future operations. The distance between the parallels of Kaliana, Col. Everest's northern station, and Formentera, the southern extremity of the French arc, is only about nine degrees; and with the exception of this interval, and another of about five and a half degrees between the parallels of the northern extremity of the Russian arc and the southern extremity of the Swedish, the whole distance (though in different meridians) has been measured between the parallels of Punnæ (lat. 8° 9′ 31″) and Pahtavara (lat. 67° 8′ 49″), being nearly two-thirds of the distance from the Equator to the Pole. In the southern hemisphere an arc of about four degrees has been recently measured by Mr. Maclear, near the Cape of Good Hope, the details of which have not yet been published; but the operation is of peculiar interest on account of the anomalous result obtained by Lacaille in the same locality about the middle of the last century, which led to the inference that the two hemispheres are dissimilar. Mr. Maclear has, however, made it known that the anomaly in Lacaille's result was caused by local attraction, and that the extended measure proves the length of the meridional degree at the Cape to be the same as in the northern hemisphere under the corresponding latitude.

In the year 1841 the astronomical arc of longitude between the Royal Observatory at Greenwich and the island of Valentia on the west coast of Ireland was determined by means of pocket chronometers carried forwards and backwards repeatedly between the two places (or rather between Greenwich and Kingston (Dublin) and Kingston and Valentia, the operation being divided into distinct parts), under the superintendence of the Astronomer Royal. The number of chronometers employed was thirty, and the number of journeys eight or ten. By this means the difference of apparent time was ascertained probably with greater certainty than could be done by the method of fire signals, hitherto chiefly relied on for this purpose, but scarcely available for so long an arc. The geodetical distance on the parallel of latitude being computed from data furnished by the trigonometrical survey and assumed elements of the earth's figure, and the result converted into time, it was found that the difference between the computed arc and the chronometrical arc amounted only to a small fraction of a second. The inference from this agreement is, that the assumed elements of the spheroid represent the curvature of the earth at this locality so accurately as to require no correction. As a definite result they give the length of 1″ in the arc perpendicular to the meridian in latitude 51° 40′ equal to 101·6499 feet.

The conveyance of local time from one place to another, by means of chronometers, has also been adopted for determining the differences of longitude between Greenwich and some of the principal observatories on the continent. A still better means is now becoming available, in the use of the electric telegraph, which has already been applied to this purpose in America, and by which instantaneous signals may be transmitted to any distance, however remote. The preparations are nearly completed for connecting Greenwich immediately with all the great continental observatories, by means of wires communicating with the terminus of the Dover railway.

The following elements of the spheroid of rotation, deduced by Bessel from the principal measures of meridional arcs, may be considered as representing, with the most probable accuracy, the present state of our knowledge on this subject:—

Equatorial radius 20923600·00 feet,
Half the polar axis 20853657·16 feet,
Ratio of equatorial to polar axis 299·1528 : 298·1528,
Ellipticity$=1\div299{\cdot}1528={\cdot}003342773$.

Let l denote the latitude, m the length in feet of a degree of the meridian between two parallels whose latitudes are respectively $l-\frac{1}{2}$ and $l+\frac{1}{2}$, and p the length of a degree of the parallel circle at latitude l; then

$$m=364575{\cdot}6-1831{\cdot}0 \cos. 2\,l+3{\cdot}9 \cos. 4\,l-\&c.$$
$$p=365491{\cdot}2 \cos. l-305{\cdot}8 \cos. 3\,l+0{\cdot}4 \cos. 5l-\&c.$$

from which formulæ the degrees of the meridian and parallel at any latitude are readily computed.

DELPHI′NIC ACID. A fat-acid obtained by saponification from the oil of the *Delphinus* or porpoise: it has also been termed *phocenic* acid. It exists in the vegetable kingdom in the berries of *Viburnum Opulus*.

DE′LPHINITE. A variety of *Epidote* from Dauphiny.

DE LUC'S COLUMN. An alternation of different substances, such as silver, zinc, and thin paper; which produce an electric arrangement. It is sometimes called the *dry pile*.

DE′NTINAL TUBES. (Lat. dens, *a tooth*.) The subparallel branching tubes which radiate from the pulp-cavity of a tooth at or nearly at right angles with the periphery of the dentine: they have a diameter of $\frac{1}{10000}$ th of an inch, at their origin, in the human teeth, and consequently admit only the plasma, or colourless liquor of the blood.

DE′NTINE. (Lat. dens, *a tooth*.) The fundamental and most constant substance or tissue of which a tooth is composed. It consists of an organised animal basis disposed in the form of extremely minute tubes and cells, and of earthy particles, which have a two-fold arrangement, being either blended with the animal matter of the interspaces and parietes of the tubes and cells, or contained in a minutely granular state in their cavities.

DEO′DORIZERS. A term applied to a class of disinfectants especially characterised by their power of destroying fetid effluvia: chlorine and several of its compounds come under this class: chloride of zinc and nitrate of lead, which are active in decomposing sulphuretted hydrogen, are also *deodorizers*. Some kinds of charcoal, and especially that obtained from peat, when mixed with manure or excrement, not only destroys the odour, but forms an excellent compost for agricultural purposes.

DEOXYDI′ZEMENT, or DEOXYDATION. The chemical process of the abstraction of oxygen: these terms are synonymous with *reduction*. A compound of a metal with oxygen may for instance in many cases be reduced or deoxydized by heating it with carbon, or in a stream of hydrogen gas, in which case it is subjected to the process of *deoxydation*, and the metal set free.

DE′SMINE. (Gr. δεσμη, *a bundle*.) A variety of foliated *Zeolite*.

DESMO'LOGY. (Gr. δεσμος, *a chain*, and λογος, *description*.) That part of anatomy which relates to tendons and ligaments.

DEVE'LOPMENT. In Physiology, is the process by which each tissue and organ of the body is formed, and subsequently transmuted, so as to be adapted to the actions of the most perfect state of the individual.

DEVO'NIAN SYSTEM. In geology, comprises the *Old Red Sandstone*. *See* GEOLOGY, in DICT.

DE'VONITE. A mineralogical synonym of the *Wavellite* or *Hydrargyllite* of Barnstaple in Devonshire.

DIALU'RIC ACID. A crystalline acid having the formula $C_8\ H_3\ O_7\ N_2, + HO$, obtained by the action of sulphuretted hydrogen on a boiling solution of alloxan.

DIAMAGNE'TIC. A term applied to bodies which appear to be *repelled* by either pole of a magnet; as opposed to the term *magnetic* bodies, the particles of which are *attracted* by either pole.

DIAPHORE'TIC ANTIMONY. In old pharmacy this term has been applied to the peroxide of antimony, and also to the antimoniate of potassa, obtained by deflagrating a mixture of antimony and nitre.

DIAPO'PHYSIS (Gr. δια, *through*; αποφυσις, *process*). In Anatomy, the upper of the two transverse processes which project from the sides of the cervical and anterior dorsal vertebræ of the crocodile, and which is usually anchylosed with a rudimental rib in the cervical vertebræ of birds and mammals; in these it forms the sole "transverse process" of the succeeding vertebræ, and is usually developed from the neural arch.

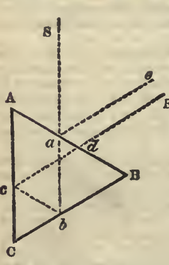
DIATO'NIC SCALE *of Colours*. Newton found, or supposed, that the spaces occupied by the seven primary colours in the solar spectrum are exactly proportional to the lengths of chords that sound the seven notes in the diatonic scale of music. On this assumption the spaces occupied by the different colours are as the intervals of the numbers $1, \frac{8}{9}, \frac{5}{6}, \frac{3}{4}, \frac{2}{3}, \frac{3}{5}, \frac{9}{16}, \frac{1}{2}$, which form the diatonic scale. It is now known, however, that the relative lengths of the spaces occupied by the different colours in the spectrum depend on the nature of the substance of which the refracting prism is formed. *See* CHROMATICS, in DICT.

DICTIOPHY'LLUM. A name given by Lindley and Hutton to a fossil leaf first described by Phillips, from the upper sandstone, shale, and coal of the Yorkshire oolite. The term *Dictiophyllum* is employed to designate all fossil leaves of a common reticulated structure, while the term *phyllite* is applied to leaves whose principal veins converge both at the base and apex.

DIE'DRAL or DIHE'DRAL. In *Geometry*, a diedral angle is the angle or corner formed by the intersection of two planes.

DIPLEI'DOSCOPE. (Lat. duplex, *double*, Gr. σκοπεω, *I view*.) An optical instrument for indicating the passage of the sun, or a star, over the meridian, by the coincidence of two images formed by a single and double reflexion.

The instrument is constructed as follows: A B, A C, and B C are three reflecting planes, one of which, A B, is transparent, and the other two of silvered glass, the three forming an equiangular prism. Suppose the side A C to be placed exactly in the plane of the meridian, and a pencil of light proceeding from the sun, S, to fall upon the transparent plane A B at *a*, in the direction S *a* parallel to A C. A portion of this light will be reflected from *a* in the direction *a e*, which is such that the angle *e a* B is equal to S *a* A. Another portion of it will pass through the transparent plane A B, and, proceeding in the same direction, will fall on the silvered mirror at *b*, where it will suffer a total reflexion in the direction *b c*, and, falling on the second silvered mirror at *c*, will be again reflected in the direction *c d*, and will pass through the transparent plane A B, and continue its course in the same direction *c d* E. Now, the angles of incidence and reflexion being equal, when S *a* is parallel to A C, then *b c* is parallel to A B, and *c d* to C B, and the direction *d* E to *a e*, so that an eye at E or *e* will see only a single image of the sun S. But if S *a* be not parallel to A C, then *d* E will not be parallel to *a e*, and a double image will appear. Suppose, for instance, the sun's course to be in the direction from A towards B; then, before the sun comes to the meridian, the pencil of light S *a* will make with A B an angle S *a* A less than 60°. Consequently, the reflected ray *a e* will make the angle *e a* B less than 60°. But in this case the angle E *d* B will be greater than 60°, and therefore two images will be seen by the eye at E, one in the direction *e a*, and the other in the direction E *d*. The first of these will appear to move with the sun in the direction A B, and the second in the opposite direction B A; they will approach each other until S *a* becomes exactly parallel to A C, when they will coincide; after this, as the angle S *a* A becomes greater than 60°, they will separate, and gradually pass off the field, one at B, and the other at A. Hence it is evident that if A C be in the plane of the meridian, the instant of the coincidence of the two images will be that of apparent noon.



When used as a meridian instrument, the dipleidoscope must be fixed so that one of the reflecting planes, A C, is exactly vertical, and also in the meridian. The latter adjustment may be made by any of the means which suffice for fixing a sun-dial, or for drawing a meridian line; the former, by suspending a fine plumb-line a few feet before the transparent glass, and moving the instrument slowly about the edge A C till the two images of the line become exactly parallel. These are the only essential adjustments; but it is convenient also to fix the instrument so that the lines of intersection of the three planes may be parallel to the axis of the earth's rotation, in order that the sun's greatest altitude above the plane of the instrument at midsummer may be equal to his greatest depression below it at midwinter. On account of the intense light of the sun, the eye must be protected by a coloured glass; and the field of view may be magnified by a small telescope. Three observations should be made; the first, of the instant at which the two images come into contact; the second, of the instant at which they exactly coincide; and the third, of the instant at which they separate. The instrument, if accurately made and fixed, is capable of giving true time within a fraction of a second.

The dipleidoscope is a patent instrument, the property of Mr. Dent, chronometer maker, of the Strand, who has published a popular description of it in a small pamphlet, in which he states that the idea was first suggested by Mr. Bloxam, but that the original form has been much improved and simplified. From its small size, and the facility of the observation, it may be conveniently employed for the regulation of time-keepers in circumstances under which recourse cannot be had to a transit instrument.

DI'STHENE. One of the varieties of *Cyanite*.

DITHIO'NIC ACID. (Gr. δις, *twice*, and θειον, *sulphur*.) Berzelius applies this term to the *hyposulphuric acid;* and he calls the hyposulphurous acid, *dithionous*. The term implies the existence of *two* atoms of sulphur in each of these acids.

DOBEREI'NER'S LAMP. A small instrument for obtaining instantaneous light, in which a jet of hydrogen gas is inflamed by coming into contact with spongy platinum.

DO'MITE. A white mineral found in the Puy de Dome, in Auvergne.

DRU'MMOND'S LIGHT. The name given to the light produced by directing a stream of oxygen gas passing through the flame of alcohol upon a small ball of quick lime. The light produced by burning lime in this manner is of extreme intensity, and Mr. Drummond, of the Engineers, while engaged in the trigonometrical survey of Ireland, suggested its use as a signal for the observation of distant stations. For this purpose the ball of lime, about a quarter of an inch in diameter, was placed in the focus of a parabolic mirror, the axis of which was directed to the point from which the observation was to be made; and such was the brilliancy of the light that it was sometimes distinctly seen, even in hazy weather, at a distance of upwards of sixty miles, when argand burners and other modes of illumination previously used were altogether ineffectual. But the use of this signal is found to be attended with some inconveniences, and the heliostat is now generally preferred in geodetical operations. (See Lieut. Drummond's paper in the *Philosophical Transactions* for 1826.)

DU'MASINE. An oily liquid obtained among other products, by distilling acetate of lime: its formula is $C_{10}\ H_8\ O$. It is named in compliment to the celebrated French chemist, Dumas.

DYNACTINO'METER. (Gr. δυναμις, *power;* ακτιν, *a sunbeam;* μετρον, *measure*.) An instrument for measuring the intensity of the photogenic (light-producing) rays, and computing the power of object glasses. It is described by Mr. Claudet in the *Philosophical Magazine* for June, 1851.

DYNAM, or DYNAMICAL UNIT. For the purpose of measuring or comparing the moving power of machines, or the useful effect procured by the exertion of animal force applied in different ways, it is necessary to adopt some standard, or unit of force, and for convenience of explanation it is desirable the unit should be designated by an appropriate name. When the steam-engine came into use, the work accomplished by it in a given time was naturally compared with that of the

moving power which it most frequently superseded; hence the term *Horse-power*, which was originally used by Watt to denote, in a rough way, the force developed by a horse of average strength drawing a load during twenty-four hours without intermission. Watt subsequently gave a definite signification to the term, by defining it to be the force which suffices to raise a weight of 32,000 lbs. avoirdupoise to the height of one foot in one second of time. C. Dupin, in his *Géometrie des Arts et Métiers et des Beaux-Arts*, proposed the term *Dyname* to denote the unit of moving force, represented by one cubic metre of distilled water at its maximum density raised to the height of one metre in an astronomical day. Dr. Whewell, in his *Mechanics of Engineering*, recommended the adoption of the English synonyme, *Dynam*, to represent the effect equivalent to a weight of one pound raised to the height of one foot in a second. The terms *efficiency*, and *duty*, are frequently applied in a similar sense.

DYNA'METER. In Optics, an instrument for measuring the magnifying power of a telescope. The magnifying power is the ratio of the solar focal distance of the object glass to the focal distance of the eyepiece considered as a single lens; and this ratio being the same as the ratio of the diameter of the aperture of the telescope to the diameter of its image or disc formed at the solar focus, and seen through the eyepiece, the object of the instrument is to measure the exact diameter of this image, which, not being projected on any solid body, can only be measured by optical means. Ramsden proposed for this purpose the double image micrometer (Micrometer, in Dict.), an instrument formed by dividing the eye lens of a positive eye-piece into two equal parts, and mounting them so that the divided edges are made, by means of a fine screw-apparatus, to slide along each other. Each semilens thus gives a separate image, and the distance of the two centres, measured by the revolutions of the screw, when the borders of the two images are brought exactly into contact, gives the distance of the centres of the images, or the diameter of one of them. The construction of this dynameter has been improved by Dollond. (Pearson's *Practical Astronomy*, vol. ii.)

E.

EAR TRUMPET, or HEARING TRUMPET. An instrument for aiding defective hearing. The ordinary ear trumpet consists of a metal tube, usually of a conical shape, the wide end being turned towards the speaker to collect the waves of sound, and the narrow end terminating in a small tube, and bent sideways so as to enter the ear of the deaf person. Various other instruments besides the *trumpet* are used for the same purpose. The *Auricle* is a small scroll-shaped instrument which is worn in the ear, the expanded mouth only being visible. *Ear-cornets* are applied outside the ear, and held in their place by a slender steel spring, a bent tube entering the ear in this case, as in that of the common trumpet. Flexible tubes, made of India rubber covered with silk, and kept open by a spiral spring of wire, terminating at one end in a tube, which enters the ear, and in a cup or hollow hemisphere at the other, into which the speaker speaks, are found to be of great efficiency. *Sonifers* are large bell-shaped instruments of metal, which are placed on a table, and turned towards the part of the room whence the sound proceeds, and the sound being collected at the bottom of the instrument is conveyed to the ear by a flexible tube. With respect to acoustic instruments in general, it does not appear that mathematical accuracy of figure is of much importance. Whatever prevents the dispersion of the undulating air, and directs it upon the tympanum, will partially assist hearing, though, of course, it is advantageous that as much as possible of the sound which enters the instrument should be reflected forward to the ear.

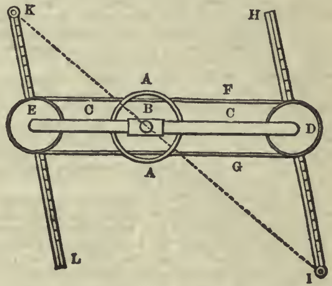
ECDY'SIS. (Gr. εκδυσις.) The act of stripping. The moulting of the skin.

EGE'RIA. One of the small planets between Mars and Jupiter. It was discovered at Naples on the 2nd of November, 1850, by Dr. De Gasparis (who had previously discovered Hygeia and Parthenope), and is the 13th of the group in the order of discovery. *See* Planet.

EI'DOGRAPH. (Gr. ειδος, *form;* γραφω, *I describe.*) A copying instrument invented by Professor Wallace, of Edinburgh, by which copies of drawings are made, reduced, or enlarged in any proportion within certain limits. It answers the same purposes as the ordinary pentagraph, but is more convenient and accurate.

The geometrical theory of this ingenious instrument is contained in the following proposition: "If two lines which contain a given angle turn in a plane about a fixed point at their intersection and have to each other a constant ratio, and the moving extremity of one of them trace a line of any kind, the extremity of the other will trace a similar corresponding line, and these two lines will have to each other the constant ratio of their distances from the centre of angular motion." To apply this property mechanically it was necessary to connect two material points moving on a plane (the tracer and the pencil) in such a way that straight lines drawn from them to a fixed centre should contain a given angle, and have to each other a given ratio. It is convenient to take the given angle equal to 180°, in which case the two moving points are in the same straight line with the centre, and on opposite sides of it.

The instrument is represented in the annexed figure.



A beam, C C, about 30 inches in length (formed of a hollow rectangular prism of brass, in order to combine strength with lightness), passes horizontally through a socket B B, attached to the top of a strong steel conical axis, which turns in a tube rising perpendicularly from the centre of a mass of metal, A A, forming the base of the instrument, and heavy enough to afford a steady support. The beam thus turns freely about the steel axis, and may be clamped at any point. Two wheels, D, E, of exactly the same size, are attached to the beam, at its extremities, by means of steel axes screwed to the wheels and entering upright sockets fixed to the beam. The wheels are connected by a metallic band, F G, part of which (as much as is applied on the wheels in making about half a revolution) is formed of thin and narrow watch spring; and they are crossed by two arms, H I and L K, about 27 inches in length, which slide through sockets placed under the centres of the wheels, and must be placed truly parallel. Both the beam and the arms have a scale of equal parts engraved on them for the purpose of adjustment.

Suppose the beam and the two arms respectively clamped in their sockets in such wise that the beam is divided at the axis b in any given ratio, and D I is equal to D b, and E K to E b; then, on turning the beam about its axis, the two arms will manifestly retain their parallelism, and the three points, I, b, K, will be always in the same straight line; consequently, in virtue of the geometrical theorem above enunciated, the two points, I and K, will have similar corresponding motions, and the lines traced by them will always be in the ratio of D I to E K. It only remains, therefore, to attach a tracing point at I, and a copying point (a pencil) at K, in order to complete the construction. These are placed in vertical tubes, and carefully adjusted to the centres of the tubes. The tracer is guided by the right hand over the contour of the figure to be copied, and the pencil accurately follows its motions, describing a similar but reversed figure on a sheet of paper placed under it. The pencil is pressed down by a small weight, and is raised from the paper, when required, by means of a rectangular lever, one end of which is connected with the pencil-carrier, and the other moved by a string which passes over a pulley, and is held by the operator in his left hand. In order to facilitate this motion the pencil is kept steadily in its place, and at the same time prevented from pressing against the tube, by small friction-wheels fixed in the tube. The motion is extremely free, and with a little practice the outlines of even the most complicated figures, anatomical drawings for example, are copied with great facility and perfect precision.

By combining two instruments adjusted to make reduced copies the reduction may be carried by a single operation to a much greater extent than could be done by one instrument. For obvious reasons, the power of enlarging a figure is more limited. Professor Wallace, likewise, proposed a form of the instrument, by which a copy of any subject is produced so reversed as to have the appearance of the image of the subject as seen reflected from a plane mirror The Eidograph was

invented about 1821, and was first described in the *Transactions of the Royal Society of Edinburgh*, vol. xiii.; it is also described in Wallace's *Geometrical Theorems and Analytical Formulæ*, 1839.

ELAIO'METER. (Gr. ελαιον, *oil*, and μετρον, *measure.*) An instrument for detecting the adulteration of olive oil.

ELAO'PTENE. (Gr. ελαιον, *oil*, and πτημι, *I fly.*) The *liquid* portion of the volatile oils, when separated from the concrete, or crystallisable portion, which had been called *Stearoptene*.

ELE'CTRIC COLUMN. An electric instrument invented by Deduc, consisting of numerous alternating discs of silver leaf, zinc leaf, and paper. *See* ELECTRICITY, in DICT.

ELE'CTRO-MAGNE'TIC CLOCK. The discovery of the mutual relations of electricity and magnetism by Oersted in 1819, necessarily led to the construction of the *electro-magnet*, and amongst its numerous applications, that to *timekeepers* was perhaps one of the most obvious. By referring to the description which we have elsewhere given of the electro-magnet, it will be seen, that a bar of iron of any required form may have any amount of magnetism conferred upon it by proper adjustments of an electric current; and inasmuch as the magnetic power ceases the moment that the electric current is discontinued, so we are enabled to render an iron bar, or horse-shoe, a strong magnet at one moment, and at the next to withdraw all such force. It will be further obvious, that these magnets may be made and unmade at any distance, by an adequate extent of metal wire; so that at one and the same moment a magnet may be made and unmade at London and at Liverpool, and simultaneously, if we please, with the vibrations of the magnetic needle which announce the signals of the electric telegraph. And, of course, the magnet may be made alternately to lift and drop a weight, or to bend and release a spring, or to raise and depress a lever. Bearing these matters in mind, the *principle* of electric clocks will be intelligible, without entering into minute details respecting their varied mechanism.

There are several ways in which electro-magnetism has been applied to these purposes; one of the first consisted in fixing upon the arbor or axis of the seconds wheel of a clock a wheel or disc of metal, the circumference or edge of which was divided into sixty alternating divisions of metal and of ivory or wood, the metal being a conductor, and the ivory or wood a nonconductor of electricity. A small platinum peg, or point, was kept in contact with this divided edge, so as, by the revolution of the wheel, to be alternately in contact with the conducting and nonconducting surfaces, and so connected with a voltaic series, as alternately to admit and resist the passage of an electric current. In this way, supposing the clock in question to be keeping accurate time, one or more electro-magnets placed any where in the circuit of the conducting wire would be made and unmade at each succeeding second. Now it is easy so to connect an electro-magnet with a lever, as to give motion to a wheel and axle, and to cause it to revolve so as to indicate seconds, and when in communication with a proper train of wheels, to move the minute and hour hands of a clock; and this secondary, or *electro-magnetic clock*, would of course be regulated in its movements by the alternating electric current derived in the way we have mentioned, from the original time-keeper. Every clock, therefore, upon the circuit, would show the same time as that shown by the regulator; and in this way, one good regulator may be made to preside as it were over any number of electro-magnetic movements, each of which will indicate the same time.

Another form of the electro-magnetic clock is that in which the pendulum is itself kept in action by electro-magnetism, and through it the other movements of the clock are sustained; and this is effected either *directly*, as in Bain's clock, or *indirectly*, as in Shepherd's clock. In Bain's clock, the pendulum, at each vibration, moves a light slide by which the electric current is alternately completed and broken, and by which magnetism is alternately conferred upon, and abstracted from a coil enclosed in a heavy hollow brass case or tube, which constitutes as it were the bob of the pendulum, and on either side of which are the poles of two common, or permanent bar magnets, which alternately attract and repel the coil of the bob, as it is magnetised and demagnetised by the alternate presence and absence of the electric current. These clocks have been kept in motion by electric currents derived from a zinc plate buried in damp earth, and so far, therefore, independent of the usual forms of voltaic battery, in which the electricity is derived from the action of dilute sulphuric acid upon zinc.

The most recent form of electric clock is that invented and patented by Mr. Shepherd; the large clock at the Great Exhibition of 1851, in Hyde Park, was of this description, and it appears to possess several advantages. In this clock, electro-magnetism is the sole moving power, its force being employed, not only to give impulse to the pendulum and to propel the ordinary movement of the clock, but also to perform the striking of the hour, no auxiliary weights or springs being employed. The pendulum is so arranged as to make and break the electric circuit, and make and unmake a horseshoe magnet at each vibration. Each time that the magnet is made, it attracts its armature, which lifts certain levers; one of these is concerned in raising a weighted lever, and causing it to be held up by a latch or detent; the magnet is then unmade in consequence of the pendulum breaking the circuit, and its armature is released, when the pendulum lifts the latch and allows the weighted lever to fall, which, in falling, strikes the pendulum, so as to give it a certain adequate impulse; then the circuit is again completed, the armature attracted, the levers moved, the weight raised and held by the detent; another vibration breaks the circuit and then releases the armature; the pendulum then raises the detent, the weight falls, and in falling its arm strikes the pendulum and gives it its impulse, and so on.

But the pendulum at each vibration not only makes and breaks the electric circuit which maintains its own action, but also, and simultaneously, that of another battery, of which the duty is to make and unmake the electro-magnets belonging exclusively to the clock or clocks which are upon this circuit. These electro-magnets act upon the extremes of one or more horizontal bar magnets so as alternately to attract and repel their opposed poles, and which carry upon their axes the pallets, by the alternating motion of which to the right and left, the ratchet-wheel is propelled onwards at the rate of a tooth each second; and the axis of this ratchet-wheel carries the pinion which moves the other wheels of the clock.

The circuit of the battery connected with the *striking* part of the clock, is only completed once in each hour, and is connected with an electro-magnet so arranged as by means of a proper lever to pull the ratchet-wheel attached to the notched striking-wheel one tooth forward every two seconds, and each tooth is accompanied by a blow on an electro-magnetic bell. The number of blows depends upon the notched wheel, the spaces in the circumference of which are adapted to the number to be struck; and when this is complete, a lever falls into the notch, and in so doing cuts off the electric current, which is not re-established through the striking electro-magnet, till the completion of the next hour, when a peg upon the hour-wheel pushes the striking lever forward so as to cause it to be depressed by a similar peg on the minute wheel.

Electro-magnetic clocks are peculiarly fitted for all large establishments where many dials, each indicating the same time, are required; the pendulum by which the whole series is controlled is placed in some safe and quiet place, and the only requisite precaution for maintaining them in order consists in careful attention to the conditions and functions of the voltaic apparatus, or source of the electric current. Smee's batteries, as they are called, consisting of amalgamated plates of zinc in proper connexion with plates of platinum, or platinised silver, and immersed in dilute sulphuric acid, or in sand moistened with that acid, are generally used; the number and dimensions of the plates or cells depending upon the extent of wire which the electrical current is required to traverse, and care being taken that the chemical action of the acid upon the plates is as small and feeble as is consistent with the object in view. These clocks also promise to become importantly useful upon lines of railway, and for a variety of other purposes, more especially when some few difficulties attending their management and maintenance are overcome.

ELECTRIC TELEGRAPH. *See* TELEGRAPH, ELECTRIC.

ELECTRICAL EEL. *See* GYMNOTUS, in DICT.

ELECTRO'LYSIS, or ELECTRO-CHEMICAL DECOMPOSITION. (Gr. ηλεκτρον and λυω, *I dissolve.*) The separation of the elements of a compound by the transmission of electricity.

ELE'CTRO-BIO'LOGY. (Gr. ηλεκτρον; βιος, *life*, and λογος, *description.*) A term that has recently been applied to certain mental phenomena produced by various applications of Mesmerism to the human body.

ELE'CTROMETA'LLURGY. The electro-chemical precipitation of the metals, as applied to various purposes in the arts.

ELECTROMO'TOR, or ELECTROMOTIVE FORCE. Terms applied to the development of electricity in Voltaic arrangements.

ELE'CTRONE'GATIVES. Those substances which in electro-chemical decompositions make their appearance at the *anode* or electropositive pole. The term has reference to the mutual attraction of bodies dissimilarly electrical, and hence those which appeared to be attracted by the positive pole in the Voltaic circuit were presumed to have an inherent *Electronegative* state.

ELE'CTROPO'SITIVES. Bodies appearing in electrochemical decompositions at the *cathode* or electronegative pole.

ELE'CTROTYPE. An impression of a medal, or bas-relief, obtained by electric precipitation. *See* VOLTATYPE, in DICT.

ELE'CTROVI'TAL CURRENTS. Two electric currents are supposed by some physiologists to move in the nerves of animals: the one external and cutaneous, moving from the extremities to the *cerebro-spinal* axis; the other internal, and proceeding from that axis.

ELLIPTIC FUNCTIONS. In the higher mathematics the term *Elliptic Function* is used to designate any integral comprised in the formula $\int \frac{P\,d\,x}{R}$, in which P is a rational function of x, and R is a radical of the form $\sqrt{(\alpha+\beta\,x+\gamma\,x^2+\delta\,x^3+\varepsilon\,x^4)}$; $\alpha, \beta, \gamma, \delta, \varepsilon$, being constant quantities. Such integrals are called elliptic functions because they either contain, or are closely connected with expressions for the arc of an ellipse. The principal works on the subject are the following: *Exercises de Calcul Integral*, 3 vols. 4to. 1811; and *Théorie des Fonctions Elliptiques*, 3 vols. 4to. 1825—1828, by Legendre; *Œuvres de* N. H. Abel, 2 vols. 4to. 1839; and Jacobi's *Fundamenta Nova Theoriæ Functionum Ellipticarum*, 4to. 1829.

ELLIPTIC POLARIZATION. *See* POLARIZATION OF LIGHT.

ELVAN COURSES. In Mining, the term *Elvan* is applied by the Cornish miners to the porphyritic and other veins and masses which occasionally traverse granite and clayslate, deranging the direction of the metallic veins.

ENCKE'S COMET. *See* COMET, in DICT.

ENDE'LLIONITE. The triple sulphuret of antimony, lead and copper found in the mine Huel Boys, in the parish of Endellion, Cornwall.

ENDLESS SCREW. A piece of mechanism formed by combining the screw with a cog-wheel, or by making a screw act on the threads of a female screw sunk in the edge of the wheel. The axis of the screw may be either in the plane of the wheel, or at right angles to it; in the latter case it is called the American endless screw. In its mechanical principle the endless screw is a combination of the inclined plane and the lever.

ENDOSMO'METER. (Gr. ενδοσμωσις, and μετρον, *measure.*) In Physiology, an instrument invented by M. Dutrochet, to measure or demonstrate the rapidity with which one or other of two mixing fluids, of different densities, will pass into each other: and by which the less dense fluids are shown to pass with greater rapidity into the more dense fluids, than *vice versâ*; in other words, that "endosmosis" is more rapid than "exosmosis." A simple form of the instrument is a graduated tube, expanded into a bell at one end, over which a portion of membrane may be tied. If the bell be filled with a fluid of much density, such as a strong solution of salt, and be immersed in one of less density, as water, the water will endosmose, or pass into the solution more rapidly than the solution will exosmose or pass out. But if the water were put into the bell and the saline solution outside, the directions of the currents would be reversed. In both cases, however, the currents would continue until the two fluids were equally mixed on both sides of the membrane.

ENTHELMI'NTHA. *See* INTESTINALIA, in DICT.

ENTO'MOLINE. (Gr. εντομα, *insects*, and λινον, *thread.*) A chemical principle called also *Chitine*, found in the elytra and wings of insects.

E'NTROCHITE. (Gr. εν, *in*; τροχος, *a wheel*). A genus of fossils constituted of the petrified arms of the sea starfish.

EPENCEPHA'LIC ARCH. (Gr. επι, *upon* or *near*; εγκεφαλον, *the brain.*) The bony arch which encompasses and protects the epencephalon: it is composed of the basioccipital, exoccipitals and superoccipitals, and, in general anatomy, forms the neural arch of the occipital vertebra.

EPENCE'PHALON. (See above.) In Anatomy, the hindmost of the four primary divisions or segments of the brain, including the medulla oblongata, pons varolii, cerebellum, and fourth ventricle.

EPIDI'DYMIS. (Gr. επι, *upon*; διδυμοι, *turns*, or *the testicles.*) In Anatomy, a body formed by convolutions of the commencement of the sperm-duct or *vas deferens*, lying upon the testicle, and more or less closely attached to that gland. In anthropotomy the epididymis is divided into a *caput minor*, *corpus* and *caput major*.

EPIME'RAL. (Gr. επι, *upon*; μηρος, *a limb.*) In Zoology, the part of the segment of an articulate animal which is above the joint of the limb.

EPITHE'LIUM. (Gr. επι, *upon*; θηλη, *a teat.*) In Anatomy, a thin and delicate kind of cuticle, like that which covers the nipple. The term is now confined to the innermost layer of the internal cavities and canals of the body, which is analogous to the cuticle of the outer surface. The epithelia of the mucous membranes consist of the secreting cells of those surfaces, and are either "tesselated," "cylindroid," or "ciliated." The tesselated, or "*pavement epithelium*," is composed of flat, roundish, or polygonal cells, arranged in one or more layers, and is spread over the mouth, pharynx, and œsophagus, the conjunctiva, and the vagina; it is the kind of epithelium which most nearly resembles the external cuticle. A tesselated epithelium also lines most of the serous and synovial membranes, the vascular system, and the secerning tubuli and ducts of many glands. The *cylindroid* epithelium is composed of close-set cells of a conical or cylindrical form, and extends from the cardiac end of the stomach along the intestinal tract to the anus, and lines the principal gland-ducts which open upon this surface. It lines the ureters and urinary bladder, and the sperm-ducts.

The cells of the ciliated epithelium support at their free extremities fine pliant hair-like appendages called "cilia," which are in constant and rapid vibration: this kind of epithelium lines the whole respiratory tract, the interior of the cerebral ventricles, the uterus and oviducts, and the Malpighian capsules of the kidneys of the Batrachia.

EPIZOO'TIC DISEASES. (Gr. επι, *upon*, and ζωον, *an animal*). When diseases prevail among inferior animals, they are said to be *Epizootic*, corresponding to *Endemics* among men.

EQUA'TION, PERSONAL. The term *Personal Equation* has of late been introduced into Astronomy to denote the interval of time by which an observer, on the average of a number of observations, notes a phenomenon before or after the instant assumed to be that of its actual occurrence. If it were possible to determine the true instant of the occurrence of any phenomenon with absolute certainty, the personal equation of an observer would be the amount of error he is in the habit of making, or the probable error of a single observation made by him; but as the true instant of the occurrence can only be assumed by taking the mean of a number of observations, the term has only a relative signification. For instance, if, on comparing a number of observations of the same phenomenon by A and B, it be found that A notes the phenomenon, on the average, half a second sooner than B, then half a second is the *difference* of their personal equations; but this does not enable us to form any judgment with respect to the amount of error due to either, and it is only by a further comparison of observations made by A and B with those of other observers, that we are enabled to assume that the true instant at which the event occurred lies between the times noted by them respectively, or before or after both. If, however, it be assumed that either A or B observes correctly, then the personal equation of the other is half a second.

Generally speaking, the personal equation of an observer is a minute quantity, seldom exceeding a few tenths of a second, but it is sometimes found even in the case of experienced observers to amount to, or even exceed, a whole second. It is found to vary with the age of the observer, and may possibly at all times depend in some measure on the state of his health. The subject is treated at length in a *Memoir on the Difference of Longitude of Greenwich and Brussels*, by Prof. Quetelet and Mr. Sheepshanks, *Mémoires de l'Academie Royale de Bruxelles*, tom. xvi. See also Introductions to the volumes of the Greenwich Observations.

ERY'THRINE. (Gr. ερυθρος, *red.*) One of a series of substances obtained from the *Roccella tinctoria*, a lichen which furnishes the blue dye-stuff called *litmus*.

ERYTHROPHY'LLINE. (Gr. ερυθρος, *red*, and φυλλον, *a leaf.*) The *red* colouring matter formed in certain leaves, when they change into their autumnal tints.

ESMA'RKITE. A species of Datholite or Borosilicate of lime, discovered by Esmark at Arendal.

ESO'CIDÆ. (Lat. esox, *the pike.*) The *Pike tribe*, a family of *Malacopterygious*, or soft-spined fishes, having the ventral fins placed under the abdomen, and including most of the voracious fresh-water fishes, as well as several marine species.

ES'SONITE. A mineralogical synonym of the *Cinnamon Stone* of Ceylon: it is a silicate of lime, alumina, and oxide of iron.

ETHIO'NIC ACID. (Gr. αιθηρ, and θειον, *sulphur.*) An acid formed by the action of the vapour of anhydrous sulphuric acid on alcohol.

EUCHRO'NIC ACID. (Gr. ευχροος, *of a fine colour.*) An acid formed by the action of heat on the mellitate of ammonia.

EUCHYSI'DERITE. (Gr. ευχυειν, *to melt easily*; σιδηρος, *iron.*) A silicate of lime, magnesia, and protoxide of iron. A species of *pyroxene*.

EUDE'MONISM. (Gr. ευδαιμονια, *happiness.*) A term applied by some German philosophers to a system of moral philosophy which makes morality to depend on the production of happiness.

EU'DI'ALITE. (Gr. ευ, *easily*, and διαλυω, *I dissolve*;

from the facility with which it is gelatinised by the action of hydrochloric acid.) A mineral from Greenland, of a red colour, and in dodecaedral crystals: it contains silica, zirconia, lime, soda, and the oxides of iron and manganese.

EUGE'NIA. A genus of plants so named by Micheli in honour of Prince Eugene of Savoy, an eminent patron of Botany. It embraces the Eugenia caryophyllata, or Clove Tree, and the E. Jambos, or Malabar plum, the ripe fruit of which has the odour of the rose.

EUGE'NINE. A crystalline substance extracted by alcohol from cloves.

EUKAI'RITE. (Gr. ευκαιρος, *seasonable.*) A native seleniuret of silver and copper from Sweden.

EU'LYTINE. (Gr. ἐυ, *easily*, and λυω, *I dissolve.*) A mineral found at Freiberg, composed of silica, oxide of bismuth, and alumina.

EUNO'MIA. One of the small planets belonging to the group between Mars and Jupiter. It was discovered by M. De Gasparis at Naples on the 29th of July, 1851, and is the fifteenth in order of discovery. At its discovery it appeared like a star of the ninth magnitude. Four sets of elements of the orbit have been computed, but they exhibit greater differences than usual, the extreme values of the mean daily motion being 824″ and 955″. (*Monthly Notices of the Royal Astronomical Society*, vol. xi. No. 9.) See PLANET.

EUPATO'RIUM. (Eupator being the discoverer of its virtues.) The herb *Agrimony*, in common use in Holland as an alterative.

EUPE'PSIA. (Gr. ευ, *well*, and πεπτειν, *to concoct.*) Good digestion.

EU'PHOTIDE. (Gr. ευ and φως, *light.*) A rock consisting of felspar and diallage. It is the *gabbro* of the Italian artists.

EUPHRA'SIA. (Corrupted from *Euphrosyne:* from ευφρων, *merry*, because it exhilarates.) The name of a genus of plants: it includes the *E. officinalis* or *Eyebright*, much esteemed as a popular remedy for diseases of the eyes: it is also an ingredient in British herb tobacco.

EUPY'RION. (Gr. ευ, *easily*, and πυρ, *fire*). A term applied to several contrivances for obtaining instantaneous light; such as lucifer matches, &c.

EURITE or WHITE STONE. (Gr. ευρυς, *broad.*) A fine-grained granite, in which felspar predominates.

EUXA'NTHINE. (Gr. ευ, and ξανθος, *yellow.*) A substance obtained from India under the name of *Purree*, or *Indian yellow*. It is supposed to be derived from the bile of the camel, or of the elephant: it forms small pale yellow crystals.

EU'XENITE. (Gr. ευξενος, *welcome.*) A mineral containing columbium, yttria, and uranium, found at Arendal in Norway.

EVERLASTING FLOWERS. Certain flowers, whose hard tissue and deficient moisture renders them little liable to change, and enables them to retain their colour for several months after having been gathered.

EVIDENCE, LAW OF. An important enactment was passed in the 14 and 15 Vict. chap. 99, by virtue of which parties to suits, actions, or other proceedings in any court of justice are admitted witnesses. It provides that on the trial of any issue joined, or of any matter or question, or on any inquiry arising in any suit, action, or other proceeding in any court of justice, or before any person having by law, or the consent of parties, authority to hear, receive, and examine evidence, the parties thereto, and the persons in whose behalf any such suit, action, or other proceeding may be brought or defended, shall be competent and compellable to give evidence either *viva voce* or by deposition, according to the practice of the court, on behalf of either or any of the parties to the suit, action, or other proceeding. By this clause, in addition to the parties offering themselves to give evidence in their own behalf, their opponents can compel them to give evidence in the cause. Nothing in the act is to compel persons charged with criminal offences to give evidence, nor is the act to apply to proceedings in consequence of adultery. Further, the new law authorises the common law courts to compel an inspection of documents whenever equity would grant a discovery. Foreign and colonial acts, judgments, &c., are to be received in evidence, without proof of the seal or signature; so, also, are apothecaries' certificates. Documents are to be admitted in England or Ireland from either place, and the colonies, without proof of seal. Persons forging the seal or signature to be guilty of felony, and punished accordingly. This act, which extends to all parts of the united kingdom except Scotland, came into force on the 1st of November, 1851.

EXA'NGIA. (Gr. εξ, and αγγειον, *a vessel.*) A term applied by some medical writers to diseases in which large blood vessels are broken or perforated, or enlarged, without any external opening: it includes *aneurism*, *varix*, and *cyanea*.

EXA'NTHALOSE. (Gr. εξανθεω, *to effloresce.*) A name given by Beudant to native *sulphate of soda*, occurring as an *efflorescence* on certain lavas, and elsewhere.

EXAN'THESIS. (Gr. εξανθεω, *to effloresce.*) An efflorescent eruption on the skin.

EXCE'NTRIC. In machinery, a wheel in which the axis is removed from the centre of the figure, or of which the periphery is not circular. Excentrics are used for converting circular motion into alternating, rectilinear, or intermitting motion, and are usually driven by bands or straps.

EXCI'TANTS. (Lat.) Medicines which excite the actions of the system: they are either *general*, such as alcoholic liquors, &c., or *local*, such as diuretics, diaphoretics, &c.

EXCITO-MOTORY ACTS. In Physiology, the term has recently been applied to the first class of nervous actions defined by Hartley as "those sensory vibrations which are excited in the external organs and ascend towards the brain, when they arrive in their ascent, at the origins of motory nerves, as they arise from the same common trunk, plexus, or ganglion, with the sensory ones affected, detach a part of themselves at each of those origins down the motory nerves; which part by agitating the small particles of the muscular fibres excites them to contraction" (*On Man*, i. p. 92). "The actions of sneezing, swallowing, coughing, hiccoughing, vomiting, and expelling the fœces and urine, with others of a like nature, are to be deduced from the first and fourth classes of motory vibrations; i. e. either from those vibrations which first ascend up the sensory nerves, and then are detached down the motory nerves, which communicate by some common trunk, plexus or ganglion; or else from those vibrations that run along the surfaces of uniform membranes, and so affect all the muscles which lie contiguous to any part of the membranes" (*Ib.* p. 97). "The yawnings and stretchings of persons disposed to sleep, the convulsive respiration of those that are just fallen asleep, and the convulsive motions which attend the extinction of the senses in epileptic fits, and the near approach of death, may be derived, perhaps, in part, from this source" (*Ib.* p. 93).

EXCRE'TORIES. The ducts which convey the secreted fluids from the glands.

EXCU'RTRICES. (Lat. excurro, *I rush hastily.*) An order of birds intermediate between the flying and walking tribes, and belonging to the *Insessores*.

EXI'NTINE. A membrane situated between the extine and intine in the pollen of yew, juniper, cypress, &c.

EXOCHNA'TA. (Gr. εξοχος, *prominent.*) A designation of the long-tailed *Crustaceæ;* as the lobster and shrimp.

EXPECTORA'TION. (Lat.) The act of ejecting matters from the chest. The term is sometimes applied to the matter ejected, which is, however, more properly termed *sputum.*

EXPERIME'NTUM CRU'CIS. (Lat.) Bacon's *Crucial*, or *decisive* experiment; so called from the *crosses*, or finger-posts on roads, as at once determining between two or more possible conclusions.

EXPIRA'TION. (Lat.) In Physiology, the movements by which the air that has been changed by the respiratory process, is expelled from the lungs: they are chiefly due to the elastic contraction of the lungs and the walls of the chest, after they have been dilated in the act of inspiration.

EXSE'RTED. (Lat. exsertus, *thrust out.*) A term applied to such stamens of plants as are longer than the corolla.

EXTE'NSOR MUSCLES. As opposed to *flexor muscles*, are those which extend any limb or part; the muscle in the fore-arm which extends the joints of the fingers, called the *extensor digitorum*, is an instance.

E'XTINE. The external membrane of the pollen-grain of plants.

EXTROVE'RSION. (Lat.) A term applied by surgical writers to those malformations of the body in which a part is, as it were, turned wrong side outwards. Such cases are congenital; thus cases are on record of *extroversion of the bladder*, in which there is a congenital defect of its anterior part, and of the corresponding portion of the parietes of the abdomen, so that the internal surface of the bladder projects and forms a tumour.

EYEBRIGHT. See EUPHRASIA.

EYE-PIECE (SOLID). The *solid eye-piece* is an invention of the Rev. J. B. Reade, of Stowe, near Aylesbury. It consists of three lenses, the anterior and posterior of which are double convex of crown glass, and the intermediate one a concave lens of flint. The contact surfaces are cemented together, and consequently the action of the rays of light is similar to that of a single lens. The advantages of this construction are that it gives a large and flat field of view, and that the defects of spherical and chromatic aberration are got rid of. These advantages arise from the great thicknest

of the flat lens, which is a perfectly new feature in the construction of eye-pieces.

EYE-PIECE (PERSONAL BINOCULAR). An eye-piece recently invented by Mr. Thomas Jones, a well-known optician of London, for enabling two persons to observe the image of the same star with the same telescope. It consists of two 3-glass eye-pieces having the first lens common to both. This first lens is contained in a tube adapted in the usual way to the telescope, and, branching off at angles of 120° from it, are two other tubes, each containing other two lenses, fixed in smaller tubes sliding in them. At the junction of the tubes is an equilateral prism, by which the pencil of rays passing perpendicularly through its first surface, is divided into equal parts at the opposite angle, and is reflected in two equal parts into the two branch tubes. All the light received on one half of the object-glass is reflected into one tube, and that received on the other half into the other tube, and thus two distinct images of the star, as well as of the wires in the focus of the object-glass, are formed.

By the use of this eye-piece, two persons may, under precisely the same circumstances, observe transits of stars, and thus obtain, much more certainly than it has been effected by other means, their *personal equation*, that is, the difference of average estimation of the time of a star's transit across the wires of a transit-instrument. In this respect the invention of Mr. Jones is likely to be of inestimable service to astronomy, since the uncertainty attending the observation of time, and the different estimations of this element by different observers, have been the greatest obstacles to a perfect system of observation since the construction of large instruments and the great improvements introduced during the present century into the systems of the great observatories of Europe.

F.

FA'CET. (Fr. façette.) In Anatomy, a small but well-defined surface of a bone or other part; as, e. g. the hexagonal divisions of the surface of the cornea of the compound eye of the insect and crustacean.

FACTO'RIALS. In Analysis, the name given by Arbogast to certain symbolical expressions representing the continued product of a series of factors such that each is greater or less than the immediately preceding one in the series by a constant quantity. For example, the expression x^{n+a} denotes the continued product

$$x\,(x+a)\,(x+2a)\,(x+3a)\;.\;.\;.\;.\;(x+\overline{n-1}\,a).$$

FÆ'CES. (Lat.) The excrements; usually confined, in Physiology, to the solid matter evacuated from the alimentary canal. According to the analysis of Berzelius, human fæces of consistence sufficient to form a coherent mass are composed of

Water			75·3
Matters soluble in water.	Bile	0·9	5·7
	Albumen	0·9	
	Peculiar extractive	2·7	
	Salts	1·2	
Insoluble residue of the food			7·0
Insoluble matters which are added in the intestinal canal, — mucus, biliary resin, fat, and a peculiar animal matter			14·0
			102·0

This term is also applied to sediments, especially in vegetable infusions, tinctures, and fermented liquors.

FAU'JASITE. A hydrated silicate of alumina, lime, and soda, from Baden; named after Faujas St. Fond.

FAVO'SE. (Lat. favus, *a honeycomb.*) In Botany, honey-combed: cellular.

FAY'ALITE. A native silicate of iron from the island of Fayal.

FE'BRIFUGE. (Lat. febris, *fever*; and fugo, *I drive away.*) A remedy which cures or relieves fever: the term is commonly applied to medicines used in the treatment of agues.

FELLIC and FELLI'NIC ACID. (Lat. fel, *gall.*) Products obtained from bile.

FENESTRA. (Lat. *a window.*) In Anatomy, the term is applied to certain holes in the osseous or petrous capsule of the internal organ of hearing; one on the outer wall of the labyrinth, which is filled by the base of the "stapes," is called the "fenestra ovalis;" a second, at the base of the cochlea, is called the "fenestra rotunda," and is separated by a membrane from the cavity of the tympanum.

FER'RIC ACID. A compound of 1 atom of iron with 3 atoms of oxygen; Fe O_3. It is very unstable, and has not been isolated.

FE'RRIDCYA'NOGEN. A compound of 2 atoms of iron and 6 of cyanogen and which, in combination with 3 atoms of potassium, forms the *Ferridcyanide of potassium*, or *red prussiate of potash.*

FE'RROCYA'NOGEN. A compound of 1 atom of iron and 3 atoms of cyanogen; or 1 of iron, 6 of carbon, and 3 of nitrogen; and which, in combination with 2 atoms of potassium, constitutes *anhydrous ferrocyanide of potassium*, the crystals of which include 3 atoms of water. This crystallized ferrocyanide of potassium is generally known under the name of *yellow prussiate of potash.*

FI'CHTELITE. A white crystalline substance found in a peat moss in Bavaria: it is a hydrocarbon.

FI'MBRIÆ. (Lat. fimbria, *a fringe.*) In Anatomy, the jagged processes of the abdominal opening of the oviduct, or "Fallopian tube," are so called.

FIRE-SHIP. A vessel filled with combustible materials for the purpose of being sent in a burning state among the ships of an enemy, in order to set them on fire, and thereby effect their destruction. As the destruction of the vessel itself is a necessary consequence, it must be abandoned by the men, and therefore cannot be steered. Hence fire-ships are formidable only to vessels which cannot be manœuvred, either by reason of their having been disabled, or on account of their occupying a confined space, as a harbour, where there is not room for escape.

FIS'CHERITE. One of the native hydrated phosphates of alumina, so called from its discoverer, Fischer.

FLABE'LLIFORM. (Lat. flabellum, *a fan.*) Fan-shaped — as the plaited leaves of some palms.

FLAGE'LLIFORM. (Lat. flagellum, *a whip.*) Whip-shaped. A term applied to a long, pliant, whip-like stem.

FLEAM. An instrument used by farriers to bleed horses and cattle: it includes a small pointed blade, which is projected from a sheath by means of a spring.

FLE'XOR MU'SCLES. Muscles, the office of which is to *bend* the joints.

FLOOD-GATE. A sluice, or gate, for drawing off the superfluous water from a canal or reservoir liable to be flooded by falls of rain.

FLORA. One of the recently discovered small planets belonging to the group between Mars and Jupiter. Flora was discovered at Mr. Bishop's Observatory in the Regent's Park, on the 18th of October, 1847, by Mr. Hind, while comparing the fourth hour of the map of Professor Knorre with the Heavens. It had then the appearance of a star of the ninth magnitude, but shortly after the discovery the brightness increased, and became equal to that of a star of the eighth magnitude. At Mr. Bishop's request, Sir John Herschel named the planet *Flora*, with a rose for the symbol. It is the eighth of the group. The period of revolution of this planet appears to be somewhat shorter than that of any other of the group, being 1193·25 days. (*Monthly Notices of the Royal Astronomical Society*, vol. viii.) See PLANET.

FLUCE'RINE or FLUOCE'RINE. The native fluoride of cerium, occurring near Fahlun, in Sweden.

FLUEL'LITE. Native fluoride of aluminum, occurring at Stennagwyn, in Cornwall.

FOG-RINGS. Banks of fog arranged in a circular or ring form; a meteorological phenomenon not unusual on the coast of Newfoundland. (See *British Association Report for* 1846.)

FO'LLICLE. (Lat.) In anatomy this term is applied to a simple gland, consisting merely of a hollow vascular membrane, and an excretory duct: hence the term *mucous* and *sebaceous follicles.*

FOMES. In medical language this term is applied to porous substances capable of absorbing and retaining contagious effluvia. Wool and woollen clothes are said to be active *fomites.*

FONT *of Type.* See FOUNT, in DICT.

FORENSIC MEDICINE. (Lat. forum, *the bar.*) The application of medical science to the elucidation or solution of judicial questions.

FOREST MARBLE. A portion of the series of the lower oolite formation, consisting of a coarse laminated shelly oolite, interposed between beds of clay and grit. See GEOLOGY.

FORESTS, SUBMARINE. The inroads of the sea have in many places submerged forests of considerable extent. A submarine forest on the coast of Lincolnshire was described in 1799 by Correa de Serra. (*Phil. Trans.*) Another was discovered in 1832 in Cardigan Bay: it is said to have been submerged in the year 520. The remains of the trees are covered by peat. A similar fir wood, beneath the mean level of the sea, exists at Bournemouth, in Hampshire. These forests are sometimes also found in inland situations, of which there is a good example about four miles west of Newcastle-on-Tyne, near the river, consisting of an immense number of trees lying a few feet beneath the surface. At the bottom of the moss of Kincardine, under a bed of peat

from 8 to 12 feet thick, are a number of trees which have been cut down, and hatchets are occasionally found in the moss. It is supposed that these are the relics of the Caledonian forest cut down by Agricola. (Lyell's *Geology*. Thomson's *Geology*, &c.)

FO'RMULA. (Lat.) In Chemistry, a concise mode of exhibiting by symbols the results of chemical changes, and dependent upon the theory of atomic equivalents. These formulæ are employed either to represent the actual results of experiment, or to indicate the different theoretical or hypothetical views which may be taken in reference to the composition of certain products. Formulæ, therefore, are either empyrical or rational. As an instance of the first-mentioned application of formulæ we may give those of water, of sugar, of carbonic acid, of alcohol, and of ether. Water is a compound of an atom of hydrogen=1, and an atom of oxygen=8; the formula, therefore, of *water* is $H\,O$. The formula of grape-sugar is $C_{12}\,H_{12}\,O_{12}$; that is, it consists of 12 atoms of carbon, 12 of hydrogen, and 12 of oxygen. Carbonic acid consists of 1 atom of carbon =6, and 2 atoms of oxygen=16; its formula, therefore, is $C\,O_2$. Alcohol is a compound of 4 atoms of carbon, 6 of hydrogen, and 2 of oxygen, its formula being $C_4\,H_6\,O_2$; and lastly, ether is a compound of 4 atoms of carbon, 5 of hydrogen, and 1 of oxygen, and is represented by the formula $C_4\,H_5\,O$. All these are *empyrical formulæ;* that is, simple statements of the composition of the several bodies.

In the act of fermentation sugar is resolved into alcohol and carbonic acid, and this change may be concisely represented by the following arrangement of formulæ:

$$C_{12}\,H_{12}\,O_{12} = 4\,(C\,O_2) + 2\,(C_4\,H_6\,O_2)$$

that is, 1 atom, or *equivalent* (for we use these terms synonymously) of grape-sugar, is equal to 4 atoms of carbonic acid, and 2 atoms of alcohol.

Now, in reference to the use of *rational* formulæ it may be remarked, that sugar may be hypothetically represented as a compound of 12 atoms of carbon, and 12 of *water;* and in that case its formula would be $C_{12} + 12\,(H\,O)$.

Again, alcohol is resolvable into ether and water; for $C_4\,H_6\,O_2$ is $= C_4\,H_5\,O + H\,O$: and lastly, ether may be regarded as an oxide of a hydrocarbon, composed of 4 atoms of carbon and 5 of hydrogen, and which has been termed *Ethyle;* in which case its formula might be written $C_4\,H_5 + O$; or ether may contain a hydrocarbon composed of 4 atoms of carbon and 4 of hydrogen, in combination with an atom of water; in which case its rational formula would be $C_4\,H_4 + H\,O$.

FO'RMYLE. The basic hydrocarbon of the formic acid $= C_2\,H$.

FO'RSTERITE. A crystalline mineral accompanying the pyroxene of Vesuvius.

FOU'SEL OIL or FUSEL OIL. (Gr. φυω, *I produce.*) An oil contained in corn-spirit and potato-spirit, and which gives to those liquors a disagreeable taste and smell. When purified it constitutes the *amylic alcohol*, or hydrate of oxide of amyle, of modern chemists; its formula is $C_{10}\,H_{11}\,O + H\,O$.

FOW'LERITE. A silicate of manganese and iron, from New Jersey.

FOWLER'S MINERAL SOLUTION. A solution of *arsenite of potassa* introduced into medicine by Dr. Fowler of Stafford, as a substitute for a similar preparation, sold as a quack medicine, under the name of *Tasteless Ague Drops*. The *Liquor Arsenicalis* of the Pharmacopœia is for the same purpose.

FRA'GARIA. (Lat. fragro, *I smell sweet.*) A genus of plants, including the *Strawberry*.

FRAGMENTARY ROCKS. A geological term applied to rocks apparently composed of the agglutinated fragments of other rocks. *Brecciæ* and *Conglomerates* are of this class.

FRA'NKLINITE. A ferriferous oxide of zinc occurring in New Jersey, N. America, so called in honour of Dr. Franklin.

FRA'XINUS. (Lat.) The ash. A genus of plants, in which the common ash, *Fraxinus excelsior*, and the manna tree, *Fraxinus ornus*, are included.

FREE CHURCH OF SCOTLAND. The name assumed by the large body of Presbyterians in Scotland that seceded from the established church in 1843. Under the head VETO in the DICT., we have detailed at some length the causes that led to this important movement, and their results; and it remains for us here only to say that, as might be expected, the Free Church embraces a large body of lay adherents. In 1851, no fewer than 570 churches had been built for the accommodation of its members; 70 more were, at the same time, in the course of being built; and others were projected. It had then, also, 613 ordained clergymen, and 197 congregations without ministers. Very conflicting estimates have been formed of the total numbers of those within the pale of the Free Church; these being exaggerated by its friends, and underrated by its opponents. On the whole, however, they may perhaps be safely estimated at about 600,000.

Nothing, perhaps, has been so extraordinary, in connexion with the history of this secession, as the zeal and liberality displayed by the public in subscribing funds for the building of churches and the support of the clergy. These amounted, in May, 1845, to no less than 776,453*l*., of which not 10 per cent. was unpaid. Large additional subscriptions have since been received. During the year ended 30th March, 1850, the sum of 306,622*l*. was received by the Free Church for its various objects. A handsome college in connexion with the Free Church has been opened in Edinburgh; and houses (manses) for the accommodation of the clergymen have been built in most parts of the country.

FRENCH CHALK. Talc, or silicate of magnesia.

FRENCH POLISH. A solution of shell-lac in spirit of wine is the basis of this compound; a small quantity of linseed oil is added to it at the time of its application, and it is laid on by a ball of cotton-wool and rapidly rubbed in the direction of the fibres of the wood; when dry it is finished off by friction with tripoli and oil.

FRENCH WHITE. Finely pulverised talc.

FRIABI'LITY. (Lat. frio, *to crumble.*) The property by which substances admit of being crumbled into powder by gentle friction.

FRIAR'S BALSAM. The *compound tincture of Benzoin* of the London Pharmacopœia. It is an alcoholic solution of benzoin, styrax, tolu balsam, and aloes; it is used as a stimulating application to wounds and ulcers.

FRIE'SLAND GREEN. *Brunswick Green.* An oxichloride, or an ammonio-chloride of copper.

FRITILLA'RIA. In Botany, a genus of *liliaceous* plants, including the *F. Imperialis* or *Crown Imperial.*

FRONTAL SINUS. A cavity in the frontal bone, placed over the orbit, on each side.

FRU'GORDITE. A silicate of alumina, lime, and magnesia, from Finnland.

FU'LGURITE. The fused or vitrified tube which is produced by the passage of lightning through a sandy soil.

FUMA'RIC ACID. An acid existing in the *fumaria officinalis*, or common fumitory: it may be produced by the action of heat on malic acid.

FU'MING LIQUORS. Certain chemical compounds which exhale visible fumes, or in common language *smoke*, when exposed to air: *Boyle's fuming liquor* is sulphuret of ammonium: *Cadet's fuming liquor* is an arsenical compound, now termed *oxide of kakodyle:* the *fuming liquor of Libavius* is the anhydrous bichloride of tin.

FUNDUS. (Lat. fundus, *a basis.*) In Anatomy, the base of any cone-shaped organ: the term is usually restricted to that part of the womb, the urinary bladder and the gall bladder.

FUNGUS HÆMATODES, *Spongoid inflammation, Soft cancer*. A species of malignant tumor, called also *medullary sarcoma.*

FU'SCIN. (Lat. fuscus, *tawny.*) A brown colouring matter obtained from empyreumatic oils.

FU'SCITE. (Lat. fuscus, *tawny.*) A yellowish variety of compact scapolite from Norway: it has also been termed gabronite.

FUSEL OIL. *See* FOUSEL OIL.

FU'SIBLE CALCULUS. That species of urinary calculus which consists of a mixture of ammonio-magnesian phosphate, and phosphate of lime, and which is characterised by the facility with which it enters into fusion before the blow-pipe.

FU'SIFORM. (Lat. fusus, *a spindle.*) Spindle-shaped; thickest at the middle and tapering towards the ends.

FU'SINÆ, in Conchology, a term used for spindle shells.

G.

GA'BIAN OIL. A petroleum or mineral naphtha exuding from the strata at Gabian, a village in Languedoc.

GA'BRONITE. (Gabbro, the Italian name of a rock composed of diallage and felspar.) A mineral found in a vein of titaniferous iron near Arendal, in Norway. It is a silicate of alumina, soda, and potassa. It has also been termed *Fuscite* and *compact scapolite*.

GA'DUS. In Ichthyology, the name of a Linnæan genus of fishes, including the haddock, cod, whiting, and many other species of the cod tribe.

GA'HNITE. A native aluminate of zinc, called also *automalite*. Named from Gahn, who first described it.

GALA'CTIC CIRCLE. (Gr. γαλα, *milk.*) A term first used by Sir John Herschel to denote that great circle of the heavens to which the course of the Milky

Way, as traced by the unaided eye, most nearly conforms. It is inclined, at an angle of about 63°, to the equator, and cuts that circle in two points, whose right ascensions are respectively about 0 h. 47 m. and 12 h. 47 m., so that its northern and southern poles respectively are situated in R. A. 12 h. 47 m., N. P. D. 63°, and R. A. 0 h. 47 m., N. P. D. 117°. This circle, Sir John Herschel observes, is to sidereal what the invariable ecliptic is to planetary astronomy — a plane of ultimate reference, the ground-plane of the sidereal system. (*Outlines of Astronomy.*) See GALAXY.

GALA'CTIC POLES. (Gr. γαλα, *milk.*) The two opposite points of the heavens, situated at 90° from the Galactic Circle.

GA'LACTINE. (Gr. γαλα, *milk.*) An ingredient in the sap of the *Galactodendron utile*, or Cow tree of S. America.

GALACTODEN'DRON. (Gr. γαλα, *milk;* δενδρον, *a tree.*) The *Palo di Vaca*, or *cow tree* of S. America: when tapped it yields a white, palatable, and nutritious liquid, much resembling milk.

GA'LAXY. (Gr. γαλαξια, from γαλα, *milk.*) The *Via Lactea* or Milky Way. This luminous zone, so remarkable in a clear night, must have attracted the notice of the first observers of the heavens, and its true nature seems to have been surmised at an early period. Manilius, in his Astronomicon, after alluding to the well-known mythological fable of its origin, asks

> Anne magis densâ stellarum turba coronâ
> Contexit flammas, et crasso lumine candet,
> Et fulgore nitet collato clarior orbis?

The explanation of the phenomenon here suggested, namely, the condensed light of countless multitudes of small stars so crowded together as to be individually undistinguishable, is ascribed to Democritus, and its truth was confirmed, or at least rendered greatly more probable, immediately on the discovery of the telescope, Galileo himself enumerating among the advantages resulting from his instrument, that of putting an end to the disputes about the nature of the milky way. About the middle of the last century, Wright of Durham, and Kant and Lambert in Germany, speculated on the connexion of the phenomenon with the general arrangement of the stars in space; but the first who undertook a systematic examination of the galaxy with telescopes of adequate power was Sir William Herschel, and it is to the indefatigable labours of this great astronomer, and to those of Sir John F. W. Herschel, who, during his memorable residence at the Cape, with the same telescope as had been used by his father, and by a similar process of examination, explored the regions of the sky which are invisible in our latitudes, that astronomers are mainly indebted for the facts upon which any sound speculation respecting the constitution of the heavens can as yet be founded.

The Milky Way, as seen by the naked eye, presents the appearance of a succession of luminous patches of varying intensity. Its breadth is very unequal, in some parts hardly exceeding 5 degrees, in others extending to 16 degrees; and there is a part between Serpentarius and Antinous where the two branches into which it is there divided occupy together a breadth of 22 degrees. Its course through the heavens is nearly that of a great circle inclined at an angle of about 63 degrees to the equator, and cutting that circle in two points whose right ascensions are, respectively, 0 h. 47 m., and 12 h. 47 m. Struve remarks that the most condensed stratum does not lie exactly in one plane but appears rather to be contained in two different planes inclined at an angle of 10 degrees, and intersecting in the plane of the celestial equator, the sun being at a little distance from the line of intersection. This slight deviation from a great circle had been remarked at an earlier period, and Lambert supposed it might be occasioned by the place of the sun being not exactly in the middle of the zone, but a little on one side. It is convenient, however, in speaking generally of the system of the galaxy, to refer it to a great circle of the sphere; and the great circle to which it most nearly conforms has been named by Sir John Herschel the *Galactic Circle.*

At several parts of its course the Milky Way throws off streams or branches. In Perseus a branch is sent off which is traceable to a considerable distance. Another proceeds from a point near the star *m Puppis*, nearly on the southern tropic. In Argus it opens out into a wide fan-like shaped expanse, nearly 20° in breadth, which terminates abruptly, and at this part its continuity is interrupted by a wide gap. At *α Centauri* it again subdivides. At *γ Sagittarii* it suddenly collects into a vivid oval mass, about 6° in length and 4° in breadth, so exceedingly rich in stars that a moderate calculation gives upwards of 100,000. On the other hand, spaces occur in the very middle of its course, which appear, to the naked eye, entirely devoid of stars, and perfectly black. The most remarkable of these is situated in the Southern Cross, where the Milky Way approaches the nearest to the south pole, and so striking is its appearance that the early navigators designated it by the name of the *coal sack.* This space is of an irregular pear-shaped form; it is about 8° in length and 5° in breadth, and was described and figured by the Abbé Feuillée in 1710. Lacuille correctly attributed its striking blackness to the effect of contrast with the vivacity of the Milky Way which surrounds it on all sides, and which in this region is remarkably brilliant.

At first view it might seem a hopeless attempt to determine the form or boundaries of the agglomeration of stars forming the galaxy, insomuch as we see only its projection on the surface of the celestial sphere, and that, too, from a position within it. If, however, the two following hypotheses be admitted: 1st, that the stars are so distributed through space as to be, on the average, at nearly equal distances from each other, and 2d, that the telescope penetrates so far as to reach the extreme limits of the agglomerated mass, — then the relative distances of the remotest stars in every direction, and consequently the shape of the mass, may be estimated by counting the number of stars in the field of view of one and the same telescope in a great number of different directions; for, granting the above hypothesis, it is obvious that the distances of the remotest stars will be proportional to the cube root of the whole number visible in the field. This was the process followed by Sir William Herschel, in his celebrated *gauges of the heavens.* The telescope he made use of was a reflector of 20 ft. focal length, having an aperture of 18 inches in diameter, and the magnifying power was 180. With this instrument he made upwards of 3400 gauges, and thereby ascertained the number of stars visible in the field of the telescope in so many different directions.

The general fact established by this process of counting was the rapid diminution of the number of stars in the field of view on increasing the angle between the direction of the telescope and the plane of the galactic circle. From a careful analysis of the gauges of Sir William Herschel, Struve deduced a formula which expresses the number of stars in a field of view of 15 minutes in diameter in terms of the angular distance from the galactic equator. At the distances of,

0°	15°	30°	45°	60°	75°	90°

the numbers (representing the average of the gauges) are, respectively,

122·00	30·30	17·68	10·36	6·52	4·68	4·15

whence it appears that the average density of the stars in the plane of the galactic circle is nearly thirty times greater than in the direction of its poles. The researches of Sir John Herschel have established the fact that a similar law of diminution is observed in the southern galactic hemisphere, the average number of stars in a field in both hemispheres being very nearly the same at equal angular distances from the galactic equator.

It is to be remarked that the great increase in the number of stars which is observed in the neighbourhood of the galaxy is occasioned chiefly by the greater abundance of telescopic stars, that is to say, of those beyond the 6th order of magnitude. Stars of the first magnitude are distributed over the sphere with tolerable uniformity. Taking, however, the whole number visible to the naked eye, a rapid increase is perceptible as we approach the limits of the galaxy; but, with respect to those of the smaller magnitudes, and particularly beyond the 11th, the accumulation along that circle and its branches almost exceeds imagination. The vast predominance of the small stars must be held to indicate the immense distances at which they are situated.

From the relatively greater abundance of stars in the plane of the galactic circle, than in the regions on either side of it, and from the indication of some preponderance on the southern side, Sir W. Herschel drew the conclusion that the galaxy is composed of a stratum of stars of which the thickness is inconsiderable in comparison of its length and breadth, and that the sun is placed not far from the middle of the stratum, but somewhat nearer to its northern than to its southern side. He was also enabled to draw a further conclusion. Assuming the real magnitudes of stars to be the same, on the average, through the whole sidereal system, he determined by a series of photometrical experiments that stars of the 6th magnitude (the least visible to the naked eye) are 12 times more remote than those of the first (Sirius, for example), and that the penetrating power of his 20-foot telescope (with the front view) was 75 times greater than that of the naked eye, so that the smallest stars visible in the telescope are at a distance equal to 900 times the distance of Sirius. Now the average apparent breadth of the Milky Way is about five degrees; consequently its linear breadth at that great distance must be 900 × sin. 5°, or equal to 78 times the distance of Sirius, or more than six times the distance of the stars of the 6th magnitude. Therefore the Milky Way, even in the direction of its poles, extends to three

times the distance of the smallest stars visible to the unaided eye, the sun being supposed at the centre of the stratum. Hence it follows that not only our solar system, but all the stars in the firmament visible to the naked eye, are plunged to a great depth in the stratum of stars forming the galaxy, and form an integral part of it.

It must be kept in mind that the above conclusions are based on two hypotheses which are, at best, very precarious; and in fact both of them appear to have been abandoned by Sir W. Herschel himself in his later years. With respect to the first, namely, the distribution of the stars in space at nearly equal distances from each other, he remarks in a paper published in 1817, that although a greater number of stars in the field of view may be taken in general as an indication of their extension to a greater distance, yet the gauges have in reality more direct reference to the condensation than to the distance, and hence a greater number in the field of view may be explained as well by a greater condensation of the nebula as by a greater extension of its figure in the direction in which the stars appear most numerous. The other hypothesis, namely, that the telescope penetrates to the extreme boundaries of the galaxy, is subject to much doubt, and cannot be easily established or disproved. Sir W. Herschel, speaking in 1818 of his 40-foot telescope, the penetrating power of which he estimated to reach to 2300 times the distance of Sirius, states, as his opinion, that even at this enormous distance the limit of the stratum was not attained, inasmuch as the telescope failed to resolve the nebulous appearance into stars, and he therefore concluded the stratum to be fathomless. Sir John Herschel thinks the limit has been attained only in certain directions, "Throughout by far the largest portion of the extent of the Milky Way in both hemispheres the general blackness of the ground of the heavens on which its stars are projected, and the absence of that innumerable multitude and excessive crowding of the smallest visible magnitudes, and of the glare produced by the aggregate of multitudes too small to affect the eye singly, which the contrary supposition would appear to necessitate, must, we think, be considered unequivocal indications that its dimensions, *in directions where these conditions obtain*, are not only not infinite, but that the space penetrating power of our telescopes suffice fairly to pierce through it and beyond it." But, on the other hand, there are parts where not the slightest indication of a limit is discernible. "Such is, in effect, the spectacle afforded by a very large portion of the Milky Way in that interesting region near the point of its bifurcation in Scorpio, where, through the hollows and deep recesses of its complicated structure, we behold what has all the appearance of a wide and indefinitely prolonged area, strewed over with discontinuous masses and clouds of stars, which the telescope at last refuses to analyse." (*Outlines of Astronomy*, 1849.)

It thus appears that the amount of knowledge which has yet been obtained respecting the constitution of the galaxy, is extremely small. The only conclusions, in fact, which can be safely drawn are the following:—

1. That the whole light of the Milky Way is nothing but the light of innumerable stars of all magnitudes down to the faintest point perceptible in the best telescopes.

2. That the phenomena, on the whole, agree with the supposition that the stars of our firmament, instead of being scattered through space indifferently in all directions, form a stratum of which the thickness is small in comparison of its length and breadth, and that the sun occupies a place near the middle of the thickness, and near the point where the stratum is subdivided into two principal laminæ.

3. That if all the fixed stars in the firmament be regarded as forming one great system — that of the galaxy — we are still in complete ignorance of its extent, and without the least idea of its external form.

GALE'GA. (Gr. γαλα, *milk*, because it is supposed to increase the milk of animals, especially of goats.) The name of a genus of plants, including G. officinalis, or *goat's rue*, a plant of little taste, and eaten in Italy in salads.

GA'LIPOT. A white resin derived from the *Pinus maritima*.

GALLI'ZENITE. A mineralogical synonym of *Titanite*.

GALT. A provincial term applied to certain beds of chalk-marl, found in the east of England, between the upper and lower greensand.

GANGUE. The mineral substances which accompany metallic ores in the veins of rocks.

GARA'NCINE. One of the colouring matters derived from *madder*.

GARCINIA. (From Dr. Garcin.) A genus of plants including the celebrated *Mangasteen tree*, the fruit of which, about the size of an orange, is said to excel in flavour and salubrity.

GASHO'LDER. A hollow cylindrical vessel open a bottom and closed at top, suspended by counterpoises i a tank of water, so that it may be filled with gas intro duced by a central pipe, and the gas afterwards distri buted by proper pressure through the mains which con vey it for service. Some of these magazines of coal-ga are of an enormous size, holding half a million cubi feet and upwards.

GASO'METER. This term is often applied to th gasholders of coal-gas works; but it should rather b limited to a smaller instrument constructed upon mor delicate principles, and capable of accurately measurin the quantity of gas of any kind which passes into an out of it. These instruments are sometimes constructe upon a much smaller scale in glass and iron, for th purpose of containing mercury, so as to be used for gase which are absorbable by water.

GASTRO'TOMY. (Gr. γαστηρ, and τεμνω, *I cut.* The operation of cutting into the abdomen.

GAYLUSSITE. A mineral named after Ga Lussac, found at Lagunilla, near Merida; it is com posed of nearly equal weights of carbonate of soda, car bonate of lime, and water.

GAZOLYTES. *See* AEROLITES, in DICT.

GEAR, or GEER. A term applied in Mill-work t wheels, or wheels and pinions, acting into each other *Spur gear* signifies wheels acting together in th same plane, with their axes parallel; for example, th wheel and trundle. *Bevel gear* is applied to wheel acting together whose axes are inclined to each other.

GE'INE. (Gr. γη, *the earth.*) The soluble brow matter which may be extracted from soils by the actio of water. *See* HUMIC ACID.

GELO'SCOPY. (Gr. γελαω, *I laugh*, and σκοπε *I view.*) A divination founded upon laughter, whenc the qualities and characters of persons might, it wa presumed, be deduced.

GEMITRI'CES. (Lat. gemo, *to moan* or *coo.*) I Ornithology, an order of birds comprising the *Columbin* or pigeons.

GENE'TTE. (Fr.) A small variety of horse. Also a animal of the weasel kind (*Viverridæ*), having a musk odour.

GE'NIOGLO'SSI. (Gr. γενειον, *the chin*, and γλωσσ *the tongue.*) In Anatomy, a pair of muscles by whic the tongue is protruded.

GENI'STA. (Lat. genu, *a knee*, so named from th inflection and angularity of the twigs.) A genus o plants including the *G. tinctoria* or *Dyer's Broom*, *&c*

GEORA'MA. (Gr. γη, *the earth*, and ὁραω, *I see.* The name given to a large concave globe, or spherica chamber, having the features of the earth delineated o the concave surface. A spectator in the interior o such a globe sees a much larger portion of the surfac at once than if he occupied an exterior position, and i has accordingly been suggested as a theatre for geo graphical lectures. (*Address to the Anniversar Meeting of the Royal Geographical Society*, 1850, b the President, Captain W. H. Smyth, R. N.)

GE'OTHERMO'METER. (Gr. γη, *the earth*, an thermometer.) An instrument for measuring th earth's heat at different places, as in wells and mine and for determining its rate of increase with the dept The temperature rises about one degree of Fahre heit's scale for every 70 or 80 feet of descent; hence th inference that at the depth of a few miles the earth mu be incandescent.

GERMAN SILVER A silver-like alloy generall composed of nickel, copper, and zinc; various propo tions are given, amongst which the following are said t be the best: 1 nickel, 1 zinc, 2 copper; and 8 nicke $3\frac{1}{2}$ zinc, 8 copper. It resembles the tutenag of th Chinese.

GERM-CELL. In Physiology, the cell which r sults from the union of the spermatozoon, or spermat matter conveyed by it, with the germinal vesicle, or i nucleus. The germ-cell assimilates the surroundi yolk and propagates its kind by spontaneous fissio whence the first or parent-cell has been termed t "primary germ-cell," and its progeny the "derivati germ-cells."

GE'RMINAL AREA. In Physiology, the circular oval space formed by liquefaction and metamorphosis a peripheral portion of the germ-mass: preparatory the appearance of the first trace of the proper embry It is divided into a central clear part called "area p lucida," and a peripheral part called "area opaca;" t portion of the latter, in which blood and blood-vess are developed, is called the "area vasaclosa."

GE'RMINAL MEMBRANE. In Physiology, t strata of cells and nuclei of cells originally formi and afterwards extending from, the germinal area: t external stratum is the "vertebral" layer, also call the "serous" and "animal" layer; the internal st tum is the "visceral" layer, also called the "mucou and "vegetal" layer.

GE'RMINAL SPOT. In Physiology, the nucleus

he germinal vesicle: it consists of a finely granulated ubstance, strongly refracting the rays of light.

GE'RMINAL VESICLE. In Physiology, a clear ucleated cell, which is the first formed and most essenial part of the ovum: it is surrounded by the yolk, and asses to the periphery of that part prior to impregnation, after which the germinal vesicle becomes opake, r disappears. It is sometimes called, after its disoverer, the "Purkingian vesicle."

GERM-MASS. In Physiology, the materials preared for the future formation of the embryo, consistng of the derivative germ-cells and the yolk which hey have assimilated.

GERM-YOLK. In Physiology, that portion of the rimary yolk of the egg which is to be assimilated by he derivative germ-cells in the formation of the germnass. In some animals the whole yolk is so assimiated; in others, as e. g. the bird, only a very small ortion; that, viz. which is included in the germ-mass r "cicatricula."

GIANT'S CAUSEWAY. See GEOLOGY, in DICT.

GIB'BSITE. The native hydrated alumina of Massachusetts, named after Col. Gibbs.

GI'LBERTITE. A white talcy mineral composed hiefly of silica, alumina, and lime, from St. Austle, in Cornwall, named by Dr. Thomson, from Mr. Davis Gilbert, late President of the Royal Society.

GILL. A measure of capacity equal to the fourth art of a pint. Miners apply the term to a pint. Physiologists to the breathing-organ in fishes and other aquatic nimals.

GI'MBERNAT'S LIGAMENT. The tendinous exansion of the lower portion of the oblique muscle of he abdomen, by some defined as the third insertion of *Poupart's Ligament.*

GI'NGLYMUS. GINGLYMOID. (Gr. *γιγγλυμος, a hinge; ειδος, like.*) Hinge-like. An anatomical term pplied to joints formed for motion in one plane.

GIROUE'TTE. (Fr. *a weathercock.*) Public characters who turn with every political breeze. The French published a *Dictionnaire des Girouettes*, conaining the names of the most celebrated revolutionary characters, with a number of weathercocks against each, corresponding to the number of his political changes.

GISMO'NDIN. A native silicate of lime, first noticed by Gismondi at Capo di Bove, near Rome. It occurs n octohedral crystals.

GIZZARD. The proper stomach of birds; its texure differs remarkably in granivorous and carnivorous birds, being thick in the one and thin in the other.

GLA'CIES MARIÆ. (Lat.) One of the old mineralogical terms applied to the large foliated *mica*.

GLANDERS. A disease in horses characterised by mucous discharge from the nostrils.

GLASS-GALL. The saline scum which rises to the urface of fused glass in the glass pots; it is also called *andiver.*

GLASS SOAP. A term sometimes applied in the lasshouse to certain substances which take away colour rom glass; thus oxide of manganese destroys the green int derived from iron.

GLASS FOR TELESCOPES. Till lately, English rtists had failed in producing large disks of glass for the ormation of object-glasses for telescopes, all the large bject-glasses in the public and private observatories eing of foreign manufacture. Since the duty has been aken off from glass, considerable energy has been shown n England with respect to this branch of manufacture; nd Messrs. Chance & Co. of Birmingham have suceeded in manufacturing a disk of pure glass 29 inches in iameter, whose thickness was 2½ inches, and weight 00 lbs. This disk was produced at the Great Exhiition of 1851, and was subjected to a very severe exmination for the purpose of detecting defects arising rom striæ, tension arising from imperfect annealing, ubbles, &c. The only serious defect which was deected after a very lengthened examination, was the xistence of a group of striæ occupying a space of about ½ inches in length, and 2½ inches in breadth, beginning t about 1½ inches from the edge, and having its longer imension directed towards the centre. It was found hat if it were ultimately thought necessary to sacrifice he defective portion, a disk of absolutely pure glass of t least 22 inches, or probably even of 25 inches in iameter, would still be left, being almost double the iameter of the largest object-glasses mounted in any bservatory at present.

GLAU'BERITE. A double sulphate of lime and oda, occasionally associated with rock salt.

GLAUBER'S SECRET SAL-AMMONIAC. Sulhate of ammonia.

GLAU'COLITE. (Gr. *γλαυκος, azure*, and *λιθος, a tone.*) A blue-green mineral from near Lake Baikal, Siberia: it is a silicate of alumina, lime, and potassa.

GLAU'CONITE. (Gr. *γλαυκος, azure.*) A constituent of the *green-sand* formation; it is also sometimes found in the cavities of certain trap-rocks. Under the name of *green-earth* it is used as a pigment. It is a hydrated silicate of iron, alumina, and magnesia.

GLAZING. The vitrified surface of pottery; it often contains oxide of lead. See POTTERY, in DICT.

GLECHO'MA. A genus of plants including the *G. Hederacea* or *Ground Ivy*, a favourite popular remedy for the cure of obstinate coughs.

GLE'NOID. (Gr. *γληνη, a cavity; ειδος, like.*) A term applied in anatomy to certain articular surfaces of bones: thus the surface of the scapula which articulates with the head of the humerus is called the *glenoid cavity* of the scapula or blade-bone.

GLI'ADINE. (Gr. *γλια, glue.*) A chemical term applied to one of the constituents of the gluten of wheat.

GLO'CHIS. (Gr. *γλωχις, a projecting point.*) A form of hair occurring in plants, forked at the apex: a *barb*.

GLO'SSOPE'TRÆ. (Gr. *γλωσσα, tongue*, and *πετρα, rock.*) The fossil teeth of certain fishes.

GLO'TTALITE. (From *Glotta*, the river Clyde.) A white mineral from the vicinity of Glasgow. It is a hydrated silicate of lime and magnesia.

GLUCO'SE. (Gr. *γλυκυς, sweet.*) A distinctive chemical term applied to the sugar of grapes, and to starch sugar, &c. See GRAPE SUGAR.

GLUME. In Botany, the *husk*, or peculiar calyx of grasses.

GLUTE'AL. (Gr. *γλουτος, the buttock.*) Of or belonging to the buttocks: as gluteal *muscles, arteries, &c.*

GLYPHO'GRAPHY. (Gr. *γλυφω, I engrave; γραφειν, to draw.*) An art by which an engraving is produced by the simple mode of drawing: in other words, an art by which the operations of drawing and engraving, which were formerly distinct, are here combined in one. Various admirable specimens of this art were displayed at the Great Exhibition. The process is as follows:— a drawing having been made through the ordinary etching-ground, the plate is then etched, and rolled up with a mixture of various substances, a copper-plate being made over the whole.

GME'LINITE. A hydrated silicate of alumina, potassa, and peroxide of iron; named after Gmelin, the mineralogist. It has also been called *hydrolite*, from the quantity of water which it includes.

GNAPHA'LIUM. (Gr. *γναφαλον, the wool of the teasel.*) The name of a genus of plants including the *G. dioïcum* or *Cotton Weed.*

GO'DBOLD'S VEGETABLE BALSAM. A quack remedy composed chiefly of honey and vinegar.

GO'DFREY'S CORDIAL. A quack medicine made by infusing 9 ounces of sassafras shavings, and of bruised caraway, coriander, and anise seeds each 1 ounce, in 6 pints of water, simmering the mixture till reduced to 4 pints, then adding 6 pounds of treacle, boiling for a few minutes, straining, and adding lastly 3 ounces of tincture of opium.

GOLD. The auriferous deposits in California were discovered so late as 1848; and the accounts of their extraordinary productiveness occasioned an unparalleled influx into the country of adventurers from the U. States and all parts of the world. For a while the accounts in question were pretty generally regarded by the less sanguine portion of the public as being in the highest degree exaggerated. But the result has shown that such had not been the case; and the produce obtained from the washings and the mines has exceeded even the most extravagant *à priori* estimates of its magnitude. It is believed, on good grounds, to have amounted in 1849, 1850, and 1851, to from 8,000,000*l.* to 10,000,000*l.* a year; and it is increasing with every increase in the numbers and skill of the diggers and miners. Whether it will continue at this rate for any considerable time it is impossible to say. But if it does, it cannot fail to exercise a powerful influence over the value of gold.

But it is not alone from California that new supplies of gold are beginning to be thrown upon the market. An auriferous region has very recently been discovered in Australia, about 160 m. W. Sydney. And though it be, at present, impossible to form any estimate of its probable productiveness, its appearances are most flattering. Some very large masses of native gold have been discovered; and the locality in which it is found bears, it is said, a striking resemblance to that of the most productive of the auriferous regions of California.

GOLDBEATER'S SKIN. The membrane used by goldbeaters, and interposed between the leaves of gold when they have attained considerable tenuity: the intestinal membrane of the rectum of the ox is generally used.

GOLDEN SULPHURET OF ANTIMONY. A preparation of antimony consisting of a mixture of the sulphuret and oxide of that metal.

GOLD LEAF. See GOLD, in DICT.

GO'LHITE. One of the mineralogical synonyms of

the *hydrated peroxide of iron*, or brown fibrous hematite or ochre.

GO'MPHOLITE. (Gr. *γομφος, a nail; λιθος, a stone.*) A term applied by Brongniart to the conglomerate rocks of the tertiary series, called by the Swiss *Nägelfloh*.

GO'RDIUS. (Lat.) The hair worm, or *seta equina*, found in stagnant water in Lapland and elsewhere.

GORGO'NIA NOBILIS. (Lat.) An old synonym of *Corallium rubrum*, or red coral.

GOSSY'PIUM. (Lat.) Cotton. The systematic name of the cotton plant is *Gossypium herbaceum*.

GRAIN. The integer of our system of weights. *See* WEIGHTS, in DICT. The troy pound contains 7000 grains, and the avoirdupois pound 5760 grains. The French decigramme is about 1·5 English grains, the gramme being =15·434 English grains.

GRAIN TIN. The purest kind of tin. The term was formerly applied to the metal obtained from the rounded pebbles of tin stone, called *stream tin*. The peculiar columnar fracture which pure tin exhibits when broken, is given by heating the ingot till it becomes brittle, and then letting it fall from a height upon a hard pavement.

GRAINS OF PARADISE. The seeds of a species of *amomum:* they are acrid, and said to be the *malagueta pepper* of Africa.

GRAMMATITE. The name originally given by Haüy to the mineral usually called *Actinolite* or *Amphibole*.

GRAMME. The French integer of weight = 15·434 English grains. *See* WEIGHTS, in DICT.

GRAMMITE. A mineralogical synonym of the variety of bisilicate of lime, commonly called *Tablespar*.

GRAPE SUGAR or GLUCOSE. The peculiar form of sugar existing in grapes, and in fruits generally: it differs from cane sugar in having much less sweetening power, and in being very imperfectly crystallisable: its chemical formula in its crystallised state is C_{12} H_{14} O_{14}; that of crystallised cane sugar being C_{12} H_{11} O_{11}.

GRASS-OIL. Some of the *grasses* yield odorous volatile oils, as the *Anthoxanthum odoratum*; the *Andropogon Schœnanthos* yields the oil of *lemon-grass;* and the *grass-oil of Namur* is distilled from the *Andropogon calamus aromaticus* or *nardoides*.

GREEK FIRE. A highly inflammable compound, supposed to have been invented by the Greeks, and to have consisted of bitumen, or asphaltum, nitre, and sulphur.

GREEN EARTH. *See* GLAUCONITE.

GREENLANDITE. A variety of the precious garnet.

GREEN LEAD ORE. The native phosphate of lead.

GRE'GORITE. The *menachanite* of Cornwall, discovered by Mr. Gregor, whose name it bears. An ore of titanium.

GRIFFITHS' MIXTURE. The Mistura Ferri Composita of the London Pharmacopœia; it is a useful ferruginous tonic, deriving its efficacy from the protocarbonate of iron.

GROUND GRU. Ice formed under peculiar circumstances at the bottom of running water. *Gru* is the name given by the people of Lincolnshire to snow swimming in or mixed with water; and the ground ice, a phenomenon of not unfrequent occurrence in that part of the country, having a considerable resemblance to this, goes by the same name.

The theory of the formation of ground ice is attended with some difficulty. Dr. Farquharson, who has carefully investigated the facts, and given the results of his observations on the ground gru of the rivers Don and Leschal in Lincolnshire, in two papers printed in the *Philosophical Transactions* for 1835 and 1841, is of opinion, that the ice is formed when the water has gone down to the temperature of the freezing-point in consequence of the bottom being cooled to a still lower temperature through the effect of radiation, in the same manner as dry land, under a clear sky, is cooled below the temperature of the air; and in corroboration of this opinion he states, that the formation never occurs excepting under a clear sky, and does not take place where the stream is shaded by bridges or high banks. It has been objected to this theory, that ground ice has been observed in the Neva under a thickness of three feet of surface ice, and an additional covering of three feet of snow, circumstances under which radiation could not take place; but Dr. Farquharson rightly remarks, that this fact can form no valid objection to his explanation, unless it were ascertained that the ground ice was formed *after* the surface ice and fall of snow, and not before. M. Arago, in the *Annuaire du Bureau des Longitudes* for 1833, after stating the observations which had then been collected on the subject, attributes the formation to three circumstances: 1. In a body of water in motion, the temperature of which is below 39° of Fahrenheit (under which water becomes specifically lighter by a further diminution of temperature), the eddies of the current throw down the coldest parts which, in still water, would remain at the surface, so that the whole stream from the surface to the bottom acquires the same temperature through this mechanical action. 2. The aptitude to the formation of crystals on the stones and asperities at the bottom. 3. Less impediment to the formation of crystals at the bottom, in consequence of the comparatively greater stillness of the water. Probably all these circumstances may concur; but as it frequently happens that they are all present when surface ice only is formed, some other conditions appear to be necessary, and Dr. Farquharson's theory, or radiation, seems the most probable which has been yet suggested. On this subject see, in addition to the works above referred to, Colonel Jackson's paper on the Congelation of the Neva, in the *Journal of the Royal Geographical Society;* Mr. Eisdale's, in the *Edinburgh New Philosophical Journal*, vol. xvii.; and Mr. Weitz's, on the Ground Gru of the Siberian rivers, in the *London Geographical Journal*.

GROUND SWELL. An undulation of the ocean caused by the continuance of a heavy gale of wind. Ground swells are rapidly transmitted through the water, sometimes to great distances, and even in direct opposition to the wind, until they break against a shore, or gradually subside in consequence of the friction of the water. They indicate, by the direction of their movement, the quarter in which a storm has raged; and occasionally they are observed to come from various points of the compass at the same time.

GUN COTTON. *Pyroxyline.* A highly inflammable and explosive substance, discovered by Schönbein, obtained by steeping clean cotton wool for a few minutes in a mixture of the strongest sulphuric and nitric acids in equal proportions; it is then thoroughly washed, and cautiously dried at a temperature of 212°. The original appearance of the cotton is little changed, but it has now become explosively inflammable, and when kindled by a spark it very suddenly flashes off with greater rapidity and energy than gunpowder, for which it has been proposed as a substitute, but the sad accidents which have occurred in the attempts to manufacture it upon a large scale have hitherto prevented its employment. When used in a gun it is much more energetic, weight for weight, than gunpowder; but, like fulminating mercury, it is apt, from the extreme suddenness of its explosion, to burst the gun. It appears to be pre-eminently fitted for blasting rocks.

The composition of gun cotton has not been very satisfactorily determined; by some it has been considered as a *nitrate of lignine;* that is, as a direct atomic combination of lignine and nitric acid, represented by the formula C_{24} H_{16} $O_{16} + 5\,NO_5$. Porret thinks that the cotton acquires oxygen from the nitric acid, and forms a new basic compound which he calls *lignea*, and he regards gun cotton as a *hyponitrite of lignea*.

Gun cotton is soluble in ether, and furnishes a glutinous liquor which has been used as an adhesive application in surgery, and even as a substitute for common sticking plaister, or goldbeater's skin. This solution has been called *Collodion*. When spread upon a surface the ether evaporates and leaves the gun cotton in the form of a transparent film, still very inflammable and explosive, and like the gun cotton itself, becoming highly electric on friction.

GU'RHOFITE. A compact magnesian carbonate of lime, from Gurhoff in Lower Austria.

GUTTA PERCHA. This important article, the uses of which in arts and manufactures are on the rapid increase, is the produce of a large forest tree (*Isonandra Gutta*. Nat. Ord. *Sapotaceæ*) growing in the mountains of Singapore, and in the forests of Johore at the extremity of the Malayan Peninsula, and in Borneo; it is plentiful at Sarawak, where it is called *Niato;* it is also supposed to abound on the clusters of islands to the south of Singapore. The gutta percha appears to separate from the juice or sap of the tree in the same way as India rubber, and its general properties in regard to solvents and to the products of destructive distillation resemble those of caoutchouc. At common temperature gutta percha is somewhat hard and very tough and unyielding, but when immersed in boiling water it softens so as to admit of being beaten into a mass and moulded into any requisite shape, and on cooling it resumes its hardness. In very thin films it has a pale yellow or pinkish tinge, but generally occurs in brown or blackish lumps or masses, of a somewhat mottled appearance upon the cut surface, and translucent at the edges. When softened it may be stretched into slips which do not recover their former shape when the force is withdrawn, but retain a kind of leathery pliability on cooling. When heated to about 350° gutta percha undergoes a kind of fusion, and remains viscid when cold. It burns with a strong yellow smoky flame. It is said to be obtainable in very large quantities, but that from the destructive mode hitherto pursued by the natives in obtaining it, there is a risk of its scarcity. It was first

made known in England in 1843 by a communication from Dr. Montgomery to the Society of Arts.

Gutta percha has been applied to the manufacture of cements, architectural and other ornaments, bookbinding, tubes, water-pipes, engine-hose, picture-frames, bottles, and drinking-cups, and to the soles of boots and shoes, &c. &c.; and when blended with caoutchouc it is used for driving machinery, for saddles, cushions, walking-sticks, &c.

GYNÆCO'NOMI. Athenian magistrates superintending the conduct of women, and having the power of inflicting punishment in cases of misdemeanour. They differed, therefore, from the *Gynæcosmi*, who were inspectors of dress.

GYRASOL. *See* GIRASOL, in DICT.

GYRATION, CIRCLE OF. If a body revolve round an axis, a point can be found in it at a certain distance from the axis at which, if the whole body were compressed, the moment of inertia would remain the same. This point is called the *centre of gyration*, and the radius of the *circle of gyration* is its distance from the axis. Thus, if M be the mass of a body and k the radius of gyration, then $k^2 \times M =$ the moment of inertia; and if r be the distance of any particle m of the body from the axis, we have the equation $k^2 M = \Sigma (r^2 m)$, where the quantity on the right-hand side of the equation will be found by integration for the particular body under consideration.

GY'RINUS. (Lat.) The water flea.

GY'ROSCOPE. (Lat. gyrus, *a circle*; Gr. σκοπεω, *I view*.) An instrument for exhibiting the effects of revolution or rotation, or both together.

H.

HABERGEON. (Fr.) A coat of mail composed of chain-work for the defence of the neck and breast.

HÆ'MACHROME (Gr. αἱμα, *blood*, and χρωμα, *colour*.) The colouring matter of the blood: called also *hæmatosyn*.

HÆMAL ARCH. (Gr. αἱμα, *the blood*.) That part of the vertebra or primary segment of the skeleton which encompasses the main axis, or its prolongations, of the vascular system. It is situated opposite the neural arch, and, except in man, is inverted and beneath the centrum.

HÆMAPOPHY'SIS. (Gr. αἱμα and αποφυσις, *process*.) The autogenous vertebral elements which close or form the hæmal arch. In the human thorax they close the arch, as "cartilages of the ribs," with the aid of a hæmal spine or "sternal bone;" in the Saurian tail they form, with the spine, the entire hæmal arch.

HÆ'MATINE. (Gr. αἱμα, *blood*.) The colouring principle of logwood.

HÆMATO'LOGY. (Gr. αἱμα, *the blood*, and λογος, *description*.) The doctrine of the blood.

HAI'DINGERITE. A double sulphuret of antimony and iron, named after Haidinger.

HAIR PENCILS. A term applied by artists to the small brushes used in painting, and often termed *camel's hair* pencils: they are composed of fine hairs, especially of the marten, badger, minever, polecat, &c., and are mounted, when small, in quills; but when larger, in tinned iron tubes.

HAIR SALT. Efflorescent sulphate of magnesia.

HAIR'S BREADTH. The forty-eighth part of an inch is sometimes so called.

HALISPO'NGIA. (Gr. ἁλς, *the sea*; and Lat. spongia.) The generic type of a group of sponges distinguished by the presence of *silicious* spiculæ.

HA'LITUS (Lat. *vapour*.) In Physiology, the term is applied to the watery vapour which rises from newly-drawn blood: the peculiar odour of blood is conveyed by this exhalation.

HALLITE. The subsulphate of alumina found at Halle.

HAL'LOYLITE. A mineral named after M. d'Halloy. It is a hydrated silicate of alumina.

HA'LOSCOPE. An instrument for the exhibition of all the phenomena connected with halos, parhelia, &c. One, invented by Bravais, was shown at the Great Exhibition of London in 1851. The instrument consists mainly of the following parts, all connected with and revolving on a vertical axis by means of a clock-movement:—Two triangular glass prisms and one quadrangular, the first of which is hollow for the reception of water; a small mirror carried by a short arm; two opaque plates of glass for the purpose of observing one or two sides of the prisms, as may be found necessary; and, finally, a plate of glass.

To produce a representation of the parhelion, it is necessary to place a candle in a darkened chamber, on a level with and from 10 to 12 ft. distant from the glass-prism on its axis of rotation, the prism having two sides covered. On looking in a horizontal direction, the parhelion circle becomes visible. By observing one side of the prism, only three horizontal lines are seen; two being found by external and one by internal reflexion.

To produce an imitation of the white parhelion, the candle is placed in the same position, and two sides of the prism are again darkened; when, on looking at the parhelion circle at a distance of 120° from the candle, the white one will be perceived.

Coloured parhelia may be exhibited by means of the prism of water, viewed at an angle of 20° or 25°. One side of the prism being obscured, the coloured parhelion, red on the side next the candle, with a white train prolonged to 15° or 20°, will be seen.

To imitate coloured parhelia, formed at a distance of 98° from the sun, the arrangements are the same. By observing the prism and looking at the distance of 98° from the candle, a coloured spot will be observed, red to the side opposite to the candle, and less bright than the parhelion.

The circumzenithal tangent of the arc may be imitated by means of the prism of water, the candle being lowered from its original position, and two sides of the prism darkened; on placing the eye in a proper position, the image will then be reflected upon the ceiling. Several changes may be produced by simply turning the prism. The circumzenithal arc may be produced by the above arrangement, the position of the eye only being altered.

To imitate the anthelion it is necessary to make use of the quadrangular prism; its large transparent surface is turned towards the observer, and the candle placed a little above the prism at the distance of six or eight feet from it. A small circular mirror is then so placed that its centre is on a level with the top of the prism. The eye being situated behind the prism will perceive a luminous circle described beneath its edge. If a little slip of paper be placed beneath, it will be perceived more distinctly without moving. By moving the position of the eye several distinct phenomena will become visible. There are means of adjusting the apparatus to render the image for a time permanently fixed. Other phenomena besides those detailed can be shown by this instrument, and great merit is due to M. Bravais, the inventor.

HAND. A measure of four inches, by which the height of a horse is computed: also the parts of a horse — as *forehand*, for the head, neck, and fore quarters; and *hindhand*, which includes the rest. It also designates the hand of the rider; the *spur-hand* being the right hand, and the *bridle-hand* the left.

HARMALI'NE. A crystallisable alkaloid contained in the seeds of the *Peganum Harmala*.

HARMA'TTAN. The dry parching wind prevailing on the coast of Africa, between Cape Verd and Cape Lopez, in the months of December, January, and February.

HARMO'NIC RATIO. In Geometry a straight line is said to be divided harmonically, or in harmonic ratio, when it consists of three segments such that the whole line is to one extreme as the other extreme is to the middle part. *See* ANHARMONIC RATIO.

HARRIER. A small hound trained for hunting the hare, remarkable for the acuteness of the sense of smell.

HA'RRINGTONITE. A mineral compound of silica, alumina, lime, soda, and water, from the North of Ireland.

HARUSPICES. *See* ARUSPICES, in DICT.

HAU'SMANNITE. Native oxide of manganese; so called in honour of Prof. Hausmann.

HAVERSACK. A strong coarse linen bag for carrying provisions on a march.

HAY'TORITE. A variety of calcedony.

HEADSTOCK. In machinery, the framing used for supporting the gudgeons of a wheel.

HEBE. One of the recently discovered small planets belonging to the group whose orbits lie between Mars and Jupiter. Hebe was discovered on the 1st of July 1847, by Hencke, of Driessen, the discoverer of Astræa, while examining the stars in Bremiker's chart. It had then the appearance of a star of the ninth magnitude, but soon after became fainter, and appeared as one of the tenth. The new planet was named *Hebe*, with a cup for its symbol, by Professor Gauss. Its periodic time is about 1380 days. (*Monthly Notices of the Royal Astronomical Society*, vol. viii.) *See* PLANET.

HECATE'SIA. In Grecian antiquity, an entertainment given every new moon in honour of Hecate.

HE'CTOGRAMME. A French measure of weight =100 grammes, or 1543·4 English grains.

HECTOLI'TRE. A French measure of volume =100 litres, or 6102·8 English cubic inches.

HECTOME'TRE. A French measure of length =100 metres, or 3937 English inches.

HEDENBE'RGITE. A silicate of lime and iron, first described and analysed by Hedenberg, in Sweden.

HE'DYPHAN. An arsenio-phosphate of lead and lime from Sweden.

HE'LENINE. *Elecampane Camphor.* A crystalline camphor-like substance, found in the root of *Muta Helenium*, or Elecampane. Its vapour has a peculiar odour somewhat resembling that of *patchouli*. Its chemical formula appears from the analyses of Dumas and Gerhardt, to be C_{21} H_{14} O_3.

HELIO'GRAPHY. (Gr. ἡλιος, *the sun*, and γραφω, *I describe.*) A general name given to the art of fixing images of objects by means of *Photography*, which see.

HE'LVINE. A mineral occurring in small crystals at Schwartzenberg, in Saxony; it is composed of the silicates of manganese, glucina, and iron.

HEMERALO'PIA. (Gr. ἡμερα, *the day*, and ωψ, *the eye.*) A peculiarity in the sight, in which persons see in broad day light but not in the evening: it is said to be endemic in some parts of Europe, and of the West Indies. The pupil is generally more dilated and less sensible than in healthy eyes.

HEMIPI'NIC ACID. Semi-opianic acid. An acid obtained by the oxidizement of the *opianic acid*.

HEMIPLE'GIA. (Gr. ἡμισυς, *half*, and πληττω, *I strike.*) Paralysis of one side of the body.

HE'MISPHERES. In Anatomy, the two moieties of which the cerebrum is chiefly composed: in man and mammalia they approach the hemispheric form; but in most of the lower vertebrata, where the cranial cavity affords more room for the small brain, both moieties are spherical.

HE'MITROPE. (Gr. ἡμισυς, and τρεπω, *I turn.*) A term applied by some crystallographers to what are usually called *twin crystals*, from their being generally conceived to result from the cutting, as it were, a crystal in half, and then turning one of the halves half round upon the other. The plane common to the two portions of the crystal is called the *twin plane*. These crystals are often distinguished by the presence of notches or *re-entering angles*.

HEPA'TIC AIR. (Gr. ἡπαρ, *the liver.*) Sulphuretted hydrogen of modern chemistry.

HE'PATITE. (Gr. ἡπαρ, *the liver.*) A mineralogical name of some of the varieties of sulphate of baryta which have a liver colour.

HERO'S FOUNTAIN. *See* FOUNTAIN, in DICT.

HE'RSCHELITE. A prismatic mineral from Catania, in Sicily, containing silica, alumina, and potassa; so called in honour of Sir J. F. Herschel.

HESPE'RIDINE. An insipid white crystalline substance obtained from the soft spongy part of orange and lemon rind. It has also been called Aurantine.

HE'TERO. (Gr. ἑτερος, *the other, one of two.*) As a prefix, or in composition, this term usually indicates *difference*; in opposition to the prefix *homo*, which indicates resemblance.

HETO'PYLITE. (Derivation unknown.) A native phosphate of iron and manganese.

HEU'LANDITE. A mineral formerly classed with the zeolites found in the basalt of the Giants' Causeway and elsewhere: it is a silicate of alumina and lime.

HIBERNATION. *See* HYBERNATION, in DICT.

HIERO'S FOUNTAIN. *See* FOUNTAIN, in DICT.

HILUM. The point by which a seed is attached to the seed vessel.

HI'PPOCRAS. Spiced wine. The following is one of the most approved recipes for its preparation: 2 ounces of cinnamon, half an ounce of canella alba, and of cloves, mace, nutmeg, ginger, cardamoms, each 1 drachm: these are to be finely bruised and digested for three or four days, in a warm place, in a mixture of 12 quarts of canary and Lisbon wines: the liquor is then to be filtered, and 3 pounds of refined sugar added.

HIPPO'CRATES' SLEEVE. *Manica Hippocratis.* An old pharmaceutical term signifying a conical bag or strainer made of flannel or linen, in the shape of a jelly-bag.

HIPPUS. (Lat.) A spasmodic affection of the iris, occasioning repeated dilatations and contractions of the pupil of the eye.

HI'SINGERITE. A hydrated silicate of peroxide of iron, found in Sweden and Germany; occurring in rounded nodules.

HISTO'LOGY. (Gr. ιστος, *a tissue;* λογος, *a discourse.*) The doctrine of the animal tissues.

HOCK DAY. HOKE DAY. A festival formerly observed in England on the second Tuesday after Easter, in commemoration of the destruction of the Danes in the time of Ethelred.

HO'GAUITE. A mineralogical synonym of a species of *natrolite* from Högau, near the lake of Constance.

HO'LMITE. A species of carbonate of lime, named after Holme, who analysed it.

HOMBERG'S PHOSPHORUS. Fused chloride of calcium.

HOMBERG'S PYROPHORUS. *See* PYROPHORUS, in DICT.

HOMBERG'S SEDATIVE SALT. Boracic ac to which Homberg erroneously assigned sedative powe

HO'MO. (Gr. ὁμος, *one and the same.*) A pre used in composition to denote *resemblance*, and th opposed to *hetero*, which indicates *difference*.

HOMŒO'PATHY. (Gr ὁμοιος, *similar;* παθος, *fection.*) A medical hypothesis promulgated at the co mencement of the present century by the late I Hahnemann, of Leipsig, according to which every me cine has a specific power of inducing a certain diseas state of the system; and if such medicine be given t person suffering under the disease which it has a te dency to induce, such disease disappears because t similar diseased actions cannot simultaneously subs in the same organ. Medicines, therefore, are adn nistered in doses sufficient to induce an action som what superior to that of the disease, and the doses whi answer this purpose are *infinitesimal*, as it is called : millionth of a grain is often an excessive quantit "With respect to the homœopathic theory of the op ration of medicines," observes a good medical authori "all that can be said is, that it is a mere whim, u supported either by reason or by facts. With respect the practice, it evidently amounts to doing nothing b regulating the diet and habits of the patient." No all judicious practitioners have long been agreed th there are many cases which are best treated in t manner just mentioned, and in which physic does mo harm than good; in which, in short, a sensible phys cian endeavours to amuse the patient, while nature cur the disorder: so that the frequent success of homœ pathic treatment may be explained, without admitti the principles upon which it is presumed to be founde

HOMO'LOGY. (Gr. ὁμος, *the same*, and λογος, *d scription.*) In Anatomy, that department of the scien which teaches the essential correspondence or answe ableness of the parts, either in different animals, or in di ferent segments of the same animal, or in the same se ment, also the correspondence of the parts of an anim with the ideal archetype which has governed the plan its organisation. Thus, firstly, the wing of a bird is, h mologically, the same limb as the arm of a man or t fore-foot of a horse: and the "os quadratum" of bird is shown to be the same bone as the "os tym panicum" of the tortoise, and as the "auditory pr cess of the temporal bone" of a man. They a said to be "homologous" parts, and the propositio are examples of what has been called "special hom logy." Secondly, the wing of a bird is the same correlative part in its segment of the body, as the leg in a more posterior segment: just as the frontal bone the correlative element in its segment, with the supe occipital bone in its segment. The wing of the rig side is also the answerable part of the wing of the l side; in the same way that the right neurapophysis any given segment answers to the left neurapophysis the same segment. Propositions of this kind are e amples of what is termed "serial homology;" and t parts so corresponding are said to be "homotypal thus the arm is the homotype of the leg, the humer of the femur, the radius of the tibia, the ulna of t fibula, &c. Thirdly, in relation to the archetype of t vertebrate skeleton, the arm is the "diverging appen age" of its segment; the superoccipital bone is the "ne ral spine;" the exoccipital bone or "condyloid part the occipital bone" in "Anthropotomy" is the "neu apophysis;" the basioccipital bone or "basilar process the occipital bone" is the "centrum" or "body" of segment: these propositions are instances of what termed "general homology," as being expressive of t highest generalisations in that philosophical departme of anatomical science. — See Owen *On the Archety and Homologies of the Vertebrate Skeleton.*

HOMO'NYMOUS. (Gr. ὁμος, *the same*, and ονυμ *a name.*) In Anatomy, syn. of Homotypal. " those of the right side arise from the left part of t brain, and *vice versâ*, which seems to be the opinion the best anatomists, then one would imagine that t homonymous nerves of the right and left side must, crossing over, lie somewhere contiguous to each oth and so impart vibrations to each other." — *Hartley.*

HO'MOTYPE. (Gr. ὁμὸς and τυπος.) In Anato the correlative in one segment with any given part another segment, or in the same segment, of one a the same animal. Thus the frontal bone is the ho type of the superoccipital bone; the humerus is t homotype of the femur; the parts on the right side homotypes of those which are repeated on the l side. It is the object of "serial homology" to de mine "homotypal" parts. *See* HOMOLOGY.

HO'NEY DEW. A sweetish substance ejected u the leaves of plants by certain *aphides*.

HO'PEITE. A mineral named after Dr. Hope, l Professor of Chemistry at Edinburgh; it is said to b hydrous phosphate of zinc and cadmium.

HOOPOO. The vernacular name of the *Up Epops*, in Ornithology.

HORSE POWER. A dynamical unit employed for expressing the power or magnitude of a steam engine.

When Mr. Watt first employed his improved steam engine in turning mills, many of which had previously been driven by horses, it became desirable to possess some measure of power whereby the size of engine proper for the supercession of any given number of horses might be approximately determined. Mr. Watt consequently made several experiments to ascertain the amount of power exerted by a horse in a given time, and he found that the strongest class of dray horses would on an average raise a weight of 33,000 lbs. through one foot in the minute, by the intervention of appropriate mechanism. This dynamic effort, therefore, he designated a *horse power*, and when he had to introduce an engine which should be capable of performing the work of any given number of horses, he had only to take care that it would be able to raise 33,000 lbs. one foot high in the minute for every horse power that it was intended to supersede. The dimensions of engine which should be capable of raising any multiple of 33,000 lbs. one foot high in the minute were at the same time determined, and that multiple expressed the number of horses power the engine was able to exert. Thus if the engine were of such dimensions as to be able to raise 5 times 33,000 lbs. one foot high in the minute, it would be 5 horses power; if it were able to raise 10 times 33,000 lbs. one foot high in a minute, it would be of 10 horses power, and so of any other number. The effective pressure on the piston of these engines, or the pressure considered available for imparting motion to any body, after deducting the power consumed by the engine itself, was reckoned to be about 7 lbs. on the square inch. The area of the piston, therefore, in square inches multiplied by 7 represented the effective moving pressure, and the space travelled through by the piston in the minute gave the distance through which the pressure or weight operated. The total effective weight or pressure upon the piston, therefore, multiplied by the space through which it passes, and divided by 33,000, would in all cases give the number of horses power that the engine was capable of exerting, and as the effective pressure upon the piston was limited to about 7 lbs. on the square inch, and as the speed of the piston was limited to about 220 feet in the minute, a certain dimension of engine was necessary to realise any prescribed power, and came to be considered as tantamount to that power. In this way, therefore, engines of certain dimensions came to be considered as of a certain power, and engines were bought and sold by the horse power in the same way that cloth is bought or sold by the yard measure, and the engine would in all cases exert just about the power at which it was nominally rated.

In process of time, however, a different state of things supervened. When Watt's patent expired, numerous other manufacturers of engines sprang into existence. By degrees the pressure upon the piston came to be increased: the velocity of its motion was also increased, and a dimension of engine answerable to a horse power became capable of raising much more than 33,000 lbs. one foot high in the minute. Engines continued, however, to be bought and sold by the horse power, just as if there had been no increase in their efficiency, and the same dimension of engine was reckoned equal to a horse power that was accepted before. There came, consequently, to be two kinds of horse power,— the one a *dynamical unit*, which measures the number of times 33,000 lbs. can be lifted one foot high per minute by the engine; and the other a *commercial unit*, which measures the dimension of the engine. The dynamical horse power is what is termed *actual horse power;* the commercial or conventional unit is what is termed *nominal horse power*. In speaking of engines great misapprehension and confusion have been caused from the want of a distinct idea of the difference between actual and nominal power.

The actual power of any engine cannot be determined except approximately, before the engine is made; but it is ascertained, when the engine is at work, by means of an instrument called the indicator. An engine sometimes exerts more actual power than at other times, although its nominal power remains unaltered. For example, when a steam vessel in entering a harbour lowers her speed, the steam is partially excluded from the cylinder, and there is consequently less pressure upon the piston than before. A similar result will follow if the coals be bad, or there be an inadequate proportion of boiler; and the efficiency with which an engine works is in all cases ascertainable by determining by means of the indicator the actual power. (See INDICATOR, in the SUPPLEMENT.) In modern engines the actual power is from 2 to 4 times greater than the nominal power. In other words, an engine purchased or popularly spoken of as 1000 horses power, will be able to lift from 2000 to 4000 times 33,000 lbs. one foot high in the minute. Such an engine, therefore, though nominally of 1000 horses power, will exert actually from 2000 to 4000 horses power; the exact amount of power exerted being determinable only by the application of the indicator to the engine. For the mode of determining the actual power of an engine see the article INDICATOR. The nominal power may be determined by the following rule: — Multiply the square of the diameter of the cylinder in inches by the cube root of the stroke in feet and divide by 47. The result is the nominal power of the engine in horses. The reader will find in the *Artizan Club's Treatise on the Steam Engine*, p. 96., a table of the nominal horse power of low pressure or condensing engines.

HU'MORAL PATHOLOGY. The doctrine which refers disease to a morbid condition of the humours or fluids of the body, as opposed to *nervous pathology*, which refers them to the nervous energy resident in the solids.

HUMBOLDTITE. So called in honour of Humboldt. A crystalline mineral found in the lava of Vesuvius; it is a silicate of lime and magnesia.

HU'MIC ACID. HUMINE. (Lat. humus, *the ground.*) The peculiar brown matter which may be obtained from bog-earth, peat, and turf, and which may also be extracted from most soils, where it is derived from the slow decay of plants; it is also contained in brown decayed wood, and in the brown exudations of the bark of certain trees, more especially in that of the elm, or *ulmine*. By the action of several chemical agents on different organic bodies, the same substance is frequently produced. It is a substance which contributes to the fertility of soil, chiefly, perhaps, in consequence of its absorptive power in regard to ammonia.

HUMMOCK. A level sheet of *ice*. A circular mound appearing at a distance is also so called.

HU'NGER. (Germ.) The sensation in the region of the stomach arising from the want of solid food: in intensity it varies considerably in different individuals, and is sometimes attended by pain and windy rumblings in the epigastrium. When severe, hunger is attended by slow respiration and circulation, and diminution of the heat of the body and of the secretions. The return of hunger is accelerated by exercise and fatigue, and by a low temperature. In debilitated constitutions excessive hunger should be carefully avoided, and in any case, the effects of fasting may prove prejudicial to the functions of the stomach.

HU'RAULITE. A phosphate of iron and manganese found at Huraux, in the Haute Vienne.

HU'RONITE. A mineral from the vicinity of Lake Huron; it is imbedded in a species of hornblende: it is a hydrated silicate of alumina, and contains also lime, magnesia, and oxide of iron.

HY'ALOSI'DERITE. (Gr. ὑαλος, *glass;* σιδηρος, *iron.*) A mineral consisting essentially of the silicates of magnesia and iron, from Sasbach, in Brisgau. It is of a glassy lustre.

HY'DROLITE. (Gr. ὑδωρ, *water;* λιθος, *a stone.*) A silicate of alumina, iron, and potassa, containing nearly 30 per cent. of water: it has principally been found in the amygdaloidan rocks of Antrim in Ireland.

HYDRO'PATHY. (Gr. ὑδωρ and παθος, *disease.*) This term is applied to a treatment of disease generally called the *cold water cure;* it was suggested in 1828, by Vincent Priessnitz of Graefenberg in Silesia, and consists in the internal and external administration of cold water, accompanied by air and exercise, early hours, and strict attention to diet; there are, therefore, many cases in which such a plan rationally pursued must be obviously useful, more especially to overphysicked individuals, residing in populous towns, eating and drinking too much, and keeping bad hours. At the same time, some parts of the treatment "are of so outrageous a character, as frequently to aggravate the disease which they are intended to cure, and occasionally to endanger or even destroy the life of the patient." (The term *hydropathy* is considered to be a corruption from *hydro-therapeutics.*)

HYDROTHIO'NIC ACID. (Gr. ὑδωρ and θειον, *sulphur.*) Hydrosulphuric acid, or sulphuretted hydrogen.

HY'DRURET, or HYDROGURET. A term applied in chemistry to some of the compounds of hydrogen, more especially with the metals.

HYGE'IA. One of the group of small planets between Mars and Jupiter. Hygeia was discovered by Dr. Annibal De Gasparis, of the Observatory at Naples, while comparing Steinheil's map with the heavens, on the 12th of April, 1849. It had then the brightness of a star between the ninth and tenth magnitudes. De Gasparis referred the naming of the planet to Capocci, who called it *Hygeia*, and selected for its symbol a serpent crowned with a star. It was the tenth in the order of discovery. See PLANET.

HYGRO'MA. (Gr. ὑγρος, *moist.*) A tumour containing serum or other nonpurulent fluid.

HYGRO'METRY. (Gr. ὑγρος, *moist*, and μετρον, *measure.*) Of the various methods which have been proposed for ascertaining the hygrometric condition of the atmosphere that which consists in deducing

the tension of the aqueous vapour contained in it from the temperatures indicated by two contiguous thermometers, one having its bulb kept wet, while that of the other is dry, is, perhaps, the most generally convenient, and is accordingly that which is usually adopted in meteorological observations. The apparatus has been called a *Psychrometer*, and is described under that name in the DICTIONARY OF SCIENCE, though the term, from its etymology, might be applied with equal propriety to any other hygrometer or instrument for measuring the quantity of vapour existing in air. On account of the importance of this instrument in meteorology, we propose, here, to state the theory upon which its application depends.

It may be proper to premise that the relation between the tension, or the elastic force of aqueous vapour, and the temperature (a relation which is the subject of experiment) is supposed to be known for all temperatures under consideration, and exhibited in a table. Hence, to determine the elastic force of the vapour existing in the atmosphere at a given temperature, is the same problem as to determine the degree of temperature to which, if the air were cooled down, it would be saturated with the same quantity of vapour as it actually contains, and begin to deposit moisture; and, reciprocally, if this temperature, which is that of the *dew point*, be determined, the tension of the vapour existing in the air becomes known from the previously ascertained relation between the tension and the temperature of aqueous vapour. Tables of the numerical expression of this relation were constructed by Dalton, and are given in most works which treat of the subject. *See* VAPOUR, in DICT.

Theory of the Psychrometer.—When water or any wetted surface is exposed to air not saturated with moisture, vapour is formed; and, in the formation of vapour, heat is absorbed or becomes latent. The heat thus absorbed being taken from the body from whose surface the evaporation takes place the body becomes colder, and the thin shell or stratum of air in immediate contact with it is cooled down to the same temperature. Now, the theory of the psychrometer is founded on this hypothesis, namely, that the quantity of heat abandoned by the thin shells of air which successively come into contact with the wetted bulb of the thermometer is precisely equal to the heat absorbed in the formation of the vapour.

From this hypothesis an equation is obtained which gives the tension corresponding to the temperature of the dew point in terms of the tension corresponding to the temperature of the wet bulb (that of evaporation), the difference of the readings of the wet bulb and dry bulb thermometers, and the height of the barometer, in the following manner: Let t denote the temperature, in Fahrenheit degrees, indicated by the dry bulb thermometer, and t' the temperature indicated by the wet bulb thermometer. The thin shell of air in immediate contact at any instant with the wet bulb, which previous to the contact had the temperature t, is cooled down to t', and consequently abandons a certain quantity of heat. But the shell is composed partly of dry air, and partly of aqueous vapour. If, therefore, we assume

A=the heat abandoned by the dry air in the shell,
B=the heat abandoned by the vapour originally existing in the portion of air forming the shell,
C=the heat absorbed by the vapour formed and taken up by the shell;

then by the hypothesis

$$A+B=C. \qquad (1.)$$

To express these portions of heat universally, we have

A=weight of dry air in shell × specific heat of dry air × $(t-t')$,
B=weight of vapour in shell × specific heat of vapour × $(t-t')$,
C=weight of vapour formed × latent heat of vapour at temperatures between t and t'.

Now let

w=weight of shell of dry air, at 32°, under a pressure equal to 30 inches of mercury,
α=coefficient of expansion of air for 1° Fahrenheit =1-480th,
δ=ratio of density of vapour to density of dry air,
h=height of the barometer in inches,
f'=elastic force of aqueous vapour, in saturated air, at temperature t', measured in inches of mercury,
x=elastic force of the vapour actually existing in the air at temperature t, or the tension of vapour at the dew point;

then, in respect of the thin shell of air surrounding the wet bulb, we have the following expressions for the several weights, viz.

Weight of dry air in shell $=w\dfrac{1}{1+\alpha t'}\cdot\dfrac{h-f'}{30}$,

Weight of vapour in shell previously to contact with wet bulb $=w\delta\dfrac{1}{1+\alpha t'}\cdot\dfrac{x}{30}$,

Weight of vapour formed $=w\delta\dfrac{1}{1+\alpha t'}\cdot\dfrac{f'-x}{30}$.

Now putting

γ=specific heat of dry air,
k=specific heat of vapour,
λ=latent heat of vapour between t and t';

and substituting these and the above expressions for the weights in A, B, and C, the equation (1.) becomes

$$\gamma(h-f')(t-t')+k\delta x(t-t')=\lambda\delta(f'-x),$$

from which we obtain

$$x=\frac{\lambda f'-\frac{\gamma}{\delta}(t-t')(h-f')}{\lambda+k(t-t')}. \qquad (2.)$$

Of the quantities which enter into this equation t, t', and h are given by direct observation, and f' is given when t' is known from the table of tensions above referred to. The remaining quantities are supposed to have been determined experimentally, and their values are as follows:—

1. From the experiments of Laroche and Berard the specific heat of dry air, γ, was found to be 0·2669, that of water being unity.

2. The specific heat of aqueous vapour, k, is less certainly determined. August assumes it to be equal to that of dry air. Laroche and Berard found it to be 3·136 times that of dry air. In the present case its accurate value is not important, for the term which it multiplies is so small in comparison of λ that it may be rejected without sensible error.

3. The density of aqueous vapour, δ, referred to that of dry air at the same temperature, was found by Gay Lussac to be 0·6235, or nearly 5-8ths. Regnault assumes δ=0·622.

4. With respect to the latent heat of vapour, λ, its value at any temperature is deduced from its known or assumed value at 212° by means of the hypothesis (confirmed by experiment) that the sum of the latent and sensible heat is constant for all temperatures. At 212° the latent heat of vapour is usually assumed, according to the determination of Lavoisier, to be 1000; that is to say, as much heat is absorbed in the formation of a certain weight of vapour as would raise the temperature of 1000 times the same weight of water one degree of Fahrenheit's scale. Hence at 32° it is 1180. Regnault ascertained by direct experiment that the formula for the psychrometer would be more accurate by taking λ equal to 610° on the centigrade scale, at the temperature of freezing; this corresponds to 1098° of Fahrenheit, and, consequently, at 0° Fahrenheit the latent heat is 1130°. For any other temperature, t', we have, therefore, $\lambda=1130-t'$.

Substituting these values of γ, k, δ, and λ, in the formula (2.), and rejecting $k(t-t')$ in the denominator, it becomes

$$x=f'-\frac{0{\cdot}429(t-t')(h-f')}{1130-t'}. \qquad (3.)$$

For $t'=50°$, this gives $x=f'-{\cdot}000397(t-t')(h-f')$.

If the temperature of the wet bulb fall below the freezing point the water surrounding the bulb is frozen, so that it is ice which is evaporated. And as 140° of heat are expended in converting ice into water the formula becomes, for this case,

$$x=f'-\frac{0{\cdot}429(t-t')(h-f')}{1270}. \qquad (4.)$$

The value of x being computed from this formula the corresponding temperature in the table is that of the dew point.

Objections of various kinds, theoretical and practical have been raised to the results obtained by this method The fundamental principle adopted by August is, tha the whole of the air which supplies heat to the wet bul falls to the temperature of that bulb, and becomes com pletely saturated with moisture. But it seems mor probable that the air coming into contact with the bul does not quite take the temperature of the bulb, an that the saturation is not complete. Regnault remark that the ratio of the quantity of heat which the air take from the bulb by the vaporisation of the water to th quantity which it loses in being cooled is probably no constant, but so much the greater as the air is drie because dry air absorbs moisture with greater avidit than when it is nearly saturated. Another objection i that the heat which is absorbed in converting the wate on the wet bulb into vapour is not supplied exclusivel by the surrounding air, but in some measure by th radiation from objects around (for example, the fram to which the thermometers are attached, or the dr bulb itself if too near), the influence of which it is perha impossible altogether to eliminate. Other objection are founded on the considerable uncertainty as to th numerical values of some of the elements which ent

into the formula, and especially with respect to the heat absorbed by water when vaporised in air. Regnault, therefore, considers that the safest course is to determine the coefficients of the formula by direct experiments under determinate conditions. One means of accomplishing this is to compare the results of a large number of observations with the temperatures of the dew point ascertained directly by simultaneous observations with a Daniell's hygrometer; but as this instrument itself cannot be relied on with certainty, the only sure method would seem to be that of separating the moisture from the air and determining their proportions by actually weighing them.

It is important to determine the influence of the wind on the results obtained by this instrument. According to theory, when the difference of the temperatures indicated by the two thermometers has become stationary, the agitation of the air should have no effect on them; for as the degree of cold ultimately produced depends on the *intensity*, and not on the *velocity*, of evaporation, the effect of wind on the wet bulb might be expected to be only that of depressing its temperature more speedily, but not to a lower point. Regnault made numerous experiments on this subject, and arrived at the conclusion that wind certainly does influence the observation, but when the instrument is exposed to free air the influence is not perceptible so long as the velocity of the wind does not exceed five or six *metres* per second (16 or 20 English feet, or from 11 to 14 miles per hour). When the wind blows strongly, another disturbance may arise from the circumstance that the masses of air successively brought into contact with the wet bulb may have very different degrees of humidity. On the other hand, when the air is perfectly calm it is not improbable that an atmosphere of saturated air may be formed and remain about the wet bulb, extending to some sensible distance; for it is known that vapour diffuses itself through air in this state slowly and with difficulty. It is scarcely necessary to add, that when the air is nearly saturated with vapour, and there is consequently little difference between the temperatures indicated by the two thermometers, the results obtained must be liable to considerable uncertainty.

The formula for computing the temperature of the dew point, from observations of a dry and wet bulb thermometer, was first investigated by Professor August, of Berlin, and is given in his work *Ueber die Fortschritte der Hygrometrie* (Berlin, 1830), the same in form as the above, but with slightly different constants. There is also an investigation on the same principle, and leading to the same results, by Dr. Apjohn, in the Dublin *Transactions* for 1834 and 1835, and tables have been constructed by Col. Boileau for facilitating the computation of the formula. But the fullest and best information on the subject is contained in a paper by Regnault, published in the *Annales de Chimie et de Physique* (3me series, tome xv., Paris, 1845). In this paper Regnault describes a new hygrometer, invented by him, for determining the dew point by direct observation, the cold being produced, as in Daniell's hygrometer, by the evaporation of ether; but in Regnault's instrument the ether, instead of being poured over the wet bulb, and much consequently wasted, is confined within a glass tube, or cylinder, of about an inch in diameter, and agitated by blowing a stream of air into it through a flexible tube. A rapid evaporation consequently takes place within the cylinder, and the cold thereby produced causes a deposition of dew on the outside. A delicate thermometer placed inside the cylinder, immediately over the ether, indicates the temperature, which must be noted at the instant the deposition commences, and should be again noted at the instant it disappears. A portion of the cylinder over the ether is blackened for the purpose of intercepting the passage of light, whereby the deposition is rendered more easily visible. Of the various hygrometers which have been proposed on the principle of condensing the vapour existing in the air, or as modifications of Daniell's, this appears to be the most satisfactory.

HYOI'DES. (From the Greek letter υ, and ειδος, *like.*) A bone situated between the root of the tongue and the larynx is called the Os Hyoides, or hyoid bone, from its supposed resemblance in shape to the letter U or upsilon.

HYPAPO'PHYSIS (Gr. υπο, and αποφυσις, *a process.*) In Anatomy, the usually exogenous process which descends from the lower part of the centrum or vertebral body: it is sometimes single, as in the cervical vertebræ of the lizard; sometimes perforated, as in certain cervical vertebræ of birds; sometimes double, in a transverse pair, as in the caudal vertebræ of certain mammals, where they support the hæmal arch.

HY'PER. (Gr. υπερ, *over, above.*) In chemical nomenclature this prefix is sometimes used to denote acids containing more oxygen than those to which the term *per* is prefixed.

HYPERÆ'MIA. (Gr. υπερ, and αιμα, *blood.*) Congestion of blood in any part.

HY'PERCATHA'RSIS. (Gr. υπερ, and καθαιρω, *I purify.*) Excessive purging.

HYPERI'CUM. (Gr. υπερ, and εικων, *an image*, so called from a supposed power of expelling evil spirits.) The *Hypericum perforatum*, or St. John's Wort, was much esteemed by the ancients as an anodyne.

HY'PO. (υπο, *under.*) In chemical nomenclature this prefix indicates the presence of a smaller quantity of oxygen than that contained in the acid or compound to which it is prefixed, thus the *hyposulphurous acid* contains less oxygen than the sulphurous, and the *hyposulphuric acid* less oxygen than the sulphuric; and the *hyponitrous* acid less oxygen than the nitrous, etc.

HY'POCYST. A pharmaceutical name of the inspissated juice of the *Cytisus hypocistis*, a parasitical plant on the roots of several species of *cystus* in the S. of Europe.

HYPOGÆ'UM. (Gr. υπω, and γη, *the earth.*) A term applied by ancient architects to the cellars and other underground parts of a building.

HYPOGA'STRIUM. (Gr. υπο, and γαστηρ, *the stomach.*) The middle part of the lower region of the belly.

HYPO'GLOSSAL NERVES. (Gr. υπο, and γλωσσα, *the tongue.*) The lingual nerves.

HYPO'PHYSIS (Gr. υπο, and φυσις, *nature* or *origin.*) In Anatomy, the gland-like body and sac which originate from the under surface of the third ventricle of the brain, and are lodged in the "sella turcica." *See* PITUITARY GLAND.

HYPSO'METRY. (Gr. υψος, *height*, and μετρον, *measure.*) The art of measuring heights either relative or absolute, by trigonometry or the barometer.

HYSON. A commercial name of one of the varieties of *green tea. See* TEA, in DICT.

HYSSOP. The name of a genus of plants including the common hyssop (*Hyssopus officinalis*), formerly used in medicine as a stimulant and expectorant.

HYSTERO'TOMY. (Gr. υστερα, *the womb;* τεμνειν, *to cut.*) The extraction of the fœtus from the uterus. The *Cæsarean operation.*

I.

IA'TRALEI'PTES. (Gr. ιατρος, *a physician;* αλειφω, *I anoint.*) A physician who cured diseases by external remedies only, as by friction, inunction, &c. There was among the Greeks a sect of Ιατραλειπται founded by Prodicus, a disciple of Esculapius.

IA'TROMATHEMA'TICI. (Gr. ιατρος, and μανθανω, *I learn.*) Physicians who explain the functions of the body, and the action of remedies on mechanical principles. These doctrines seem to have originated with Asclepiades, and in modern times were promulgated by Borelli as founded on the atomic philosophy of Descartes.

ICE. (Ger. eis.) Frozen water. At the temperature of 32°, water, in its ordinary condition, crystallises into ice, which if slowly produced forms prisms crossing each other at angles of 60° and 120°; the primitive figure has not been ascertained, though it is probably rhomboidal. The arrangement of the acicular prisms in flakes of snow is very various, but in the same snow storm the same forms of arrangement generally prevail. The specific gravity of ice in its densest form is about ·950. It is a nonconductor of electricity, and becomes electric by friction. The expansion of water in the act of freezing, takes place with irresistible force, and the frequent rupture of thick iron and leaden pipes from this cause is a familiar instance of this. Exposed to air ice loses considerably by evaporation. In the act of freezing water parts with all soluble matter, so that coloured water becomes colourless ice; saline solutions become pure water; and spirituous liquors part with their alcohol. To effect this purification perfectly, the ice must be formed under circumstances which prevent the accumulation of blebs and air bubbles, and the entanglement in the ice of any of the unfrozen or ejected liquor, for the foreign matters held previously in solution in the water, are, in the act of freezing, transferred to the portion which remains unfrozen, when the whole of the water becomes a mass of porous ice the impurities are retained in the pores; but those brilliant and perfectly transparent and dense masses of ice which we find in the American and Norway ice as imported into this country, yield, when thawed, water equal in purity to that which has been distilled; and nearly free from air.

ICHTHYO'PHAGIST. (Gr. ιχθυς, and φαγω, *I eat.*) A fish eater: some savage tribes who live almost entirely on fish were called by the ancients *Ichthyophagi.*

I'GLOITE. A mineralogical synonym of one of the varieties of carbonate of lime, or *Arragonite.*

ILLU'DERITE. A mineralogical synonym of *Epidote*.

I'LMENITE. The titaniferous iron ore from Ilmensea, near Minst.

I'LVAITE. A mineral from *Elba*, in black prismatic crystals: it is a silicate of iron and lime.

IMBIBI'TION. (Lat. in, and bibo, *I drink*.) The absorption of a liquid into the pores of a solid: much importance has been attributed to this property as belonging to the organic tissues and as affecting their functions.

IMPE'RIAL. A beverage formed by dissolving one drachm or one drachm and a half of cream of tartar in a pint of boiling water, and flavouring with lemon peel and sugar. When cold, it may be taken *ad libitum*.

INCLINO'METER. An apparatus for determining the vertical element of the magnetic force. The difficulty of determining this element by a direct method is considerable, on account of the delicacy of the apparatus which is requisite. Various indirect methods have been proposed. Dr. Lloyd, in the *Account of the Magnetical Observatory at Dublin*, describes an Inductive Inclinometer, "the principle of which is the measurement of the intensity induced on a vertical bar of soft iron by the deviation it is capable of causing in a horizontal bar suspended near it." Weber, of Gottingen, proposed a method, in which "the deflexion of the horizontal magnet is produced by the earth's magnetism, induced not on a vertical bar of soft iron at rest, but on a ring, sphere, or plate of copper made to revolve about a vertical axis." Dr. Lamont, of Munich, proposed a third and less simple method: "As in Dr. Lloyd's process, a bar of soft iron is used as a temporary magnet. The bar so temporarily magnetised is made to act unequally on the two bars of an astatic magnetic couple, thereby tending to draw them aside from a given position in which they would otherwise be held by a fixed magnet of a given power. This tendency is, however, destroyed by another magnet placed in a given position at a given distance. A series of reversals and changes of distance in the soft iron bar and the neutralising bar is then operated, which furnishes equations by means of which every quantity excepting the intensity sought and known quantities can be eliminated." — (*British Association Report*, 1842.) See MAGNETOMETER.

INDIAN RUBBER. *See* CAOUTCHOUC, in DICT. A curious and important modification of this article has been discovered by Mr. Thos. Hancock; it is generally known under the name of *Vulcanised India-rubber*, and is, in fact, caoutchouc combined with a very small proportion of sulphur: the several modes of effecting this are fully described in the specification of his patent. Vulcanised India-rubber, does not, like the ordinary article, become hard and rigid by cold, and it bears a very high temperature without change of properties. It is much more perfectly elastic than the common rubber, so that when stretched it does not acquire a set, but returns, when released, to its former dimensions. This discovery has rendered caoutchouc applicable to an infinity of purposes, for which, in its ordinary state, it is either unfit or objectionable. Among the most remarkable properties of Vulcanised caoutchouc, is the resistance which it affords to naphtha, oil of turpentine, ether, oils, and a variety of other substances which are comparatively without action upon it, whereas they either soften, or dissolve common rubber.

INDIAN YELLOW. *See* EUXANTHINE.

I'NDICATOR. (Lat. indico, *I point out*.) An instrument for determining the power exerted by a steam engine. This instrument consists of a small cylinder and piston, which is placed in connexion with the cylinder of the engine by means of a pipe and stop-cock fitted into the cylinder cover. The cylinder of the indicator is open at the top, so as to permit the access of the atmosphere, and its piston is kept at about the middle of its stroke by means of a spring, when the instrument is out of connexion with the engine; but when the stop-cock is opened so that the space beneath the piston of the indicator is put in connexion with the cylinder of the engine, the piston of the indicator is pressed up and down every stroke by the alternate steam pressure and vacuum existing within the cylinder of the engine. The extent to which it is pressed up and down indicates the amount of pressure urging the piston of the engine; and a scale is attached to the side of the indicator, graduated with pounds pressure, upon which a pointer in connexion with the indicator piston shows the number of pounds pressure above the atmosphere that is exerted by the steam, and also the number of pounds pressure below the atmosphere that is exerted by the vacuum.

I'NDIGOGE'NE. *Indigo white*. *See* INDIGO, in DICT.

I'NDIGOTI'NE. The sublimate obtained by heating indigo. *See* INDIGO, in DICT.

INFUNDIBU'LIFORM. A botanical and anatomical term, signifying *funnel shaped*. The *Infundibulum* of the brain is a canal proceeding from the lower and anterior part of the third ventricle of the brain to the pituitary gland.

I'NGUINAL. (Lat. inguen, *the groin*.) Appertaining to or situated in or near the groin: as *inguinal artery*, *inguinal hernia*, etc.

INHALA'TION. (Lat.) The drawing of air, gases, or vapours, into the lungs. Many substances are medicinally applied in this form, by means of an *inhaler*, an instrument so contrived as to admit of the inhalation of a variety of vapours mixed more or less with atmospheric air. The steam of hot water, the vapour of tar, of ether, of chloroform, of iodine, chlorine, &c. are often thus administered.

INJE'CTION. A liquid thrown into a cavity of the body by means of a bladder, syringe, or elastic bottle. Injections thrown into the rectum are called *enemata*, or *clysters* (from κλυζω, *I wash*).

I'NOLITE. (Gr. ινεω, *I cleanse*, and λιθος, *a stone*.) A variety of carbonate of lime.

INOSI'NIC ACID. (Gr. ινοω, *I absorb*.) An acid said by Liebig to exist in the juices of the flesh of animals.

INTERCO'STAL. (Lat. inter, and costa, *a rib*.) In anatomy, a designation of certain bloodvessels, nerves, and muscles, situated between the ribs.

INVERMINA'TION. (Lat. in, and vermis, *a worm*.) The morbid state of the intestinal canal occasioned by the presence of entozoary animals. *See* INTESTINALIA, and ENTOZOA, in DICT.

I'ODATES. Salts of the iodic acid.

IRE'NE. One of the small planets belonging to the group whose orbits lie between those of Mars and Jupiter, and the fourteenth in the order of discovery. Irene was discovered by Mr. Hind, at Mr. Bishop's observatory in the Regent's Park, on the 19th of May, 1851. When first observed, its brightness rather exceeded that of a star of the ninth magnitude; its light is very blue, and it appears to be surrounded with a faint nebulous envelope, not perceptible about the stars in its vicinity. Its period is about 1519 days. (*Monthly Notices of the Royal Astronomical Society*, vol. xi.) *See* PLANET.

IRIDE'SCENT FILMS. Iridescent films are produced by dropping a little oil or spirit of varnish upon the surface of water contained in a vessel. When the water becomes tranquil, the varnish spreads in all directions, becoming exceedingly attenuated, and reflects the most vivid colours of the spectrum. If any objects that require ornamenting, such as insects, shells, birds, bronzes, paper-hangings, &c., are previously immersed in the water and slowly raised to the surface after the film has been formed, the latter will adhere to their surfaces, and when they are completely dried, it will be found firmly attached to them, and perfectly iridescent, having lost nothing of its brilliancy of colouring. This is a beautiful illustration of the production of colours on a thin transparent surface, by the agency of light, such as is commonly seen in an ordinary soap bubble.

I'RIS. (Lat. *the rainbow*.) One of the newly discovered planets of the group between Mars and Jupiter. Iris was discovered by Mr. Hind, at Mr. Bishop's Observatory, on the evening of August 13. 1847, while engaged in a systematic comparison of the Berlin charts with the heavens, which soon after rewarded him with the discovery of a second planet, *Flora*. Iris, when discovered, had the appearance of a star between the eighth and ninth magnitudes. The symbol adopted for its designation is a semicircle, to represent the rainbow, with an interior star and a bare line, for the horizon. Its period is about 1342 days. Iris is the seventh of the group in the order of discovery. (*Monthly Notices of the Royal Astronomical Society*, vol. vii.) *See* PLANET.

I'RISCOPE. (Lat. iris, *the rainbow*; and Gr. σκοπεω, *I view*.) An instrument proposed by Dr. Joseph Reade for exhibiting the prismatic colours, thus described by Sir David Brewster, in the *Philosophical Transactions* for 1841: — "This instrument consists mainly of a plate of highly polished black glass, having its surface smeared with a solution of fine soap, and subsequently dried by rubbing it clean with a piece of chamois leather. If we breathe upon the glass surface, thus prepared, through a glass tube, the vapour is deposited in brilliant coloured rings, the outermost of which is black, while the innermost has various colours, or no colour at all, in proportion to the quantity of vapour deposited. The colours in these rings, when seen by common light, correspond with Newton's *reflected* rings, or those which have *black centres*, the only difference being, that in the plate of vapour, which is thickest in the middle, the rings in the Iriscope have black circumferences."

IRISH MOSS. The *Chondrus Crispus*. *See* CARRAGEEN MOSS.

I'SCHIOCE'LE. (Gr. ισχιον, *the hip*; and κηλη, *tumour*.) A hernial tumour at the foramen of the ischium.

I'SERINE. *Titaniate of iron*, from the Iser in Bohemia.

I'SINGLASS. The term Isinglass is sometimes said to be derived from *ice* and *glass* in consequence of the transparent and vitreous appearance of the concrete jelly which may be obtained from it; but the word is more evidently a corruption of the German *hausenblase*, "sturgeon's bladder."

ISOCHROMA'TIC. (Gr. ισος, *equal;* χρωμα, *colour.*) A term in Optics, applied to two or more bodies of which the colours are identical, or undistinguishable.

ISOGO'NIC LINES. (Gr. ισος, *equal;* γωνια, *angle.*) In Terrestrial Magnetism, are the lines passing through all places on the surface of the earth at which the horizontal magnetic needle makes the same angle with the meridian, or at which the *declination* is the same. *See* MAGNETISM, TERRESTRIAL.

I'SOPYRE. (Gr. ισος, *equal;* πυρ, *fire;* because the effect produced upon it by the blowpipe is the same as that produced on several other minerals!) A silicate of alumina, iron, and lime, found imbedded in granite from Cornwall.

ITACO'NIC ACID. An acid formed by the action of heat on *aconitic acid.*

ITA'LIAN JUICE. The extract of liquorice prepared in *Calabria.* That grown on the estates of the Marchioness of Solazzi, and known in commerce under the name of *Solazzi juice*, being so stamped, is the most esteemed. The *Spanish juice* is prepared in *Catalonia.*

J.

JA'LAPINE. The purgative principle of jalap root: it is a basic resin.

JAMES'S POWDER. (*Pulvis Jacobi.*) A mixture of bone-earth, or phosphate of lime, and oxide of antimony: it is often called *fever powder*, and acts as a diaphoretic, and also on the bowels, and sometimes nauseates or vomits, according to the dose in which it is exhibited. It is an uncertain remedy, and may be properly replaced by emetic tartar mixed with a little chalk or magnesia. The *pulvis antimonialis*, or *antimonial powder* of the London Pharmacopœia is intended as a substitute for James's preparation, but it also is open to the objection of uncertain activity, dependent upon the state of oxidizement of the antimony, the protoxide of that metal being virulently active, while the peroxide is nearly inert. The usual dose of James's powder is from one to five grains.

JE'RVIA. (from *Jerva*, the Spanish name of a poison obtained from white hellebore.) A basic crystalline substance, contained, together with *veratria*, in the root of *veratrum album*, or white hellebore.

JE'SUITS' DROPS. The *compound tincture of benzoin* of the Pharmacopœia: called also *Friar's balsam.*

JE'SUITS' POWDER. Powdered Cinchona bark.

JEWS' PITCH. *Asphaltum.*

JU'NKERITE. A native crystalline proto-carbonate of iron from Pullouen.

JU'RINITE. A mineral from Dauphiny, containing *titanium.*

K.

KA'KODYLE. (Gr. κακος, *bad;* and οζειν, *smell.*) A compound hydrocarbon and arsenic, having the formula $C_4 H_6$ As. It is a clear liquid which takes fire when dropped through the air, burning with a blue flame, and forming water, carbonic acid, and arsenious acid; the latter rises as a white smoke. *Cadet's fuming liquor*, called also *Alkarsine*, is an oxide of Kakodyle=$C_4 H_6$ As O.

KA'RSTENITE. Anhydrous sulphate of lime: *Anhydrite.*

KE'RATOPHY'LLITE. (Gr. κερας, *a horn;* and φυλλον, *a leaf.*) A mineralogical synonym of Amphibole or Actinolite.

KEY'SER'S PILLS. A once celebrated mercurial preparation, the active ingredient in which is the *acetate of mercury.*

KIKEKUNE'MALO, a resin, much resembling copal, brought from America, where it is said to be used medicinally. It forms excellent varnishes.

KILKENNY COAL. *Anthracite.*

KI'MMERIDGE CLAY. The clay formation of Kimmeridge, on tho coast of the Isle of Purbeck; it contains beds of bituminous shale, used as fuel, and called *Kimmeridge coal.* In the neighbourhood are found the pieces called *coal money;* they are about 3 inches diameter, flat on one side, and convex on the other, and on the flat side are two or four small holes. They are supposed to have been either money or amulets. In the same neighbourhood there has been found a shallow bowl of Kimmeridge coal containing coal money.

KINEMA'TICS, or KINE'TICS. (Gr. κινεω, *I move.*) A term used by some writers to denote the doctrine which treats of the effects of motion without reference to its causes, and in contradistinction to dynamics. Curves produced by combined movements, or by machinery, are called kinematic curves, of which many beautiful specimens are given in Mr. Henry Perigal's work on the subject. The term is used chiefly by German writers, and applies to the same subjects as are usually treated of in analytical mechanics.

KI'RWANITE. A silicate of lime, iron, and alumina, from the basalt of the North East coast of Ireland, named after Kirwan the mineralogist.

KISH. A substance occasionally produced in iron smelting furnaces: in appearance it resembles plumbago, but is said to consist chiefly of carbon and manganese.

KNE'BELITE. A silicate of iron and manganese.

KOME'NIC ACID. A substance resulting from the action of heat on *meconic acid*, and formed when a solution of the latter acid is boiled. It has also been called *parameconic acid.*

KO'REITE. A mineralogical synonym of the Chinese *figure stone*, called also *Agalmatolite.*

KRE'ATINE. (Gr. κρεας, *flesh.*) A crystallisable organic substance contained in the juice of the muscular fibre of animals.

KREMNITZ WHITE. A pure variety of *White Lead.*

KROKI'DOLITE. (Gr. κροκις, *woof.*) A mineral of a fibrous asbestiform texture; it is a hydrated silicate of iron and soda: there is also a compact variety; it is occurs near the Cape of Good Hope.

L.

LAGGING OF THE TIDES. In Terrestrial Physics, a phenomenon of the tides, consisting in the irregularity of the lengths of the successive tide-days or intervals of the occurrence of high water at any particular place, and caused by the combined action of the sun and moon on the ocean. If the tides were caused by the moon's attraction only, the intervals between two successive arrivals at the same place of the same vertex of the tide-wave would be the lunar day, that is, the interval between two successive arrivals of the moon at the same meridian. In like manner, if the tides were caused by the sun's attraction only, the tide-day would be of the same length as the solar day. In consequence of the moon's revolution about the earth in the same direction as the diurnal rotation, the lunar day is longer than the solar; and the actual or lunisolar tide being the result of the superposition of the two tides caused by the sun and moon respectively, it follows, that from the time of a coincidence of these two tides the actual tide-day (reckoned in mean solar time) will become longer and longer, until the moon has completed a quarter of a revolution, after which the lunar wave will fall back on the next following solar wave, and the tide-day will become shorter and shorter during the next quarter of the moon's revolution, and the coincidence will again take place when a semi-revolution is completed. This alternate acceleration and retardation of the tidal intervals is called the *priming and lagging of the tides*, and is most remarkable about the time of new and full moon. *See* TIDES, in DICT.

LAGOPHTHA'LMIA. (Gr. λαγωος, *a hare;* and οφθαλμος, *an eye.*) A disease in which the eye cannot be closed. Sometimes it is a paralytic affection, and sometimes depends upon enlargement of the eye; it is also occasionally connate. The term has reference to the notion that hares sleep with their eyes open.

LA'PIS DIVI'NUS. (Lat.) A compound of nitre, alum, and verdigris, melted together; camphor is sometimes added, and white vitriol substituted for verdigris. A portion of this fused compound dissolved in water formed a celebrated eye lotion; it was hence also called *Lapis Ophthalmicus.*

LA'PIS LY'DIUS. (Lat.) Lydian stone. A silicious slate, used as a *touchstone* for trying the quality of gold and silver by the colour of the streak.

LA'PIS SPECULA'RIS. (Lat.) Selenite or spathose gypsum: formerly used as a remedy for fits.

LA'RDITE. A mineralogical synonym of the Chinese *figure-stone*, or Agalmatolite.

LA'SIONITE. A mineralogical synonym of Wav-

ellite or hydrargylite: the hydrated phosphate of alumina.

LECA'NORINE. *Lecanoric Acid.* A crystallisable substance obtained from several species of *Lecanora*, and some other *lichens*.

LECCA GUM. The gum of the olive tree, which is abundantly collected at Lecca in Calabria.

LEHU'NTITE. A compact *zeolite* found in Antrim by Captain Lehunt.

LE'MANITE. A synonym of felspar, so called from Lake Leman, where it is found.

LEPIDO'KROKITE. (Gr. λεπις, *a rind*, and κρο-κος, *saffron*.) Fibrous brown hematite.

LEVA'NT NUT. One of the commercial names of the berries of *Cocculus Indicus*.

LIBE'THENITE. The native phosphate of copper from Libethen, in Hungary.

LI'CHANUS. (Gr. λειχω, *I lick*.) The fore-finger, used in tasting a small quantity of anything.

LI'CHTENBERG'S FIGURES. When the knob of a charged Leyden phial is drawn over a flat surface of lac or resin, as, for instance, the plate of an electrophorus, it leaves a charge in its track, positive or negative, as we choose; and if, after this, a mixture of certain powders be sifted upon the plate, as, for instance, of powdered sulphur and red lead, the sulphur will adhere to the one, and the red lead to the other electrified surface, and with a little management, groups of figures resembling flowers may be thus brought out, as Lichtenberg first observed.

LIEBERKU'HNIAN GLANDS. In Anatomy, are simple secerning cavities, having the form of blind tubular depressions of the intestinal mucous membrane, thickly distributed over the whole surface of the large and small intestines. They are so called after their discoverer Lieberkühn, who observed them in the small intestines, where they are visible only with the aid of a lens, their orifices appearing as minute dots scattered between the villi. They are larger in the large intestine.

LI'ENTERY. (Gr. λειος, *the spleen :* soft or smooth.) A medical term formerly applied to a form of diarrhœa in which the food passes rapidly through the bowels in an apparently undigested state. Lubricity of the intestines.

LIE'VRITE. A crystallised mineral discovered by Le Liévre. It is a silicate of iron and lime; it has also been called *Jenite*, in commemoration of the battle of Jena in 1806, and specimens from Elba have been termed *Ilvaite*.

LIFT-TENTER. The name given in some parts of England to a sort of regulator or governor applied to wind-mills to counteract the irregular action of the wind. In a wind-mill for grinding corn, the distance between the upper and lower millstones is regulated according to the velocity; and if, when the mill is at work, the velocity should receive any considerable increase, the corn is forced rapidly through the mill without being sufficiently ground. To prevent this is the object of the lift-tenter. Like the governor of a steam-engine, it acts by the centrifugal force of one or more balls which fly out when the velocity is augmented, and as they rise in the arc of a circle, allow the end of a lever to rise with them, while the other end descends with the upper millstone, and brings it a little nearer to the under one.

LI'GATURE. (Lat. ligo, *I bind.*) In surgery, a waxed thread of silk used in tying arteries or veins.

LIGHTHOUSE. The Light Tower recently erected on the small island or rock of Skerryvore, on the west coast of Scotland, is one of the most remarkable works of this class, both by reason of its magnitude and the difficulties encountered in its construction. The following particulars are extracted from the very able and interesting account of it, drawn up by the engineer, Mr. Alan Stevenson, and published under the authority of the Commissioners of the Northern Lighthouses.

Skerryvore is the largest of a group of rocks lying in the channel between the western isles of Scotland and the north coast of Ireland, and in the track of the larger vessels proceeding round the north of Ireland from the Clyde or the Mersey. It is of inconsiderable extent, the surface of the solid rock being only about forty square yards, and consequently the stones had to be quarried, and the greater part of the works carried on in the island of Tyree, the nearest land, situated about eleven nautical miles to the north east. Much of the difficulty attending the operation arose from the distance of this latter island from the site of the works, from its being destitute of any shelter for shipping, and from the exposed and stormy situation, which frequently rendered communication impossible.

The dimensions of the tower were determined with reference to the situation and circumstances. The great distance of the outlying rocks, some of them not less than three miles right seaward of the rock, made it desirable that the light should command an extensive range, and consequently that the tower should be of considerable height; and the great difficulty of landing on the rock, and the consequent uncertainty of keeping up the supplies, demanded a large internal space for the accommodation of the light keepers and the stowage of stores. It was accordingly determined that the light should be elevated 150 ft. above the level of high-water at spring tides, so as to illuminate a visible horizon of not less than eighteen miles radius; and that the void space within the pillar should be about 13,000 cubic feet.

In determining the form of the tower the object is to obtain the greatest strength with the smallest consumption of materials, having regard to the necessary conditions of height and internal accommodation. The shaft of the Skerryvore pillar is a solid generated by the revolution of a rectangular hyperbola about its asymptote as a vertical axis. Its exact height is 120·25 feet; its diameter at the base 42 feet, and at the top 16 feet. The first 26 feet of height is a solid frustrum, containing about 27,110 cubic feet. Immediately above this level the walls are 9·58 feet in thickness, whence they gradually decrease through the whole height of the shaft until, at the top, they are reduced to two feet in thickness. Above the shaft is a cylindrical belt 18 inches deep, which is surmounted by a cavetto 6 feet high and having 3 feet of projection. The cavetto supports an abacus 3 feet deep, the upper surface of which forms the balcony of the tower, and above it rest the parapet wall and lantern. The whole masonry of the tower contains 58,580 cubic feet, weighing about 4308 tons.

The general arrangement in the interior of the tower is as follows: "The ascent to the outside door is by a ladder or trap of gun metal 26 feet high. The first apartment on the level of the entrance door is chiefly appropriated to the reception of iron water tanks, capable of holding a supply of 1251 gallons. The next story is set aside for coals, which are stored in large iron boxes. The third apartment is a workshop, the fourth is a provision store, and the fifth is the kitchen. Above are two stories, each divided into two sleeping apartments for the four light keepers. Over them is the room for the visiting officers; then follows the oil store, and lastly comes the light room, making in all 12 apartments."

In its general arrangement the illuminating apparatus is identical with that of the tower of Corduan. (*See* DICT. OF SCIENCE.) It consists of eight annular lenses (of the first order in the system of Auguste Fresnel) of 36·22 inches focal distance, revolving round a lamp with four concentric wicks, and producing a bright blaze as each lens passes before the lamp. Above these principal lenses there are placed eight pyramidal lenses of 19·68 inches focal distance, inclined at an angle of 50°, with the horizon, and combined with eight plane mirrors inclined in the opposite direction under the same angle of 50°, by means of which the rays which would pass upwards are turned into the horizontal direction. The light appears in its brightest state at intervals of one minute, and is well seen as far as the curvature of the earth permits.

The works were begun in 1838, and the tower was finished in 1842, but considerable time was required for completing the internal fittings, and the light was not exhibited as a sea light till February 1844. The expense of the lighthouse, including the opening of quarries and forming wharfs for shipping the stone both in Mull and Tyree, amounted to 90,268*l*. 12*s*. 1*d*. (*Account of the Skerryvore Lighthouse with Notes on the Illumination of Lighthouses; by Alan Stevenson, LL.B. etc., Engineer to the Northern Lighthouse Board*, 4to. *Edinburgh*, 1848.)

LIGHTHOUSES. A plan of the arrangement of the reflectors for lighthouses was produced by Messrs. Chance at the Great Exhibition of 1851, which combines the principles of Fresnel's fixed and revolving lights with an improved method of reflexion; and does away with the use of metal reflectors.

The system of reflectors and refractors may be divided into three compartments, the upper and lower of which are composed respectively of thirteen and six catadioptric zones, which produce a vertical strip of light extending the whole length of the apparatus, similar to Fresnel's fixed dioptric light. The central compartment consists of eight lenses of three feet focal length, each of which is the centre of a series of eleven concentric prismatic rings, designed to produce the same effect as a solid lens of equal size. These compound lenses are mounted upon a revolving frame, and transmit horizontal flashes of light as they rotate. Motion is communicated by clock-work, and one revolution is performed in the space of four minutes, and, consequently, a flash of light is transmitted every thirty seconds to the horizon by each of the lenses in succession. The apparatus is lighted by an Argand lamp, with four concentric wicks; it is provided with four burners, the

largest of which is $3\frac{1}{4}$ inches and the smallest $1\frac{6}{10}$ inches in diameter.

LIGNO'NE. (Lat. lignum, *wood.*) A liquid which may be separated by distillation from commercial wood spirit. It has also been called *Xylite.*

LI'GNOSULPHU'RIC ACID. A peculiar acid resulting from the action of sulphuric acid upon lignine. It is more properly termed *Sulpholignic acid.*

LIGNUM VITÆ. (Lat.) The wood of the guaiacum tree.

LI'LACINE. A bitter crystallisable principle contained in the leaves of the *Syringa vulgaris.* It has also been termed *Syringine.*

LI'MBILITE. A granular mineral found in the volcanic formation of Limbourg.

LI'MONITE. (Gr. λειμων, *a meadow.*) In Mineralogy, brown iron ore.

LIMO'SIS. (Gr. λιμος, *hunger.*) A genus of diseases distinguished by excessive or defective appetite.

LI'NARITE. In Mineralogy, the cupreous sulphate of lead from Linares, in Spain. It also occurs in Cumberland, and at Leadhills in Scotland.

LINCTUS. (Lat. lingo, *I lick.*) A medicinal preparation of the consistence of thick syrup, or honey, which requires to be licked off the spoon.

LINDEN TREE. The Lime tree, *Tilia Europœa.*

LI'NINE. A bitter principle obtained from the *Linum catharticum*, or purging flax.

LINNE'ITE. In Mineralogy, native sulphuret of cobalt; first noticed in Sweden by the celebrated Linnæus.

LINNÆAN SYSTEM. *See* BOTANY, in DICT.

LI'NSENERZ. In Mineralogy, octohedral arseniate of copper.

LINT. A soft woolly material made by scraping old linen by hand: it is also made by machinery. It is used in surgery for dressing wounds and ulcers, either alone, or spread with some ointment.

LIPAROCE'LE. (Gr. λιπαρος, *fat;* κηλη, *a tumour.*) A fatty tumour.

LI'PIC ACID. (Gr. λιπος, *fat.*) An acid formed by acting upon stearic and oleic acid, by means of nitric acid.

LIPO'MA. (Gr. λιπος, *fat.*) An encysted fatty tumour.

LIQUA'TION. *See* ELIQUATION, in DICT.

LI'QUIDA'MBER. A balsam procured in Mexico and Louisiana from the stem of *Liquidamber styraciflua.* It is, probably, identical with the so called *White Balsam of Peru.*

LI'QUORICE. The extract of the root of the *Glycyrrhiza glabra*, or officinal liquorice: it is often called Spanish liquorice or Spanish juice, of which that stamped with the name Solazza, and imported in sticks or bars six or eight inches long, is considered the best. It is in common use as an emollient in catarrh and cough. The so-called *refined liquorice*, rolled into pipes or quills, is often much adulterated.

LIQUOR SANGUINIS. *See* PLASMA.

LI'RIODE'NDRINE. (Gr. λιριον, *a lily*, and δενδρον, *a root.*) A bitter crystallisable principle obtained from the bark of the root of the *Liriodendron tulipifera.*

LI'THAGOGUE. (Gr. λιθος, *a stone*, and αγω, *I drive away.*) Medicines supposed to have the power of expelling calculous matter from the kidney or bladder.

LI'THOCHROMA'TICS. (Gr. λιθος, *a stone*, and χρωμα, *colour.*) A term applied to a recent invention, which consists in painting in oil upon stone, and taking impressions upon canvass.

LITHOCO'LLA. (Gr. λιθος, *a stone*, and κολλα, *glue.*) A cement for stone-work.

LI'THOFE'LLIC ACID. (Gr. λιθος, *a stone;* and Lat. fel, *gall.*) A substance obtained by Göbel from a Bezoar stone. In 1844, Taylor made the curious discovery of the identity of the substance constituting the so-called *Oriental Bezoars*, which are probably the intestinal concretions of a species of antelope, with the acid called *Ellagic acid*, contained, along with tannic and gallic acids, in the gall nut.

LITHO'PHAGI. (Gr. λιθος, and φαγω, *I eat.*) *See* LITHODOMES, in DICT. Molluscous animals which bore into stones.

LI'THOPHYTES. (Gr. λιθος, and φυτον, *a plant.*) Polypes which have a stony axis; as distinguished from the Keratophytes, or horny polypes.

LIVER ORE OF MERCURY. *Hepatic ore.* A bituminous cinnabar, or sulphuret of mercury, from Idria.

LO'BELINE. A peculiar acrid oil contained, along with *Lobelic acid*, in the leaves of the *Lobelia inflata.*

LO'BOITE. In Mineralogy, a magnesian idocrase from Norway.

LONDON CLAY. A very extensive tertiary geological deposit of a bluish clay, superficially brown, and abounding in Middlesex, Essex, Suffolk, and part of Norfolk. *See* GEOLOGY, in DICT.

LO'PEZ. *Radix Lopeziana.* The name of the root of an unknown tree, supposed to grow at Goa: it is said to be remarkably effective in checking diarrhœa.

LO'RIMER. A name formerly given to the makers of bits, spurs, and other articles of iron used for horses.

LOVE APPLE. The Tomata. The fruit of *Solanum lycopersicum.* An excellent ingredient in soups and sauces, in especial use in Spain and Portugal.

LU'PIA. (Gr. λυπεω, *I molest.*) An encysted tumour.

LUSTRE. Several varieties of *Lustre* are referred to in descriptive mineralogy, such as splendent, glistening, glimmering, shining, dull, &c.

LU'TEOLINE and LUTEOLE'INE. Peculiar colouring principles, said by Preisser to be obtained from *weld.*

LUZ. The name of a bone in the human body, celebrated in Rabbinical writings, and supposed to be indestructible: according to some it was a vertebra; others regard it as having been the sesamoid bone of the great toe, and others one of the triangular bones near the lambdoidal suture of the cranium.

M.

M. In medical prescriptions M stands for *misce*, or mix: also for *manipulus*, a handful.

MA'CER. The bark of the root of a tree growing in Malabar. It is astringent, and celebrated for the cure of diarrhœa.

MACQUERS SALT. A pharmaceutical designation of the binarseniate of potassa.

MA'CROCOSM. (Gr. μακρος, *large;* κοσμος, *world.*) A term applied to the world at large, or *universe*, as opposed to *microcosm*, having reference to man.

MADARO'SIS. (Gr. μαδαρος, *bald.*) A falling off of hair, especially of the eyelashes.

MAGDEBURGH EXPERIMENT or HEMISPHERES. A hollow sphere composed of two hemispheres which fit air-tight, intended to show the amount of the air's pressure, by the amount of force with which they are so held together after the interior air has been removed by the air-pump. This apparatus was first suggested by Otto Guericke of Magdeburgh, the inventor of the air-pump.

MAGELLA'NIC CLOUDS. These singular objects were carefully examined by Sir John Herschel during his residence at the Cape of Good Hope, from 1834 to 1838, and are minutely described in his "Results of Astronomical Observations," &c. The greater nebula, or *Nubecula major*, is situated between the meridians of 4 h. 40 m. and 6 h. 0 m., and the parallels of 156° and 162° of North Polar Distance, occupying an area of about 42 square degrees. The lesser is situated between the meridians 0 h. 28 m. and 1 h. 15 m., and the parallels of 162° and 165° N. P. D., and covers about ten square degrees; their general shape is round, or somewhat oval; and the larger, which deviates most from the circular form, exhibits the appearance of an axis of light very ill defined, and by no means strongly distinguished from the general mass which seems to open out at its extremities into somewhat oval sweeps. "When examined through powerful telescopes," Sir John observes, "the constitution of the nubeculæ, and especially of the Nubecula major, is found to be of astonishing complexity. The general ground of both consists of large tracts and patches of nebulosity in every stage of resolution, from light irresolvable with 18 inches of reflecting aperture, up to perfectly separated stars, like the Milky Way, and clustering groups sufficiently insulated and condensed to come under the designation of irregular, and in some cases pretty rich clusters. But besides those, there are also nebulæ in abundance, both regular and irregular; globular clusters in every state of condensation; and objects of a nebulous character quite peculiar, and which have no analogue in any other region of the heavens. Such is the concentration of the objects, that in the area occupied by the Nubecula major not fewer than 278 nebulæ and clusters have been enumerated, besides 50 or 60 outliers, which (considering the general barrenness of such objects in the immediate neighbourhood) ought certainly to be reckoned as its appendages, being about six and a half per square degree, which very far exceeds the average of any other, even the most crowded parts of the nebulous heavens. In the Nubecula minor the concentration of such objects is less, though still very striking, 37 having been observed within its area, and 6 adjacent but outlying. The nubeculæ, then, combine, each within its own area, characters which, in the rest of the heavens, are no less strikingly separated, — viz. those of the galactic and the nebular system. Globular clusters (except in one region of small extent) and nebulæ of regular elliptic forms are comparatively rare in the Milky Way, and are found congregated in the greatest abundance in a part of the

heavens the most remote possible from that circle; whereas, in the nubeculæ, they are indiscriminately mixed with the general starry ground, and with irregular though small nebulæ." (*Outlines of Astronomy*, p. 613.)

MAGNETISM, TERRESTRIAL. During the last quarter of a century immense efforts have been made to determine the phenomena and laws of terrestrial magnetism. The impulse given to the study of this department of science is mainly due to the celebrated Humboldt, who, in 1828, formed an association at Berlin for the purpose of verifying an inference which had been drawn from the comparison of corresponding observations made at London and Upsala by Graham and Celsius in the last century, and recently at Paris and Kazan by Arago and Kupffer, namely, that the irregular movements of the needle take place simultaneously at places very distant from each other. At first the operations were on a very limited scale, being confined to hourly observations on some particular days, previously agreed on, at Berlin and Freyberg; but in the following year the plan received an immense extension in consequence of the establishment by the Russian government of magnetical observatories, acting in co-operation with those of Germany, at St. Petersburg, Kazan, Nicolaieff, and Sitka (on the north-west coast of America); that is to say, across the whole continent of Europe and Asia. A second association was soon after formed at Gottingen by Professor Gauss, through which very important improvements were effected both in the instruments of observation and the methods of observing, which have been since generally adopted. In 1836 the indefatigable Humboldt addressed a letter to the late Duke of Sussex, then President of the Royal Society, on the best means of perfecting the knowledge of terrestrial magnetism; and, his suggestions being approved by the Council of the Society, the government was induced, through the representations of that body, to sanction the establishment, in several of the British colonies, of observatories, equipped with appropriate instruments, and superintended by military or naval officers, with sufficient assistance at their disposal for making continuous *hourly* or *two-hourly* observations of the different magnetic elements. The places selected were Toronto, St. Helena, the Cape of Good Hope, and Hobarton, in Van Diemen's Island; and, as it was considered important to obtain observations in high southern latitudes, the expedition to the Antarctic seas, under the command of Sir James Clarke Ross, was projected and ordered at the same time. The East India Company likewise promised its co-operation by providing for the establishment and maintenance of observatories at Bombay, Madras, Lucknow, Singapore, and Simla. At home, a magnetical and meteorological department was added to the Royal Observatory at Greenwich, and another is kept on foot at Dublin. It was originally proposed that the colonial observatories at the four stations above named should be continued for three years only; but the grant of the requisite funds has been renewed from time to time, and they are still (1852) in operation. The observations have been made systematically, according to rules drawn up by a Committee of the Royal Society, and are reduced under the superintendence of Colonel Sabine, at an establishment also maintained by the government, at Woolwich. Several volumes of observations have been published, containing a regular series, since 1841, made at Toronto, Hobarton, and St. Helena; and including those made in 1841 and 1842 by the officers of the Antarctic expedition. In addition to these official volumes, Colonel Sabine has also contributed a series of interesting papers to the *Philosophical Transactions*, and the *Reports of the British Association*, containing the results deduced from a comparison of the observations at the different places. The observations made at Greenwich are reduced at the observatory, and the whole were for some years (till 1847) published annually; at present only a portion of those made continuously by a photographic process are published in an Appendix to the volumes containing the astronomical observations. By all these means a very large collection of well observed facts has been accumulated, but it cannot be said that the theory has yet made corresponding advances.

A magnetical observation is complete when three elements are determined, — the *declination* of the magnetic needle, its *inclination*, and the intensity of the force. The two latter, however, are not usually observed directly, but in lieu of them the horizontal and vertical components of the intensity are observed, and, from the variations of the two components, those of the inclination and of the force itself, are computed. The declination and inclination indicate the direction in reference to the horizontal and vertical planes which a freely suspended needle would assume, so that, in fact, the direction of the magnetic force and its intensity are the two elements sought to be determined. The instruments employed are called by the general name of *Magnetometers*. (*See* the term.)

In order to obtain a knowledge of the laws of terrestrial magnetism, it is necessary that the mean values of the three elements, and the variations of those elements, should be determined at a great number of points taken all over the earth's surface. For the purpose of comparison, the points or stations at which the observations have been made are projected on maps, and lines being drawn through those points at which the mean values are the same in respect of each element, a series of curved lines is obtained, which indicate the values of the elements at the intermediate points with more or less accuracy, according to the proximity of the stations at which observations are made. The curves thus traced through the points of equal declination are called *Isogonal;* those through the points of equal inclination, *Isoclinal;* and those connecting the points of equal force, *Isodynamic*.

Declination, or *Variation*. Although the general direction of the horizontal needle is nearly north and south, there are few places at which it points exactly in the direction of the meridian. At London, and over the greater part of Europe, the north end of the needle declines to the west, while in Siberia and some parts of the North American continent it declines to the east. In the northern hemisphere the isogonal lines, though extremely irregular, appear to converge towards two separate points or poles, whence it has been inferred that there are four magnetic poles, two in each hemisphere. Supposing this to be the case, the declination of the needle will be east or west, according as the place of observation is to the west or east of the meridian passing through the nearest or most powerful pole, and there will be in each hemisphere two isogonal lines of no declination, or in which the direction of the needle coincides with the meridian. These lines, accompanied by others passing through the series of points at which the declination is respectively 5°, 10°, 15°, &c. were first laid down by Halley, in 1700, in a *Sea Chart* or *Variation Chart;* and since that time similar charts have been published by various persons, — Hansteen, Barlow, Erman, and others. Halley supposed they would be useful as a means of finding the longitude at sea; but, on account of the changes which the declination is undergoing at almost every place where correct observations have been made, they are not only useless for this purpose, but do not long continue to represent the actual declinations.

The changes which take place in the declination are of three kinds, — secular, annual, and diurnal. The laws and period of the secular change are very imperfectly known. At London, in 1550, the declination was 11° 17′ E.: about 1660 it was 0°. Soon after that year the needle began to deviate to the west; and the westerly declination continued to increase till 1815, when it seems to have attained its maximum of 24° 27′ 18″, inasmuch as it has gradually decreased since that time. The mean declination deduced from the observations at the Greenwich Observatory in 1846 was 22° 49′ 35″. At Paris, the observations give a similar increase up to the same period. But this agreement is by no means general: in Jamaica, for example, the declination seems to have remained nearly constant. The explanation of these phenomena forms one of the greatest difficulties in the theory of terrestrial magnetism.

The annual variation of the declination was first remarked at Paris by Cassini. From a comparison of observations made at Paris from 1784 to 1788, and at London from 1793 to 1805, Arago found a minimum of declination towards the vernal equinox, and a maximum towards the summer solstice. But it may be doubted whether these ancient observations were sufficiently accurate to determine this question, more especially as the result is not confirmed by the recent observations in the colonial observatories. At St. Helena and Toronto no variation of the rate of the secular change in the different seasons is perceptible. At Hobarton the east declination appears to be, on the average, somewhat greater in the summer months than in the winter months, but the differences are extremely small.

Diurnal Variation. The declination is also subject to a diurnal change, which was first remarked by Graham, at London, in 1722. The remark was confirmed by the observations of Celsius, and by Hiorter in Sweden (1740—1746), and subsequently by those of Wargentin, who found that the needle declined towards the west from the hours of 8 or 9 before noon till 1 or 2 after noon, and then towards the east till 8 or 9 in the evening. The same observers also remarked that the needle was affected by Aurora, or polar light, and that in the presence of this phenomenon the change in its mean direction was sometimes as much as 5° in the course of a day. In the *Philosophical Transactions* for 1759 there is a paper by Canton, giving the results of observations on the daily variation during 603 days. On 574 of those days the deviations were regular, and nearly the same as those found by Celsius; on the remaining days they were irregular, and on those days there were displays

of Aurora. Canton ascribed the diurnal change to the effect of the sun's rays in heating the earth, and thereby diminishing the magnetic force; so that in the morning, when the earth is heated on the eastern side of the meridian, the magnetic force on that side is weakened, and the needle consequently declines to the west; and in the afternoon, as the earth becomes heated on the western side of the meridian, the needle begins to move in the opposite direction, and declines to the eastward of its mean place. The amount of the diurnal change is different at different places, and at different seasons of the year. At London, for the years 1817—1819, it was found by Col. Beaufoy to be from 4′ to 5′ in December and January, and above 11′ in June and August. At the Royal Observatory the mean diurnal range for the year 1846 was, in summer, 15′ 14″; in winter, 11′ 53″; and the mean for the whole year, 13′ 34″. At Toronto and Hobarton the diurnal range is also greatest in the summer months and least in the winter months, and the changes take place at nearly the same hours of local time.

Inclination, or *Dip*. The inclination has a general dependence on the latitude, but it varies considerably at different places under the same latitude. A line drawn through all those places where the dipping needle becomes horizontal (usually, though perhaps improperly, called the magnetic equator) appears to intersect the equator of the earth in four points. In the Atlantic Ocean, between Africa and America, it lies wholly to the south of the terrestrial equator, its greatest south latitude being about 25°. According to Hansteen the nodes or points intersective with the equator of the earth are on the meridians 22° E., 187° E., 120° W., and 108° W.; but these determinations must be taken as subject to considerable uncertainty, the observations being by no means accordant. The other isoclinal lines follow, with more or less irregularity, the direction of the magnetic equator until a high latitude is attained. In Boothia Felix, in latitude 70° 5′ 17″ N., and longitude 96° 45′ 48″ W., Sir James Clarke Ross found the dip to be 89° 59′, within a minute of the vertical; and the needle had there altogether lost its directive power. In the southern hemisphere, on board the Erebus, in 1841, Sir J. C. Ross observed an inclination of 88° 36′ in latitude 75° 22′ S., and longitude 161° 48′ E. (Sabine, *Phil. Trans.* 1843). The places at which the dipping needle becomes exactly vertical, and to which the above most nearly approach, are usually styled the *magnetic poles;* but, as will be seen presently, they not only do not coincide with, but are at a great distance from, the places at which the intensity of the magnetic force is a maximum,—a circumstance which it is necessary to keep in mind, as the term *pole* is also frequently applied to the points of greatest force. Like the declination, the dip is subject to secular, annual, and diurnal changes. At London it was observed by Graham, in 1720, to be 74° 42′; and by Captain Kater, in 1830, to be 69° 38′. The mean of the Greenwich observations for 1846 is 68° 58′·1; whence it appears that the dip at London is diminishing. The annual variation is scarcely perceptible. At Toronto and Hobarton the range of the diurnal variation of the dip is about 1′·25; at Greenwich, for 1846, the difference of the means of the daily observations at 9 A. M. and 3 P. M. was 1′.

Intensity. The absolute intensity of the magnetic force, like the declination and dip, varies at different places, and probably at different times. It is compared at different stations by observing the number of oscillations made in a given time by a magnetic bar suspended horizontally by a fine wire or silk fibre. If F denote the force, D the inclination of the dipping needle, and N the number of oscillations made by the suspended bar in a given time at any station, and F′, D′, N′, denote the same things at a second station, then the following proportion holds, which gives the relative value of the two forces, *viz.*

$$F : F' :: N^2 \cos^2 D : N'^2 \cos^2 D'.$$

From the large table of results given by Hansteen, it appears that if the intensity at the magnetic equator in Peru (where it was supposed by Humboldt to be a minimum) be unity, then the intensity at Naples is 1·275, at Marseilles 1·294, at Madrid 1·394, at Paris 1·348, at London 1·370, at Christiania 1·420, in Baffin's Bay (lat. 76° 45′ N., long. 58° 20′ W.) 1·705. The maximum intensity hitherto observed is 2·052, and the minimum 0·706. Both observations were made at places in the southern hemisphere, the former by Sir James Clarke Ross, in lat. 73° 47′ S., long. 171° 50′ E. (of London), where the dip was observed to be 87° 4′; and the latter by Erman, in lat. 19° 59′ S., and long. 35° 4′ W., off the eastern coast of Brazil, where the dip is 7° 55′: the two extreme intensities are therefore in the ratio of 1 : 2·906. In both hemispheres there are two points, or rather regions, of maximum intensity, which may be regarded as centres of separate magnetic action. The position of the principal or strongest northern maximum intensity was ascertained by Captain Lefroy, in 1842 and 1843, to be in lat. 52° 19′ N., long. 268° E. (Sabine, *Phil. Trans.* 1846); that of the minor maximum was determined in 1828 and 1829 by Hansteen, and Erman, in the Russian expedition, to be in the meridian of 111° 27′ E. The interval between the two meridians is consequently 270°—111°=159°, so that they are not directly opposite. Both points appear to have undergone progressive changes from west to east, though not at the same rate. In the southern hemisphere the two centres of maximum force are still nearer each other in respect of geographical longitude, and the intensity is greater than in the northern hemisphere (Sabine, *Phil. Trans.* 1850). The isodynamic lines are in general nearly parallel to each other, and also to the isoclinal lines, though at some particular places the two sets of lines are nearly at right angles. The intensity does not appear to be affected by elevation above the surface.

Simultaneous Perturbations. In the volume of Hobarton Observations, 1841 to 1848, Col. Sabine gives an interesting comparison of the simultaneous affections of the three elements at Hobarton and Toronto, on one of Gauss's term days, April 21, 1842, these two stations being specially selected for comparison as being geographically situated at nearly opposite points of the globe. The result showed that the amount of disturbance on this day was nearly the same at both stations, and that the instants of extreme disturbance are not unfrequently as nearly identical at both as the nature of the observations enables us to determine. The inference is that many of the perturbations or particular disturbances observed, must be regarded as general affections of the whole globe, manifesting themselves at stations the most remote from each other.

Theory. On considering all the phenomena, and particularly those of the diurnal and annual variations (which obviously depend on solar heat), as well as the disturbances accompanying displays of polar light, it must appear extremely improbable that the magnetic force on which these phenomena depend is deeply seated in the earth. If it belongs to the earth it must be supposed to be near to or at the surface, in order to account for the correspondence of the phenomena with the diurnal variations of temperature. Accordingly it has been suggested that the cause must be looked for in the atmosphere. Sir D. Brewster (*Treatise on Magnetism*, 1837) adopts this view, and considers it to be proved, by certain experiments of Fusinieri, that iron is diffused through the atmosphere in a state of vapour. But a new light has very recently been thrown on this subject by Faraday, who has demonstrated that the oxygen of the atmosphere is magnetic, and that the intensity of its magnetism, like that of iron, is diminished by an increase of temperature. This fact renders the hypothesis of a diffusion of ferruginous vapour through the atmosphere unnecessary; and as the constituent gases of the atmosphere are every where in the same proportion, the phenomena depending on the magnetic properties of its oxygen must be precisely the same as if the whole atmosphere were magnetic. In a paper published in the *Philosophical Transactions* (Part I. 1851), Professor Faraday has shown how these properties may be applied to explain the variations of the terrestrial magnetic force. The earth, he remarks, is a great magnet: its power, according to Gauss, being equal to that which would be conferred if every cubic yard of it contained six one-pound magnets. The disposition of this magnetic force is not regular, nor are there any points on the surface which can properly be called *poles;* still the regions of polarity are in high north and south latitudes. These regions are connected by lines of magnetic force, which, generally speaking, rise out of the earth in one (magnetic) hemisphere, and, passing in varied directions over the equatorial regions into the other hemisphere, then enter into the earth to complete the known circuit of power. A free needle shows the presence and directions of these lines, which invest the globe with a system of forces like that about an ordinary magnet, and wherever they pass through the atmosphere the forces are subject to the changing action of the magnetic oxygen. There is every reason to suppose that these lines are *held* in the earth, just as the lines which originate in a magnet are held by it; and that any disturbance from above will cause a greater change in their place and direction in the atmosphere than in the earth. When space, traversed by uniform lines of magnetic force, is occupied by a uniform body, as air, the disposition of the lines is not altered; but if a better conducting substance is introduced, the lines are concentrated or drawn closer together in it; and if a worse conducting substance is introduced, they are opened out, and stand at greater distances from each other. Now, supposing the whole atmosphere to have a mean temperature, the lines of force would have the direction determined by the arrangement of the power within the earth. Then the sun's presence in the east would make all the atmosphere in that region a worse conductor, and the lines of force

would be opened out; and as the sun came up to and passed the meridian, similar changes in the directions of the lines of force would there take place, so that in the morning a needle would be deflected towards the west, and in the afternoon towards the east. As the night came on, and with it a lower temperature than the mean, the lines of force would be concentrated, and a reverse variation of the needle would take place. The magnetic properties of oxygen and its daily variations of temperature, manifestly produce effects similar to those which actually take place; but whether they cause the whole of the observed variations, or are competent to do so, is a question that can only be decided after a very careful inquiry. Professor Faraday states that the hypothesis has been compared with the mean daily variation for all the months in the year at north and south stations, as Toronto and Hobarton, and at many others near to and far from the equator, and the agreement is very remarkable. Thus, according to the hypothesis, the paths described by the upper ends of free needles in the north and south hemispheres should be closed curves with the motion in opposite and certain directions, and so they are;—the curves should be larger in summer and smaller in winter, and so they are;—the northern hemisphere ought to have a certain preponderance over the southern, because of its superior temperature, and that is so; — the disposition of land and water ought to have an influence, and the observations indicate one in the right direction. What still remains to be done, to verify this ingenious theory, is to ascertain the amount of change in the conducting power of the air for given changes of temperature, in order that it may be seen whether the effect on the magnetic instruments thereby produced corresponds with that which actually takes place.

MA'GNETITE. In Mineralogy, magnetic ore of iron.

MAGNETO'METER. An instrument or apparatus for determining the elements of terrestrial magnetism, in direction and force. When adapted to the purpose of determining the declination of the needle, it is called a *Declinometer*; for the inclination and vertical force, it becomes an *Inclinometer* (*see* the terms). From the experience obtained in the British colonial observatories, it appears that these instruments, at least in the form recommended in the *Instructions* drawn up by the Committee of the Royal Society, are liable to certain sources of irregularity; one depending on the liability of the magnetised bar to lose a portion of its magnetism, and others on causes not perfectly understood. (Sabine, *Phil. Trans.* 1850.) The instruments used at the Greenwich Observatory, and the modes of using them, are described in detail in the Introductions to *Greenwich Magnetical Observations*, which were published annually from 1841 to 1847.

MALABA'THRUM. The leaf of the Cassia laurel, from Malabar.

MALACO'STEON. (Gr. μαλακος, *soft*, and οστεον, *a bone*.) A diseased softening of the bones: *mollities ossium*.

MAL DE LA ROSA. A disease endemic in the Asturias, attended by redness of the skin.

MALPI'GHIAN. In Anatomy, this term is applied to certain parts, especially of the kidney, in allusion to the anatomist Malpighi, by whom they were discovered or first definitely described. Thus the numerous secreting tubes (*tubuli uriniferi*), where they are collected into conical bundles, form the "Malpighian" cones or pyramids; the more tortuous parts of the tubes which pass towards the surface of the kidney, terminate in or bear on small pedicles appended to their walls, flask-shaped sacculi, named "Malpighian capsules." The arteries of the kidney, before dividing into capillaries, form, by tortuous convolutions, little balls, called "Malpighian corpuscles or glomerules."

MA'LTHAZITE. A white tallow-like mineral from Lobau.

MANDE'LIC ACID. (Germ. mandeln, *almonds*.) A white crystalline acid obtained by the action of hydrochloric acid on bitter-almond oil. Its chemical formula is $C_{16} H_7 O_5 + H O$. It has also been called *Formobenzoilic acid*, inasmuch as it contains the elements of formic acid and hydruret of benzoyle.

MA'NDRIL. The part of a turning lathe which carries the chuck upon which the *work* (that is, the material to be turned) is fixed. It consists of a pulley, fixed upon an axle, which is supported in the headstock, and receives its motion from the foot wheel (or the treadle, in the case of the pole-lathe), by means of a catgut band passing over the mandril pulley, into which grooves are cut for receiving the band. Mandril, also, is the name given to the iron rod upon which a gun barrel is welded. In Zoology, a species of baboon is so called.

MA'NGANITE. In Mineralogy, grey ore of manganese.

MA'NNACROUP. A granular preparation of wheat deprived of bran, used as an article of food for children and invalids.

MARASCHI'NO. A liquor prepared from a peculiar cherry growing in Dalmatia; it is bruised, fermented, and then distilled, and afterwards sweetened with sugar. It is stated by some, that maraschino is the alcoholic liquor distilled from the fermented juice of the liquorice root.

MA'RCASITE. In Mineralogy, white iron pyrites. A sulphuret of iron.

MA'RIOTTE'S LAW. This important relation between the elastic force and the density of gaseous matter, ought, in justice to the first discoverer, to be called *Boyle's Law*. In a tract published at Oxford in 1668, under the title of "New Experiments touching the Spring and Weight of the Air," the Hon. Mr. Boyle announced that the spring — that is to say, the elastic force — of air is directly proportional to its compression; which is equivalent to saying, that the elastic force is directly as the density, or inversely as the volume, under the same temperature. Boyle's experiments were made on atmospheric air confined in the closed end of a U-shaped glass tube, and compressed by the weight of a column of mercury. It does not appear that he took the precaution to expel the moisture from the air, and the greatest pressure he applied was only equal to four atmospheres, so that it may, perhaps, be said that his experiments were neither sufficiently accurate nor extensive to establish the general law, even in respect of atmospheric air, without mentioning the other gases. Mariotte's experiments were described in the Memoirs of the Paris Academy of Sciences, published about eleven years later, namely in 1679, without any reference to Boyle's announcement, which was possibly unknown to him; and as it was through this channel that the law became known to the continental philosophers, who were the first to perceive its importance, they naturally distinguished it by the name of the person whom they supposed to be its discoverer.

The relation in question has recently been investigated by M. Regnault of Paris, in a series of experiments, conducted with the utmost attention to every circumstance affecting their accuracy; and the results are interesting. If v denote the volume of a gas under the pressure p, and v' its volume under pressure p', then the law gives $vp=v'p'$, whatever the pressures may be, if the temperature remains unaltered. But, on comparing the results of his experiments, M. Regnault has found that the above equation is not strictly true for any gas; and that, assuming $vp=v'p'(1+q)$ (where q is a small correction), the value of q increases with the pressure. In respect of atmospheric air, the elastic force, under a pressure of twenty-five atmospheres, is less by a quantity somewhat exceeding the seventh part of an atmosphere than it would be if the law were strictly true. With respect to carbonic acid the deviation is considerably greater. In the case of hydrogen the correction q becomes negative, so that while air and the other gases experimented upon were more compressed than they would be if the law were exactly followed, hydrogen was less compressed, and its compressibility was found to diminish as the pressure increased. But temperature has a considerable influence on these results; and as it was found that the deviation from the law diminishes as the temperature is increased, M. Regnault concludes that the law is only rigorously true when the gases are infinitely dilated, and that it becomes less and less exact in proportion as they are in a state of greater condensation. (*Mémoires de l'Institut*, tome xxi.)

MA'RTIAL ETHIOPS. An old pharmaceutical name of black oxide of iron.

MA'RTIAL REGULUS. Metallic antimony, obtained by decomposing sulphuret of antimony by means of iron.

MA'STICIN. That part of mastic which is insoluble in alcohol: it has some of the characters of caoutchouc. The part of mastic soluble in alcohol, has been termed *Masticic acid*.

MATE'RIA HERMAPHRODITA. A term applied by Boerhaave to a peculiar substance soluble both in alcohol and water, and contained in vegetable extracts. Scheele called it *Materia saponacea*. It is the *extractive* of later chemists.

MA'TICO. The leaves of a Peruvian plant, said to be a species of pepper, have been brought under this name to England, and much extolled for their medical virtues.

MAULSTICK. (Germ. *Mahlstock*.) A painter's stick on which he rests his hand whilst painting.

MECCA BALSAM. The produce of the *Balsamodendron Gileadense*, growing at Gilead, in Judæa. It is also called *Opobalsamum*.

MEDU'LLA OBLO'NGATA. (Lat. *the oblong pith*.) In Anatomy, is the name given to the mass of grey and

white neurine contained in the occipital segment of the cranium, and forming the medium of connection between the spinal marrow (myelon) and the brain (encephalon): it is sometimes described as the cephalic prolongation of the myelon; but it has distinct and higher functions, and constitutes the chief part of the epencephalic division of the brain.

MEDU'LLA SPINALIS. (Lat. *the spinal pith.*) In Anatomy, the part of the nervous axis which is contained in the vertebræ of the trunk. *See* MYELON.

MELA'MPYRINE. (Gr. μελας, *black*, and πυρ, *fire.*) A crystallisable substance, soluble in water and nearly insipid, contained in the *Melampyrum nemorosum.*

MELANO'CHROITE. (Gr. μελας, *black*, and χροα, *colour.*) A mineralogical variety of chromate of lead.

ME'LANOGA'LLIC ACID. A synonym of *Metagallic acid.*

ME'LANOTA'NNIC ACID. (Gr. μελας, *black.*) The black substance formed by the action of excess of potassa upon tannic or gallic acid.

MELASSES. *See* MOLASSES, in DICT.

ME'NDIPITE. A native oxychloride of lead from the Mendip Hills, Somersetshire.

MENINGI'TIS. (Gr. μηνιγξ, *a membrane of the brain.*) Inflammation of the membranes of the brain.

MENSIS PHILOSOPHICUS. (Lat.) A chemical or philosophical month; its duration is variously stated; it is generally considered as including three days and nights.

MENTHENE. A liquid hydrocarbon obtained by distilling the crystallisable portion of peppermint oil, or *peppermint camphor*, with anhydrous phosphoric acid. Its formula is $C_{20}\ H_{18}$.

MESENCE'PHALON. (Gr. μεσος, and εγκεφαλον, *brain.*) The natural primary division of the brain, which is usually encompassed by the parietal segment of the cranium, and consists of the lobe of the third ventricle, the optic lobes, with the appendages called the "conarium," "hypophysis," and in fishes the "hypoaria." Chaussier gave the term "mesocephale" to an artificial combination of the pons varolii with the optic lobes, dissociating the one from the medulla oblongata and cerebellum, and the other from the lobe of the third ventricle. By some Anthropotomists the term "mesocephalon" is used synonymously with that of "pons varolii."

ME'SITE. (Gr. μεσος, *middle.*) A liquid existing in pyroligneous spirit, the formula of which appears to be $C_6\ H_6\ O_2$: it is, therefore, the hydrocarbon mesylilene $(C_6\ H_4)+2\ H\ O$.

MESOXA'LIC ACID. An acid obtained by boiling a saturated solution of alloxanate of baryta, which is thus resolved into *mesoxalate of baryta*, and other products. This acid is crystallisable, and very sour and soluble. Its formula is $C_3\ O_4+2\ H\ O$.

MESLIN. (Fr. mesler.) A mixture of various kinds of grain.

META'CETONE. (Gr. μετα, indicating *change*, and acetone.) A product formed during the distillation of a mixture of 1 part of starch with 8 of quick lime: it is a colourless liquid, insoluble in water, but soluble in alcohol and ether, and of an agreeable odour. Its formula is $C_6\ H_5\ O$. It is converted by oxidising agents into *Metacetonic (metacetylic)* acid $= C_6\ H_5\ O_3+H\ O$.

METAGE'NESIS. (Gr. μετα, indicating *change*; γιγνομαι, *I produce.*) The changes of form which the representative of a species undergoes in passing, by a series of successively generated individuals, from the egg to the perfect or imago state. It is contradistinguished from "metamorphosis," in which those changes are undergone by the same individuals. The following is an example of Metagenesis: — The egg of the Medusa is developed into a polype, which, assuming a form called *Strobila*, separates into numerous individual young Medusæ. The larval polype propagates other similar polypes by gemmation, each of which becomes a *Strobila*, and is resolved into numerous Medusæ. Thus there is a successive production of procreating individuals from a single impregnated ovum of a Medusa, according to the law of Parthenogenesis.

META'LLIC TRACTORS. Towards the end of the last century Dr. Elisha Perkins, of Norwich, in Connecticut, introduced a method of treating diseases by drawing over the affected part two small metallic rods made of different metals, which he called *metallic tractors*, and the operation was called *tractoration.* The use of tractors has been called *Perkinism*, as that of animal magnetism has been called *Mesmerism.* It is almost needless to say that metallic tractors only operate in the fancy of the patient. (Hooper's *Medical Dictionary.*)

METALLOCHRO'MES. (Gr. μεταλλον, *metal*, and χρωμα, *colour.*) When very thin films of peroxide of lead are deposited by electrolytic action upon polished steel plates they give rise to those beautiful prismatic tints which Nobili first described under the above name.

For the method of their production, see *Brande's Manual of Chemistry*, p. 1518.

METAME'RIC. (Gr. μετα, indicating *change*, and μερος, *part.*) A term applied in Chemistry to bodies having one and the same composition, and atomic weight, but yet differing remarkably in certain of their properties, probably in consequence of dissimilar molecular constitution. Thus, formiate of oxide of ethyle (formic ether), and acetate of oxide of methyle (methylo-acetic ether), may both be correctly represented by $C_6\ H_6\ O_4$, but the elements in each are no doubt dissimilarly grouped, as represented in the following formulæ:

$$\left.\begin{array}{l}\text{Formiate of oxide of ethyle } C_4\ H_5\ O+\\ C_2\ H\ O_3\ \ -\ \ -\ \ -\ \ -\ \ -\\ \text{Acetate of oxide of methyle } C_2\ H_3\ O+\\ C_4\ H_3\ O_3\ \ -\ \ -\ \ -\ \ -\ \ -\end{array}\right\}=C_6\ H_6\ O_4.$$

METAPOPHY'SIS. (Gr. μετα, *between*, αποφυσις, *a process.*) In Anatomy, the exogenous process commonly situated between the diapophysis and anterior zygapophyses: in the human skeleton it is best developed in the last dorsal and first lumbar vertebræ; the metapophyses are developed more, and from more numerous vertebræ, in most of the inferior mammalia, arriving at their maximum of length in the armadillos, in which they equal the neural spines in length in the posterior dorsal and the lumbar vertebræ; they relate in these singular quadrupeds to the support of the carapace, the neural spines representing the "king-posts," and the metapophyses the "tie beams," in the architecture of a roof.

ME'TEOROLITE. *See* AEROLITE, in DICT.

METHIO'NIC ACID. (Gr. μετα, indicating *change*, and θειον, *sulphur.*) An acid obtained by the action of anhydrous sulphuric acid on ether; althionic acid is at the same time formed.

METHO'DIC MEDICINE. Medicine as practised by the methodic sect of physicians, of which Themison was the head. They endeavoured to reduce medicine to exact rules, and assumed that all diseases arose from constricted fibre.

METHYLE. *See* METHYLENE, in DICT.

ME'TIS. One of the small planets belonging to the group between Mars and Jupiter. Metis was discovered by Mr. A. Graham, at Mr. Cooper's observatory, Markree Castle, on the 25th of April, 1848, and is the ninth of the group in the order of discovery. Its brightness was equal to that of a star between the 9th and 10th magnitudes. The symbol chosen to designate it is an eye and star. Its period of revolution appears to be about 1346 days, nearly the same with that of Iris. *See* PLANET.

METO'PION. (Gr.) An ancient ointment containing galbanum, which was formerly called *Metopium.*

METRE. The French standard measure of length. *See* MEASURE, in DICT. The metre is $= 39{\cdot}371$ or nearly $39\frac{3}{8}$ English inches.

MICROCO'SMIC SALT. (Gr. μικρος, *small*, and κοσμος, *the world.*) The ammonio-phosphate of soda; it is obtained among the products of the evaporation of urine, and was formerly used as a blowpipe flux.

MI'DDLETONITE. A fatty substance found in the coal strata at Middleton, near Leeds.

MI'LLIPEDES. Several insects formerly used in medicine were included under this name: amongst them, the *Armadillo vulgaris*, or *pill millipede*; the *Porcellio scaber*, or *Sclater* of the Scotch: the *Oniscus asellus*, or common *Woodlouse.*

MIMOTA'NNIC ACID. The astringent acid of *catechu*, called also *tanningenic* acid.

MIRA'GE. From observations of this phenomenon made by Mr. T. Hopkins on the sea coast of Lancashire, it appears that mirage is produced by vapour when the atmosphere is loaded nearly to saturation, at which time there is consequently little or no evaporation as indicated by the difference of temperature of a dry and wet bulb thermometer. He found, that when the sky was cloudy and apparently threatening rain, evaporation in the air near the surface of the earth was very active, and there was no mirage; but at other times, when the sun was shining brightly, evaporation was checked, and at such times mirage might be seen. Mr. Hopkins supposes that in strong sunshine the direct rays raise the temperature of the ground considerably, when energetic evaporation from the wet sand takes place, and sends much vapour into the adjacent strata of the atmosphere, the presence of which checks the evaporation from the wet bulb. It is not improbable that some of the vapour thus formed is condensed by the comparatively cool air at a small distance from the surface of the sand, and a stratum of cloud formed, from the surface of which light is reflected, and the phenomenon of mirage produced. But, however this may be, the presence of vapour in sufficient quantity to saturate, or nearly saturate, the air at the place where the mirage appeared, always accompanied its appearance. (*Reports of the British Association*, 1849.)

MOH'SITE. In Mineralogy, crystallised titaniate of

iron from Dauphiny; so named, in honour of Mohs, the crystallographer.

MOLE. Different productions of and excretions from the uterus are so called by medical writers. Small soft excrescences of the cuticle are also termed moles.

MONGO'LFIER BALLOON. A balloon filled with atmospheric air considerably dilated by heat, so called from its inventor. A fire-balloon.

MONI'LIFORM. (Lat. monile, *a necklace.*) A botanical term: it is applied to the pod of the *Hedysarum moniliferum*, from its necklace-like appearance.

MONOPHY'ODONTS. (Gr. μονος, *one;* φυω, *I generate;* οδους, *tooth.*) In Zoology, those mammals which generate one set of teeth, as, *e.g.* the Sloths, Armadillos, Cape ant-eater, Ornithorhynchus, and the true Cetacea: all other mammals that have teeth generate two sets, called "deciduous" and "permanent." *See* DIPHYODONTS.

MO'RINE. The colouring principle of the wood of *Morus tinctoria*, or *fustic*.

MORMONS. The name assumed by a religious sect in the United States of North America, which derives its origin from a person called Joseph Smith, whose account of his own mission is as follows:—He all at once found himself labouring in a state of great darkness and wretchedness of mind—in the first stage, in fact, of what is ordinarily known among Methodists as "receiving a call." He was bewildered among the conflicting doctrines of the Christian world, and could find no comfort or mental rest. In this state he resorted to earnest and "vocal" prayer, kneeling in the woods and fields, and after long perseverance in this course, his prayers were answered by the appearance of a bright light in heaven, which gradually descended until it enveloped the worshipper, who found himself standing face to face with two supernatural beings. Of these he inquired which was the right and true religion of the world? The reply was, that all religions were equally erroneous, but that the true doctrine and the crowning dispensation of Christianity should at a future period be miraculously revealed to himself. Several similar visitations ensued, and at length he was informed that the North American Indians were a remnant of Israel; that when they first entered America they were a great, enlightened, and favoured people; that their priests and rulers kept the records of their history and their doctrines; but that, having fallen off from the true faith and worship, the great body of the nation were supernaturally destroyed—not, however, until after a priest and prophet named Mormon had, by celestial direction, drawn up an abstract of their national record and religious opinions. This abstract, Joseph Smith was told, still existed, buried in the earth, and he it was whom God had selected for the instrument of its recovery and its manifestation to all nations. The record, he was told, contained many prophecies as to "these latter days," and would give instructions for the "gathering of the saints" into a temporal and spiritual kingdom, preparatory to the second coming of the Messiah, which was at hand. After several of these preliminary visions, the spot in which the book lay buried was at length indicated. Joseph Smith went there, and after digging, discovered a sort of box formed of upright and horizontal flags, within which lay a number of plates "resembling gold," and about the thickness of common tin. These plates were bound together by a wire, and were engraved with "Egyptian characters." Beside them lay two transparent stones, "called by the ancients Urim and Thummim," which were evidently divining crystals, and the angels informed Joseph Smith that by using them he would be enabled to decipher the characters on the plates. What ultimately became of the plates in question—if such things existed at all—does not appear. They were said to have been seen and handled by eleven witnesses. But, it should be noticed, that with the exception of three persons, these witnesses were either members of Smith's family, or of a neighbouring family of the name of Whitmer. Professor Anthon described a document submitted to him as having been a sort of *pot pourri* of ancient marks and alphabets. "It had evidently been prepared by some person who had before him a book containing various alphabets; Greek and Hebrew letters, crosses and flourishes, Roman letters, inverted or placed sideways, were arranged in perpendicular columns, and the whole ended in a rude delineation of a circle, divided into various compartments, decked with various strange marks, and evidently copied after the Mexican Calendar given by Humboldt, but copied in such a way as not to betray the source whence it was derived."

The result of these facts is startling. In spite of two bitter persecutions accompanied by murder, robbery, and arson, and two expulsions from flourishing settlements, in the course of twenty years the number of firm adherents to this faith has increased to upwards of 300,000 persons, of which a large number are now settled as an independent state, having a regular charter and organised local government, on a territory of which they possess not only the sovereignty, but the *fee simple*—a beautiful and exceedingly fertile tract as large as England, and situated upon the best "trail" from Eastern America to California and the Pacific. This state is called Deseret, or Utah, and will probably soon be added to the group of the American Union. Its capital is Salt Lake City, a large and flourishing town, which has sprung up like magic in the wilderness. Such being their head-quarters, the Latter-day Saints have agencies and missions in every capital in Europe, and in every large town in the United Kingdom. The great object of these undertakings is to make converts and to "gather the saints" to Deseret. From Great Britain, since 1840, upwards of 14,000 persons have inclined to the doctrines of Mormon, and have gone forth to join the settlement. The Mormon emigration, in 1849, passing through Liverpool, amounted to 2,500 persons, all of the better class of emigrants; and it is calculated that 30,000 Latter-day Saints then remained behind. In June, 1850, there were in England and Scotland 27,863 Mormonites, of whom London contributed 2,529; Manchester, 2,787; Liverpool, 1,018; Glasgow, 1,846; Sheffield, 1,920; Edinburgh, 1,331; Birmingham, 1,909; and Wales—South Wales principally—4,342. And the Mormonite census was taken in last January, giving the entire number in the British Isles as 30,747 "Saints." During the last fourteen years more than 50,000 had been baptised in England, of which nearly 17,000 had emigrated from her shores "to Zion." (The above details are borrowed from an interesting little work called "The Mormons, or Latter-Day Saints," published by the proprietors of the "Illustrated London News.")

MO'TORY, or MOTO'RIAL. (Lat. moveo, *I move.*) In Physiology, this term was applied by Hartley, in 1749, to the nerves conveying the stimulus to the muscles in contradistinction to the nerves conveying the impressions to the neural axis, which he called "sensory;" but he distinguished those actions which result from the conveyance of impressions to the brain, producing sensation and exciting volition, from those actions that are now called "reflex;" as where he states that "the actions of sneezing, swallowing, coughing, hiccoughing, vomiting, and expelling the fœces and urine, with others of a like nature, are to be deduced from those vibrations which first ascend up the 'sensory' nerves, and then are detached down the 'motory' nerves which communicate with these by some common trunk, plexus, or ganglion."

MOUNTAIN BLUE and GREEN. The blue and green carbonates of copper.

MOUNTAIN CORK. MOUNTAIN LEATHER. In Mineralogy, varieties of asbestos.

MULE. A machine for spinning cotton. This very ingenious piece of mechanism was invented, about the year 1777, by Samuel Crompton, formerly of Hall-in-the-Wood, Lancashire. For many years the machine was worked by hand only, the variety of its movements rendering it difficult to accomplish the moving of it by the power of water or of steam, so simply as to be of common use. One form of the mule was in use in Manchester in the year 1797. (Buchanan's *Essays on Mill-Work*, 1841.)

MUM. A malt liquor made chiefly at Brunswick of the malt of wheat, with the addition of a little oat and bean meal.

MU'MIA MINERALIS. (Lat.) A bituminous substance resembling brown asphalt.

MUNJEET. Indian madder.

MU'REXAN. The *Purpuric acid* of Dr. Prout. Its formula is $C_6\ H_4\ O_5\ N_2$.

MURE'XIDE. (Lat. *Murex*, a molluscous animal giving a purple dye.) The *Purpurate of ammonia* of Dr. Prout. It is best obtained by adding 4 grains of alloxan, and 7 of alloxantine, dissolved in half an ounce of boiling water, to one-sixth of an ounce of a saturated solution of carbonate of ammonia. The liquor acquires a magnificent purple colour, and deposits small crystals of murexide, which are green, and iridescent by reflected light, but deep red by transmitted light: they form a beautiful microscopic object. The chemical formula of murexide is $C_{12}\ H_6\ O_8\ N_5$.

MUSCADI'NE. MUSKATEL. A rich sweet wine made of Muscadine grapes in the South of France.

MUSCOVY GLASS. Mica. It is used in Siberia as a substitute for window-glass.

MUSK, ARTIFICIAL. A substance obtained by the action of nitric acid upon oil of amber, and having an odour which some have thought to resemble that of musk.

MY'ELON. (Gr. μυελος, *marrow.*) The single-worded equivalent of "spinal marrow" and "spinal cord."

MY'KOMELI NIC ACID. An acid resulting from the mutual action of alloxan and ammonia. It forms a yellow powder $= C_8\ H_5\ O_5\ N_4$.

MYRIORA'MA. (Gr. μυριας, *a myriad*, and ὁραω, *I view*.) A picture made up of fragments of buildings, landscapes, &c., so as to admit of an infinity of combinations.

MYRI'STIC ACID. (Gr. μυρον, *an odorous oil*.) One of the fatty acids contained in the expressed oil of nutmeg.

MYRO'NIC ACID. (Gr. μυρον, *an odorous oil*.) A substance existing in black mustard seed.

MYROXY'LIC ACID. (Gr. μυρον, *an odorous oil*, and οξυς, *sharp*.) A substance obtained from the Peruvian balsam, the produce of the *Myroxylon Peruiferum*.

MYRRHIC ACID. A substance obtained by heating the resin of myrrh.

N.

NARCOGENI'NE. (Gr. ναρκη, *stupor*, and γιγνομαι, *I produce*.) A basic substance resulting from the oxidation of narcotina.

NATURAL SCIENCE. The term has been applied, arbitrarily, to signify the science of organic bodies, in contradistinction to *Physical Science*, by which is meant the science of inorganic matter.

NAVI'CULAR. (Lat. navicula, *a little boat*.) Boat-shaped. The *navicular* bone is one of the bones of the tarsus. The termed is also used in botany.

NE'BULÆ. In the *Philosophical Transactions* for 1850 (Part II.), the Earl of Rosse has given a description of several remarkable nebulæ, as seen in the great reflecting telescope erected at his Lordship's seat in Ireland. This noble instrument has a mirror of six feet in clear aperture, with a focal length of 53 feet, and by reason of the great extent of reflecting surface it gives a better means of observing faint objects of this class than any other which has ever been applied to the heavens.

Among the new features which Lord Rosse's telescope has brought out, the most remarkable, perhaps, is the spiral arrangement of the nebulous matter, or what appears to be so, observed in various cases. The most strongly developed instance is the 51st nebula of Messier's catalogue, one of the first known, and which has been often described. Messier describes it as a double nebula without stars, Sir W. Herschel as a bright round nebula with a halo or glory surrounding it, and attended by a companion; and Sir John Herschel observed the subdivision of the ring, through about two-fifths of its circumference, as if into two laminæ, one of which has the appearance of being turned up towards the eye out of the plane of the other portion. Viewed through Lord Rosse's telescope, this upturned portion of the ring assumes the aspect of a nebulous coil tending in a spiral form towards the centre, and a general tendency to a spiroid arrangement of the streaks of nebulæ becomes apparent. The companion is also seen to be connected with the general nebula. The number of nebulæ in which the spiral arrangement had been observed to prevail was fourteen at the time the paper was communicated to the Royal Society, but some have been detected since. They are in general difficult to be seen, and the full powers of the instrument are required to bring out the details.

When the catalogue of Sir John Herschel was published only two *annular nebulæ* were known to exist in the northern hemisphere. Now there are seven; five of the planetary nebulæ having been found to be annular. One of them has two perforations; but it is remarked, in reference to this class of objects, that in no instance is the central opening entirely dark. Lenticular or long elliptic nebulæ are very numerous.

With respect to the structure of these strange objects it is very difficult to form any satisfactory opinion. Lord Rosse in speaking of the spiral nebula, Messier 51, observes, that "with each successive increase of optical power the structure has become more complicated, and more unlike any thing which we could picture to ourselves as the result of any dynamical law of which we find a counterpart in our own system." All that can be safely inferred seems to amount merely to this, that the distant parts of the nebulous object are held in connexion by some dynamical law which gives rise to the symmetrical forms which prevail, though those forms, particularly in the case of the spiral nebulæ, are very different from those which we should expect to result from the operation of any laws with which we are acquainted. It is to be kept in mind, however, that, on account of the great difficulty of tracing the outlines, we are by no means certain that we yet know what the forms really are. Frequently, says Lord Rosse, "there is a gradual fading away at the edge, the last trace of which is rather a luminous mist, becoming rarer until imperceptible; a gauze-like tissue of the faintish imaginary flocculi or hairy filaments which become finer and more scattered till they cease to be visible, showing that the real boundary has not been seen, and that the form of the object would alter if additional optical power could be brought to bear upon it."

The considerable number of nebulæ which have been resolved by Lord Rosse's telescope into separate stars must be considered as strengthening the probability that they have all a similar constitution; for since every increase of optical power has multiplied the number of resolvable nebulæ, it seems reasonable to suppose that a further increase would accomplish the same result in those cases in which they have not yet been resolved. But since there are still many with respect to which the large telescope does not give the slightest idea of separate stars, the question of the existence of nebulous matter in contradistinction to stars, cannot be said to be decided.

NEPHRA'LGIA. (Gr. νεφρος, *the kidney*; αλγος, *pain*.) Pain in the kidney.

NE'PTUNE. In astronomy, one of the principal planets of the solar system, and the remotest at present known. The mean distance of Neptune from the sun is 30·0368 times the sun's distance from the earth, or about 2800 millions of miles. Its mean sidereal period is about 60,127 mean solar days, or 164⅔ years. The orbit is nearly circular, the eccentricity in parts of the semi-axis being only 0·00872, and is inclined to the ecliptic in an angle of $1^{\circ}\ 46'\ 59''$. Its apparent diameter is about $2''\cdot8$, and its real diameter 41,500 miles, a little more than half that of Saturn. Its density is about one-seventh of that of the earth, and its mass has been computed to be $1 \div 19840$ of the sun's mass. The time of its rotation about its axis is not known. It is attended by one satellite certainly, and the existence of a second has been suspected. Some observers have also suspected the existence of a ring. On account of the distance of the planet, the difficulty of observing satellites, or any circumstances connected with its physical constitution, is very great even in the most powerful telescopes.

Neptune was first observed as a planet on the 23rd of September, 1846; and the circumstances attending its discovery are extremely remarkable. For a number of years it had been remarked that the observed motions of Uranus were not in accordance with theory. About 1795 the true longitude began to be in advance of the computed longitude, and this acceleration continued till about 1822, after which the true motion began to be slower than the computed, and has continued to be so till the present time. Various hypotheses were formed to account for the phenomena, all of which were found, upon examination, to be untenable, with the exception of one, namely, the existence of an exterior and unknown planet disturbing the motion of Uranus according to the known laws of gravitation. This hypothesis acquired greater probability as the irregular motions of the disturbed planet were more fully developed, and at length a systematic examination of the question was undertaken by Le Verrier, an astronomer attached to the observatory of Paris, and already distinguished by an admirable investigation of the orbit of Mercury. Le Verrier first applied himself to the revision of the tables of Uranus, and the result showed that the observed irregularities could not be explained by the perturbations of Jupiter and Saturn, the only planets then known which exert any sensible action on Uranus. This result was published in the *Compte Rendu* of the Paris Academy of Sciences for Nov. 10. 1845. Le Verrier next proceeded to inquire whether the irregularities were explicable on the hypothesis of disturbance by an exterior planet, and in the *Compte Rendu* for June 1. 1846, he announced that such was the case, and that, assuming the mean distance of the disturbing planet according to Bode's law, its true longitude for the beginning of 1847 must be about 325° — an important determination, inasmuch as it was sufficient for the guidance of any observer who might wish to undertake a search for the planet. In a third memoir, which appeared in the *Compte Rendu* for August 31. 1846, Le Verrier gave the final results of his investigation, containing elements of the orbit of the hypothetical planet, namely, its distance from the sun, periodic time, eccentricity, and longitude of the perihelion; and, in order that nothing might be wanting, he likewise computed the limits within which the deduced place of the planet would be varied by any supposable amount of error in the observations made use of, thus indicating the precise portion of the heavens within which it was necessary to institute a search; and he also assigned the limits of its mass, and in addition pointed out that the planet would probably have a disc of about three seconds, and be visible in ordinary telescopes.

Having completed the theoretical investigation, Le Verrier next proceeded to consider the best means to be adopted for the discovery of the planet, and for this purpose addressed a letter to Dr. Galle of Berlin, one of the best observers of the day, calling his attention to the memoir of August 31, and requesting him to search for the planet according to the indications therein given. The letter was received at Berlin on the 23rd of

September (1846); and so well had the determination been made, that the planet was actually discovered by Dr. Galle on the evening of the same day, and within 52 minutes of a degree of the place assigned by the mathematician. An announcement of the discovery was immediately published, and the astronomers of all countries concurred in regarding it as the most remarkable triumph of the theory of gravitation which had ever been achieved.

Soon after the existence of the planet had been verified by Dr. Galle, it began to be rumoured that Le Verrier was not the only claimant of the honour of the discovery, but that he had even been anticipated in some of his principal conclusions. Nothing, however, was generally known of the circumstances till the publication of the *Monthly Notice* of the Royal Astronomical Society of London for November, 1846, which contained a detailed statement of them drawn up by the Astronomer Royal, about the accuracy of which there could consequently not be a question. From this statement it appeared that so early as February, 1844, the Astronomer Royal was requested to furnish Mr. Adams, of St. John's College, Cambridge, with some observations of Uranus from the records of the observatory, as data for investigations in which he was engaged respecting the theory of Uranus; and that in the month of October in the following year (1845) Mr. Adams, having completed his calculations of the perturbations of that planet on the assumption of their being caused by the attraction of an exterior planet, left at the Royal Observatory a paper containing a complete set of elements of the orbit of the hypothetical planet, a value of its mass, and a table of differences of mean longitudes of Uranus as deduced from the theory, and as determined by actual observation. It further appears that the Astronomer Royal having only results before him, and being well aware of the difficulty of the investigation, requested from Mr. Adams some explanations to enable him to form a better opinion as to the sufficiency of the hypothesis made to explain the observed discrepancies; that, from some unexplained reason, no answer was given to this request; that the matter rested in this state from the end of October, 1845, till the appearance of Le Verrier's second paper in June, 1846, which contained, as above stated, a determination of the longitude of the hypothetical planet; and that on comparing the two results they were found, when reduced to the same epoch, to differ only by 3° 19′.

The parties acquainted with Mr. Adams' results had now far stronger reasons than other astronomers for believing in the existence of the hypothetical planet as well as in the accuracy of its computed place. In so intricate an investigation, founded on data liable to more or less uncertainty, the risks of error were sufficiently numerous to justify hesitation even on the part of those best acquainted with the subject; but when the same result had been arrived at by two different computors independently of each other, the chances of error were almost annihilated. There could then hardly be a doubt as to the accuracy of the conclusion; and if Mr. Adams and his friends had immediately published the fact, it is not improbable that other observers would have been led to look out for the planet. They did not, however, adopt this course, nor does it appear that they acquainted Le Verrier with the remarkable confirmation of his results, but they resolved to institute a search for the planet themselves with the great equatorial of the Cambridge Observatory. The plan adopted was one which, though it virtually ignored the accuracy of the calculations, could scarcely fail of being successful in time. It consisted, simply, in making a close examination of a part of the heavens 30° long, in the direction of the ecliptic, and 10° broad, having its centre at the place indicated by Le Verrier and Adams, and observing all the stars to the 11th magnitude inclusive, from time to time, so as to detect the planet by its change of place. Observations in pursuance of this plan were actually begun on the 29th of July, 1846, and continued during two months. On the 29th of September, Mr. Challis, the director of the observatory, read Le Verrier's paper of August 31, in which the possibility of detecting the planet by its disc was suggested. Concurring in this idea Mr. Challis at once abandoned the plan he had been following, and on the evening of the same day began to observe within the limits indicated by Le Verrier. The planet, however, though observed as a star, was not recognised; on the next night observations could not be made, and on the following day information was received of Dr. Galle's discovery on the 23d of September.

It is to be remarked that Dr. Galle had an advantage over Mr. Challis in the possession of a star-map, then recently published at Berlin, of the part of the heavens to which his search was directed. A star appeared in the field of the telescope which was not laid down in the map, and his attention was consequently directed to it till its true nature became evident by its proper motion.

A circumstance deserving of notice is, that notwithstanding the near coincidence of the predicted place with that at which the planet was actually found, the elements of the hypothetical orbits determined both by Le Verrier and Adams were very wide of the truth. The mean distance they gave was rather more than 36 times the mean distance of the earth from the sun (Le Verrier 36·1539, Adams 37·2474), and the period of revolution about 220 years. It is now known, however, that the periodic time is less than 165 years, and the mean distance only about 30 times that of the earth from the sun, the error in this respect being greater than the radius of Jupiter's orbit. It seemed difficult at first to conceive how elements so faulty should give so close an approximation to the true place of the planet, but the reason has been satisfactorily explained.

NERVE. *See* NERVOUS SYSTEM, in DICT.

NEURAL ARCH. (Gr. *νευρον*, *a nerve.*) In Anatomy, the arch of the vertebra or primary segment of the skeleton which protects a corresponding segment of the neural axis: it is posterior in Man, superior in other Vertebrates, and is formed by the "centrum," "neurapophyses," and "neural spine."

NEURAL AXIS. (Gr. *νευρον*, *a nerve.*) In Anatomy, the central trunk of the nervous system, consisting of brain and myelon: it is sometimes called "cerebro-spinal axis."

NEURAPOPHY'SIS. (Gr. *νευρον*, and *ἀποφυσις*, *a process.*) In Anatomy, the autogenous vertebral element which forms the side or wall of the arch protecting the neural axis or central trunk of the nervous system: it has been called the "vertebral lamina," and by Soemmerring the "radix arcus posterioris vertebræ."

NINIVEH MARBLES. The name given to the collection of Assyrian Antiquities, recently procured by the researches of Mr. Layard at Niniveh, and deposited in the British Museum.

NODAL POINTS. NODAL LINES. Under the term VIBRATION (DICT. OF SCIENCE) it is stated that a vibrating chord may spontaneously divide itself into any number of aliquot parts, each of which will vibrate separately as if it were fixed at its two extremities and formed a separate chord. The points of separation between two such contiguous parts, which participate neither in the vibration of the one nor the other, but remain at rest, are called *Nodal Points*. And in like manner, when elastic plates are put into a state of vibration, the molecules separate themselves into parcels which vibrate independently of each other, and the lines of separation thus formed, or lines of repose in which no vibration takes place, are called *Nodal Lines*. *See* VIBRATION.

NO'NTRONITE. A nodular silicate of iron from Nontron, in France.

NOPAL. The cactus upon which the cochineal insects breed.

NORDHAU'SEN ACID. A peculiar sulphuric acid, intermediate between the anhydrous, and monohydrated acid, or oil of vitriol, so called from the place of its manufacture.

NU'SSIERITE. In Mineralogy, a species of *phosphate of lead* from Nussières, near Beaujeu.

O.

O. A contraction for *Octarium*, a pint.

O'CTROIS. (A corruption of Lat. auctoritas.) The name given in France to the taxes levied on objects of consumption at the gates of many towns and cities, and applied partly to the general uses of the state, and partly to local purposes. There are nearly 1500 communes subjected to this tax, which amounts in some years to nearly 100,000,000 of francs. The revenue of Paris from this source alone is upwards of 30,000,000 of francs.

ŒNANTHIC ETHER. (Gr. *οινος*, *wine*; *ανθος*, *a flower.*) A peculiar compound, upon which the fragrancy and persistent odour of certain wines depends.

ŒNANTHY'LIC ACID. (See above.) An acid of a peculiar aromatic odour, obtained by the action of nitric acid on castor oil.

OE'RSTEDITE. In Mineralogy (in honour of Oersted), a silico-titaniate of zirconia, from Arendal in Sweden.

ŒSOPHAGI'TIS. (Gr.) Inflammation of the œsophagus.

ŒSOPHAGO'TOMY. (Gr. *οισοφαγος*, *the gullet*, and *τεμνω*, *I cut.*) The operation of cutting into the œsophagus, or gullet, for the purpose of removing some foreign substance.

O'KENITE. In Mineralogy (in honour of Oken), a hydrated silicate of lime.

O'LANIN. (Gr. *ολειον*, *oil.*) One of the ingredients

of the fetid empyreumatic oil, obtained by distilling bone and other animal matters.

O'LEOSA'CCHARUM. (Gr. ολεον, and Lat. saccharum, *sugar.*) In Pharmacy, powdered sugar mixed or imbued with certain essential oils; called also *Elæosaccharum.*

O'LIGISTE. (Fr.) In Mineralogy, the *fer oligiste* of Haüy. A variety of hæmatite or specular iron.

O'LIGOCLASE. (Gr. ολιγος, *few*, and κλαω, *I break.*) In Mineralogy, a silicate of alumina and soda.

ONO'NINE. A sweet crystalline principle contained in the root of the *Ononis spinosa.*

OPERA'METER. A piece of machinery for registering the number of revolutions made by the shafts or wheels of mill-work.

O'PHITE. (Gr. οφις, *a serpent.*) In Mineralogy, serpentine. Green speckled porphyry.

OPHTHA'LMODY'NIA. (Gr. οφθαλμος, *the eye*, and οδυνη, *pain.*) A violent pain in the eye without apparent inflammation; it is sometimes of a gouty character.

OPHTHALMOPTO'SIS. (Gr. οφθαλμος, *the eye;* πτωσις, *a fall.*) A protrusion of the whole globe of the eye.

OPIA'NIC ACID. A crystallisable acid formed by the action of peroxide of manganese on a solution of narcotine in dilute sulphuric acid. Its formula appears to be $C_{20} H_9 O_9 + HO$.

OPTO'METER. (Gr οπτομαι, *I see;* μετρον, *measure.*) An instrument for measuring the focal distance of the eye, or the distance at which a minute object is distinctly seen. As the distance varies in respect of different individuals, the instrument is applicable to the purpose of determining the focal lengths of spectacles required for myopic or presbyopic eyes.

The principle upon which the optometer is constructed appears to have been first established experimentally by Scheiner, and subsequently by Dr. Motte of Dantzic, and by Dr. Porterfield. If we look at any minute object through two pin holes, or two parallel slits made in a card or any opaque thin body, the distance between the holes or slits being less than the diameter of the pupil of the eye, then, if the object be at the point of perfect vision, the image on the retina will be single, but in every other case it will be double; and, on varying the distance of the object from the eye, the two images will be seen to approach to or recede from each other. As a consequence of this, if the object looked at be a line pointed nearly towards the eye, it will appear as two lines crossing each other in the point of perfect vision at a very acute angle.

The practical application of this principle is extremely simple. As proposed by Dr. Thomas Young, the optometer may be made of a slip of card paper, or ivory unpolished, about eight inches in length (this being the distance of distinct vision for most eyes) and one in breadth, divided longitudinally by a black line which must not be too strong. The end of the card is bent into a position nearly perpendicular to its length, or a detached piece may be applied in the same inclined position. In this part (which is applied to the eye) a hole of about half an inch square must be made, the side being so cut as to receive a slide of thick paper, with slits of different sizes from a fortieth to a tenth of an inch in breadth, divided by spaces somewhat broader, so that each observer may choose that which best suits the aperture of his pupil. The slide is then brought close to the eye, and the black line viewed through two adjacent slits: it appears as two lines intersecting each other; the point of intersection is marked, and distance of this point from the slide is the focal length of the eye. (Young's *Lectures on Natural Philosophy*, vol. ii. p. 576, or p. 354. of Kelland's Edition; Priestley's *History of Discoveries relating to Vision*, etc., p. 641.)

O'RCINE. A crystallisable substance obtained from certain *lichens*, which, when exposed to air, gradually reddens. By ammonia it is converted into a purple substance called orcéine or orceic acid, which forms the beautiful blue or purple colours yielded by lichens.

ORE'LLINE. A colouring principle obtained from annotta (*Bixa orellana*).

ORGAN. The plan of Mr. Willis's instrument, which attracted great attention at the Exhibition in 1851, was as follows: Three complete rows of keys from C C C C to G, with two octaves and a fifth of pedals.

Great Organ.

Stops.		Feet
1. Double diapason (metal) largest pipe		16
2. Bourdon, closed	(wood)	16
3. Trumpet		16
4. Open diapason		8
5. Open diapason		8
6. Stopped diapason with claribella		8
7. Trumpet		8
8. Principal		4
9. Principal		4
10. Flute, open	(wood)	4
11. Clarion		4
12. Twelfth		4
13. Fifteenth		2
14. Fifteenth		2
15. Piccolo		2
16. Octave clarion		2
17. Doublette		1
18. Sesquialtera	3 ranks	
19. Mixture	3 ranks	
20. Fourniture	3 ranks	

Swell Organ C C to G.

Stops.		Feet
1. Double diapason, lower octave	(wood)	16
2. Double dulciana		16
3. Open diapason		8
4. Open diapason		8
5. Dulciana		8
6. Viol de Gamba		8
7. Stopped diapason		8
8. Trumpet		8
9. Trombone		8
10. Oboe		8
11. Cremona		8
12. Principal		4
13. Principal dulciana		4
14. Flute, open	(wood)	4
15. Clarion		4
16. Twelfth		3
17. Fifteenth dulciana		2
18. Fifteenth		2
19. Dulciana	3 ranks	
20. Sesquialtera	3 ranks	
21. Mixture	3 ranks	
22. Fourniture	3 ranks	

Pedal Organ C C C C to G.

Stops.		Feet
1. Double diapason, open	(wood)	32
2. Open diapason do.	(do.)	16
3. Open diapason	(metal)	16
4. Violin	(do.)	16
5. Bourdon	(do.)	16
6. Tromba		16
7. Trumpet		8
8. Octave	(metal)	8
9. Octave	(wood)	8
10. Quint		6
11. Super-octave	(metal)	4
12. Clarion		4
13. Sesquialtera	3 ranks	
14. Mixture	3 ranks	

Choir Organ.

Stops.		Feet
1. Bourdon		16
2. Open diapason		8
3. Dulciana		8
4. Viol di Gamba		8
5. Stopped diapason		8
6. Corno di bassetto		8
7. Viola		4
8. Principal		4
9. Flute	(wood)	4
10. Flute, closed	(metal)	4
11. Octave cremona		4
12. Fifteenth		2
13. Piccolo		2
14. Orchestral oboe (the only half-stop)		8

Copular.

1. Great organ to swell.
2. Swell to great organ.
3. Choir to great organ.
4. Swell to choir organ.
5. Swell to pedals.
6. Great organ to pedals.
7. Choir organ to pedals.

being in all 77 stops.

Of the above stops, all except the Orchestral Oboe were of the same compass as the various Claviers, a circumstance, we believe, without parallel in any large English organ.

ORGEAT. (Fr.) A sweetened emulsion of almonds usually flavoured by a few bitter almonds and a little orange-flower water. Mucilage of gum arabic is also sometimes added.

ORSEDEW. Brass leaf. Dutch, or Manheim gold.

O'RTHOCLASE. (Gr. ορθος, *straight*, and κλαω, *I break.*) A mineralogical synonym of *Felspar.*

ORTHOPÆ'DIA. (Gr. ορθος, *straight*, and παιδεια, *the bringing up of children.*) That department of medicine and surgery which relates to the prevention and cure of deformity.

O'STEODE'NTINE. (Gr. οστεον, *a bone;* and Lat. dens, *a tooth.*) That modification of dentine in which the tissue is traversed by irregularly disposed and ramified vascular or medullary canals, and in which some of the branches of the dentinal tubes communicate with cells, like the radiated cells of true bone: this modification of dentine is found in the central part of the tooth of the Cachalot and some other cetaceans; also in the teeth of the Cestracion, Acrodus, Lepidosiren, and many other existing and extinct fishes.

O'XALYLE. (Gr. οξυς, *sharp*, and υλη, *principle.*) The hypothetical radical of the oxalic acid $= C_2 O_2$.

OXA'MIC ACID. (Gr. οξυς, *sharp*, and ἁμα, *together.*) One of the products of the destructive distillation of binoxalate of ammonia. Its composition is represented by the formula $C_2 H_4 O_5 N + HO$.

OZO'KERITE. (Gr. οζειν, *to smell*, and κηρος, *wax.*) A species of *mineral tallow.*

OZO'NE. (Gr. οζειν, *to smell.*) A substance occasionally existing in the atmosphere, and having a peculiar odour resembling that produced when repeated electric sparks, or the electric discharge from a point, is passed through the air. It is supposed to be a peculiar modification of oxygen. It is also formed in certain cases of the slow action of air upon phosphorus.

P.

P. In some medical formulæ is used as the abbreviation of *Pugillus*, the eighth part of a handful.

P. Æ. The abbreviation of *partes æquales*, or equal parts.

PACI'NIAN CORPUSCLES. Small oval bodies situated on some of the cerebro-spinal and sympathetic nerves, especially the cutaneous nerves of the hands and feet, are so called, after their discoverer, Pacini.

PACKWAX. The ligaments of the neck of ruminants. It differs from common ligament in resisting the action of boiling water.

PADDING-MACHINE. An apparatus used by calico-printers for uniformly imbuing a piece of cotton cloth with any mordant.

PALÆOSAURUS. (Gr. παλαιος, *ancient*, and σαυρος, *a lizard,*) A genus of extinct lizards, characteristic of the magnesian conglomerate.

PALA'GONITE. A mineral found in the tufa of Palagonia, in the Val di Noto, Sicily. It is a hydrated silicate of alumina, iron, and lime.

PA'LPEBRÆ, (Lat., a palpitando, from their fre-

quent motion.) The eyelids; the upper and under uniting at each end to form the *canthi.*

PALPITA'TION. A throbbing; the term is especially applied to irregularities of the heart's action, which are frequently the result of indigestion, of nervous excitement, or mental agitation.

PA'LMIC ACID. The acid resulting from the saponification of the *palmine* of castor oil. (*Palma Christi.*)

PALMI'TIC ACID. The acid formed during the saponification of *palm oil.*

PANA'DA. (Ital. pane, *bread.*) Bread or biscuit steeped or boiled in water so as to acquire a soft consistence.

PANDICULA'TION. (Lat. pandiculo, *I gape.*) The gaping, yawning, and stretching that characterises some diseases. It sometimes occurs in the cold fit of an ague.

PANOPHO'BIA. (Eng. panic, from Lat. Pan, and Gr. φοβεω, *I frighten.*) That form of hypochondriasis or melancholy which is chiefly characterised by groundless apprehensions.

PANTOCRA'TIC MICROSCOPE. (Gr. παν, *all;* κρατος, *power.*) The name given by Professor A. Fisher, of Moscow, to a microscope so arranged that the observer is enabled by simple movements to vary the magnifying power from 270 to 550, without in any degree obscuring the object; thus avoiding the inconvenience of having to shift the different parts of the microscope when he desires to observe the same object under different magnifying powers.

PAPI'LLÆ. (Lat. papilla.) In Anatomy, are minute conical or cylindriform elevations, usually well supplied with vessels and nerves: they are close-set, and prominent on the palmar surface of the fingers and the plantar surface of the toes, where they are disposed in double rows, along parallel curved lines. They are very numerous, and of different kinds; *e. g.* "conical," "fungiform," "calyciform," on the upper surface of the tongue.

PA'RA. A very small Turkish coin, equal to the fortieth part of a piastre.

PARABA'NIC ACID. One of the acids resulting from the action of nitric acid upon uric acid: it forms colourless and transparent six-sided prisms, very soluble and sour. Its composition is represented by the formula $C_6\,O_4\,N_2+2\,HO$.

PARABOLE. *See* PARABLE.

PA'RALLAX. In 1846, Mr. Peters, of the Pulkova Observatory, presented to the Imperial Academy of Sciences of St. Petersburg, a very important memoir on the Parallax of the Fixed Stars, of which an analysis has been given by Struve in his *Etudes d'Astronomie Stellaire*, 1847. Among the results obtained by Mr. Peters are the parallaxes of eight stars, determined by observations of zenith distances made at Pulkova in 1842 and 1843 with the great vertical circle of Ertel. The divided circle of the instrument is 43 inches in diameter, and the object glass of the telescope nearly six inches; the magnifying power employed was 215; and the whole number of observations was 711, of which 289 were of Polaris alone. The names of the stars, their resulting parallaxes, and the probable errors of the respective results, are as follows:—

Star's name.	Parallax.	Prob. Error.
61 Cygni	+0″·349	0″ 080
Groombridge, 1830	+0 ·226	0 ·141
ι Ursæ Majoris	+0 ·133	0 ·106
Arcturus	+0 ·127	0 ·073
α Lyræ	+0 ·103	0 ·053
Polaris	+0 ·067	0 ·012
Capella	+0 ·046	0 ·200
α Cygni	—0 ·082	0 ·043

The parallax of 61 Cygni was determined by Bessel from a series of observations with the Konigsberg heliometer, and found to be 0″·348 (*see* DICT. OF SCIENCE); and the confirmation thus given by Peters may be considered as not only placing the fact of a measurable parallax of this star beyond all doubt, but as proving that its amount cannot differ more than a small fraction from the above value. With respect to the next star in the list (Groombridge, 1830), Mr. Faye, of the Paris Observatory, had announced that he had detected a parallax exceeding 1″, a result which Mr. Peters' observations prove to be erroneous. Struve found the parallax of α Lyræ to be 0″·261. The negative value found in the case of α Cygni must be considered as indicating merely the absence of any sensible parallax. In fact, the relative magnitudes of the probable errors in respect of the four stars Capella, ι Ursæ Majoris, Arcturus, and α Cygni, show that very little reliance can be placed on the numerical results in any of those cases.

Another conclusion deduced by Peters is, that the mean parallax of stars of the second magnitude is +0″·116, with a probable error of 0″·014. This result is obtained from 33 stars, of which the absolute or relative parallaxes have been determined with a degree of certainty presumed to be sufficient to establish the conclusion. Assuming the scale of relative distance adopted by Struve for stars of the different orders o magnitude (*see* GALAXY), he thence concludes that th mean parallax of the stars of the first magnitude 0″·209, and that the mean parallax of those of the thir is 0″·076. On this it is to be remarked that, althoug the hypothesis that the stars which have the greates apparent magnitude are those which are nearest th earth, and consequently those which have the larges parallax, is very probable in itself, it is not established b any conclusive facts; on the contrary, there does no appear, in the case of those stars whose parallaxes ar supposed to have been determined by direct observation to be any relation between the parallax and the apparen magnitude.

In the *Memoirs of the Royal Astronomical Society* vol. xix., the parallax of the double stars α^1 and α^2 Cen tauri is determined by Mr. Maclear from a series of ob servations with the mural circle, made at the Cape i the years 1842, 1843, 1844, and 1848. The final result i given as follows:—

Parallax of α Centauri = 0″·9187, Prob. error = 0·034
Constant of aberration = 20″·53 , Prob. error = 0·038

This result scarcely differs from that which was de duced in 1842, by M. Henderson (who first discovere the parallax of this remarkable star), from observation made at the same place, namely, parallax = 0″·913. I must be remembered, however, that both results are de duced from observations made with the same instru ment, and the agreement therefore may perhaps b considered as not so conclusive as in the case of 6 Cygni.

PARAPOPHY'SIS. (Gr. παρα, *across;* αποφυσις, *a process.*) In Anatomy, the process which extends outwards, or outwards and downwards, from the body o the vertebra in Fishes, and from the same part in th cervical and anterior dorsal vertebræ of the Crocodile where it has been called the "inferior transverse process." It is sometimes ossified from an independen centre.

PARI'LLINE. The supposed active principle of sarsaparilla. It has also been called Smilacine. It appears to be identical with the Parillic acid of Batke.

PA'RISITE. A crystallised mineral containing cerium, found in the mines of the Musso Valley, in New Granada.

PA'RTHENOGE'NESIS. (Gr. παρθενος, *a virgin*; γιγνομαι, *to be born.*) In Physiology, the procreatio of offspring by a plant or animal independently of th immediate stimulus of the male principle. The impregnated seed of a plant produces a "phyton" of the prope species, usually in the form of a leaf, with a stem an root; from this a succession of "phytons" may be developed by gemmation, most of them having the form of leaves; but, in the higher species of plants, some may take on the form of petals; others of stamens, developing the male principle, or "pollen;" others o pistils, forming the female principle, or "seed." By th union of these two principles the seed is impregnated, and may germinate; but the series of individuals successively developed from the first individual from th seed are procreated by "parthenogenesis." The different individuals being organically connected, accordin to a definite pattern for each species, form a compoun whole, which is commonly regarded as the individua "tree" or "shrub."

In the compound Polypes the first individual polyp from the impregnated ovum develops a succession o individuals, by gemmation, most of which may resembl the first-formed polype; but others are modified so a to reproduce the male principle, or the ova: thes generative polypes are also, sometimes, as in *Coryn* and *Campanularia*, set free. For other instances o this alternating kind of generation, see Steenstrup, *O Alternate Generation*, and Owen, *On Parthenogenesis.*

PARTHE'NOPE. One of the small planets belonging to the group between Mars and Jupiter, and th eleventh in the order of discovery. It was detecte at Naples on the 11th of May, 1850, by Dr. De Gasparis who, in announcing its discovery, remarked that he ha used his utmost endeavours to realise a Parthenope i the heavens; this name having been suggested by Si John Herschel upon the occasion of the discovery o Hygeia (also by De Gasparis) in 1849. The symbol i a fish crowned with a star. *See* PLANET.

PAU'LITE. A variety of hypersthene or prismati schiller-spar, from Paul's Island and the coast of La brador.

PEACHWOOD. A dye-wood extensively used i calico printing. It is the produce of a species of *Cæsal pinia.*

PE'ARLWHITE. The subnitrate of bismuth; fo merly used as a cosmetic under the above name.

PE'CTOLITE. (Gr. πηκτος, *bound together*, an λιθος, *a stone.*) A species of zeolite, which, after havin been heated, forms a gelatinous solution with muri atic acid.

PE'GANITE. A species of wavellite, or hydrated phosphate of alumina, from Strigis in Saxony.

PE'GMATITE. (Gr. πηγμα, Lat. aliquod compactum.) A granular mixture of quartz and felspar, found chiefly in granite veins, and closely resembling the so-called *graphic granite*, having the appearance of laminar compression.

PELIO'MA. (Gr. πελιος, *black*.) A mineralogical synonym of iolite or allochroite.

PE'LOKONITE. (Gr. πηλος, *mud*, and κονια, *clay*.) In Mineralogy, a native phosphate of manganese, iron, and copper.

PELOSI'NE. (Gr. πελος, *black*.) A bitter extractive matter obtained from the root of the *Cissampelos Pareira*, or *Pareira Brava*.

PENDULUM EXPERIMENT. An experiment proposed by M. Foucault of Paris, which, in 1851, excited great interest both in this country and in France; its object being to afford a visible proof of the rotation of the earth. It is this: By the theory of dynamics, if a simple pendulum be made to oscillate in a plane, the plane of oscillation, in reference to the meridian of the place, will not remain fixed, but will appear to rotate uniformly about the vertical passing through the point of suspension, and the time of rotation will be twenty-four hours increased in the ratio of the cosecant of the latitude to radius. This is easily understood in respect of a pendulum supposed to be suspended directly over the pole, where the terrestrial meridians would successively pass under it, and the earth's rotation would have no tendency to alter the direction in space of the plane of oscillation; but for any place between the pole and the equator the conception of the phenomenon is more difficult. Upon trial, the experiment is liable to failure from various causes, but principally from the great difficulty of adjusting the suspension so accurately that the vibrations shall continue to be made in a plane; for if the pendulum acquires an elliptic motion, however slight, the greater axis of the ellipse, or line of apsides, immediately begins to revolve from a cause entirely independent of the rotation of the earth, and the two motions cannot easily be distinguished. (See *Notices of the Royal Ast. Soc.* vol. xi. p. 199.; and *Memoirs of R. A. S.* vol. xx.)

PE'PSINE. (Gr. πεψις, *digestion*.) A peculiar animal principle contained in the gastric juice, and which, in conjunction with acid matter, also present in that secretion, confers upon it its solvent or digestive powers in regard to certain components of the food.

PERCU'SSION. (Lat. percutio, *I strike*.) In medical language, signifies the striking or tapping upon any part of the surface of the body, with a view of ascertaining the condition of the subjacent parts by the sound so produced. It is a valuable mode of exploration in some diseases of the chest. Attention was first called to this mode of diagnosis in 1761, by Dr. Avenbrugger, of Vienna: his work was translated into French in 1808, by Corvisart, and the subject was further illustrated in 1816, by the celebrated work of Laennec on *Auscultation*.

PE'RICLASE. (Gr. περι, and κλαω, *I break*.) A crystalline mineral, composed of magnesia with about 7 per cent. of protoxide of iron, found at Monte Somma, near Naples.

PE'RICLINE. (Gr. περι, and κλινειν, *to lie*.) A variety of felspar.

PE'RILYMPH. (Gr. περι, and Lat. lympha, *water*.) The fluid between the membranous and osseous labyrinth of the ear, or that in which the membranous labyrinth is suspended.

PE'RMANENT WHITE. Sulphate of baryta, when used as a pigment, it not being liable to discolouration, as is the case with white lead.

PERMANGA'NIC ACID, called also *Hypermanganic* acid. A compound of 2 atoms of manganese with 7 atoms of oxygen. It has been obtained in carmine-red acicular crystals. Its salts are of a fine red or purple hue.

PERONE'AL MUSCLES. (Gr. περονη, *the fibula*.) Muscles arising from the fibula and concerned in the movements of the foot.

PE'ROWSKITE. A crystallised titaniate of lime found in the chlorite slate of Slatoust in the Ural.

PE'RSIAN BERRIES. The berries of the *Rhamnus infectoria*, called in France *grains d'Avignon*. They are used by calico-printers and dyers, as a source of a yellow colouring matter, which has been called Rhamnine.

PE'RTHITE. A variety of felspar, from Perth in Upper Canada.

PERU'VINE. One of the products of the distillation of Peruvian balsam. Its formula is $C_{18}\ H_{12}\ O_2$. It is a light oily fluid.

PE'TZITE. An ore of silver with from 30 to 40 per cent. of tellurium, analysed by Petz, and found in the mines of Nagyag.

PEUCEDA'NINE. A crystallisable principle existing in the root of *Peucedanum officinale*, hog's fennel or sulphur-wort.

PEU'CILE. (Gr. πευκη, *a fir tree*.) A liquid obtained by the action of lime upon the hydrochlorate of oil of turpentine, of which oil it appears to be an isomeric modification. Its formula is $C_{10}\ H_8$.

PEYER'S GLANDS. Small glandular sacculi peculiar to the mucous membrane of the small intestines, and either scattered singly, when they are called "glandulæ solitariæ," or aggregated into groups, when they are termed "glandulæ agminatæ," or "Peyer's patches," from the anatomist who first described them.

PHA'COLITE. (Gr. φακος, *a wart*, and λιθος, *a stone*.) A silicate of alumina, lime, and soda (zeolite), from Leipa in Bohemia.

PHA'NTASCOPE. The name given by Prof. Locke, of the United States, to an apparatus for enabling persons to converge the optical axis of the eyes, or to look "cross-eyed," and thereby observe certain phenomena of binocular vision. It consists of a flat base-board, with an upright rod at one end bearing two sliding sockets which may be clamped at any height, like those of a retort stand. The upper socket supports a small screen or card having a slit or aperture a quarter of an inch wide and about three inches long, so that both eyes may be applied to it at once, the middle of the aperture being directly over the centre of the base-board. The lower socket bears a moveable screen of pasteboard or thin wood, having an opening of about three inches long, and an inch wide, and so adjusted that its centre is in the same straight line with the centre of the set in the upper card and the centre of the base-board. This screen has an index marked across its middle. In experimenting with the apparatus the observer places an object on the base-board, looks downward through the slit in the upper screen, and slides the lower up or down till the required adjustment is attained. For example, let the letter A be written twice on the base-board, about two and a half inches (the width between the eyes) apart, and in the line of the axis of the apertures of the screens; and suppose the lower screen to be close down to the base-board. On gradually raising this screen, and keeping the eyes directed to the index and not to the letters, each letter will separate and appear double, so that four letters will be seen. As the screen is raised the two internal images gradually approach, and become optically superimposed, or coalesce into one, so that there are only three letters visible, and the middle or superimposed figure is the *phantom* or *image* where there is really no object. On ceasing to look at the index, and directing the eyes on the base-board itself, the phantom figure instantly vanishes. The experiment may be varied so as to produce various amusing illusions; and the author thinks the apparatus will illustrate many important points in optics, and especially the physiological point of single vision by two eyes. (*London, Edinburgh and Dublin Philosophical Magazine*, June, 1850. It may be remarked that whether the apparatus be new or not, the phenomena have long been well known, and are fully explained in *Smith's Optics*, 1738.)

PHA'RMACOSI'DERITE. (Gr. φαρμακον, *poison*, and σιδηρος, *iron*.) Native arseniate of iron.

PHENAKI'STOSCOPE. (Gr. φενακισμος, *illusion*; σκοπεω, *I view*.) A philosophical toy, which illustrates the principle of the *persistence* of impressions on the retina of the eye in a very ingenious manner. It is thus described by Sir D. Brewster (*Ency. Brit.* art. OPTICS). "This instrument was, we believe, originally invented by Dr. Roget, and improved by M. Plateau, at Brussels, and by Mr. Faraday. It consists of a circular disc from six to twelve inches in diameter, with rectilinear apertures on its margin in the direction of its radii. A series of figures, of a rider, for example, leaping a fence is drawn on the circumference of a circle, parallel to the rim of the disc. The *first* figure represents the rider and horse standing *before* the fence; and the last figure represents them standing *over* the fence, when the leap is completed. Between these two figures there are several others, representing the rider and the horse in various parts of the leap. The observer then stands in front of a looking glass, with the disc in his left hand, attached to a handle, and by a piece of simple mechanism he whirls it rapidly round, looking at its image in the glass through the notches in its margin. He is then surprised to see the horse and his rider actually leaping the fence, as if they were alive, and returning and leaping again as the disc revolves. If we look over the margin of the disc at the reflected picture on the face of the disc, all the figures are effaced, and entirely invisible; but when we look through the notches, we only see the figure of the horse and rider at the instant the notch or aperture passes the eye, so that the picture instantaneously formed on the retina is not obliterated by preceding or subsequent impressions. Hence the eye receives in succession the pictures of the horse and rider in all the attitudes of the leap, which are blended as it

were into one action. The apparent velocity with which the horse and rider advance (supposing the disc always to have the same velocity) depends on the proportion between the number of apertures in the margin of the disc, and the number of figures of the horse and rider."

PHE'NAKITE. (Gr. φεναχιζειν, *to deceive.*) A rare mineral, containing glucina. The Rhomboedral Emerald of Mohs.

PHE'NE. (Gr. *an eagle.*) One of the chemical synonyms of the hydrocarbon usually called benzole, C_{12} H_6. It is isomeric with bicarburet of hydrogen. It has also been called *Hydruret of Phenyle*, and is in that case represented by the formula C_{12} H_5 + H.

PHENIKO'CHROITE. (Gr. φηνη, and χςοα, *colour.*) A native chromate of lead from Beresow in Siberia.

PHE'NYLE. (Gr. φηνη, and υλη, *matter.*) A radical hydrocarbon = C_{12} H_5.

PHI'LLIPSITE. A variety of zeolite. So called in honour of Phillips the geologist.

PHILOSO'PHIC CANDLE. An inflamed jet of hydrogen gas.

PHILOSO'PHIC WOOL. Oxide of zinc formed during the combustion of the metal, when it floats about in white flocks in the air. It has also been called *nihil album.*

PHLEBI'TIS. (Gr. φλεψ, *a vein.*) Inflammation of a vein.

PHLE'BOLITE. (Gr. φλεψ, and λιθος, *a stone.*) A venous calculus, commonly called "vein-stones." Very small concretions have sometimes been found in certain veins, varying in size from a pin's head to that of a pea. They consist chiefly of carbonate and phosphate of lime and animal matter.

PHLEGMA'SIÆ. (Gr. φλεγω, *I burn.*) Inflammatory diseases. The term *phlegmasia dolens* has been applied to a peculiar inflammatory condition of the leg, which sometimes occurs in females soon after delivery.

PHLORI'DZINE, or PHLORIZINE. (Gr. φλοιος, *bark*; ῥιζα, *root.*) A white crystalline substance obtained from the bark of the roots of apple, pear, cherry, and plum trees, giving to it its bitter astringency. Its composition is represented as C_{21} H_{15} O_{12}. Acids, aided by heat, resolve it into sugar, and *Phloretine*. By the joint action of oxygen and ammonia it is converted into a gum-like substance which has been called *Phloridzéine.*

PHŒ'NICIN. (Gr. φοινιξ, *purple.*) A purple substance obtained by the action of sulphuric acid on indigo.

PHO'LARITE. (Gr. φολις, *a scale.*) A mineralogical name applied to a hydrated silicate of alumina, occurring in pearly scales.

PHO'SGENITE. Native chlorocarbonate of lead, occurring in transparent yellowish crystals at Matlock. It is a very rare mineral.

PHO'SPHORIC ACID. *See* PHOSPHORUS.

PHO'SPHURET. Compounds of Phosphorus with the metals have been termed *Phosphurets* or *Phosphides.*

PHO'SPHOROCHA'LCITE. The native hydrated phosphate of copper found near Rheinbreitenbach, and also in the Ural.

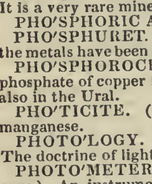
PHO'TICITE. (Gr. φως, *light.*) A native silicate of manganese.

PHOTO'LOGY. (Gr. φως, *light*; λογος, *discourse.*) The doctrine of light. *See* LIGHT.

PHOTO'METER. (Gr. φως, *light*, and μετρον, *measure.*) An instrument for measuring the intensity of light, or of illuminations.

The most elegant instrument which goes under this name is the photometer invented by the late Sir John Leslie. It is merely the differential thermometer of the same ingenious philosopher, having one of its balls diaphanous, and the other coated with China ink, or blown of deep black enamel; and the whole covered by a case of thin transparent glass, to defend the balls from the disturbing influence of currents of air. The photometer has two general forms; the one *portable* (fig. 1.) in which the black ball is about an inch higher than the other, and bent forward to the same vertical line, or the axis of the translucent cylindrical case; and the other *stationary* (fig. 2.), having both its balls of the same height, and reclining in opposite ways; the case being composed of a wide cylinder surmounted by the larger segment of a hollow glass sphere. The latter form of the instrument, though less commodious, is better adapted for nice observations; since, besides receiving the light more regularly, its balls, from being on the same level, are not liable to be disturbed by different strata of unequally heated air.

(1.) (2.)



The theory of this photometer depends on the assumed principle that the intensity of light is proportional to the heat excited by its incidence on the black ball. When the instrument is exposed to light, the rays which fall on the clear ball pass through it, without suffering obstruction; but those which strike the dark ball are stopt and absorbed at its surface, where, assuming a latent form, they act as heat, which, by expanding the air within the ball, causes the liquid in the stem to descend. This heat will continue to accumulate till its farther increase comes to be counteracted by an opposite dispersion, caused by the rise of temperature which the ball has acquired. But, in still air, the rate of cooling is, within moderate limits, proportional to the excess of the temperature of a given surface above that of the surrounding medium. Hence the space through which the coloured liquid sinks in the stem will measure the momentary impressions of light, or its actual intensity. (*Leslie on the Relations of Air to Heat and Moisture.*)

The graduation is entirely arbitrary, and may be regulated according to fancy or convenience. Leslie adopted the same scale of divisions as in the differential thermometer, ten degrees of which correspond to one of the centigrade thermometer. When the temperature of both balls is exactly the same, that is, when the instrument is excluded from light, the liquid in the stem next the coloured ball stands at zero. In this country the direct impression of the sun at noon, about the summer solstice, forces the liquid down to 90° or 100°. The greatest force of the solar beams, in the depth of winter measures only about 25°. At the altitude of 3° above the horizon, the whole effect of the sun's rays does not exceed one degree. The indirect light from the sky at noon in summer is from 30° to 40°; in winter from 10° to 15°. Comparing the illuminating power of the solar rays with that of artificial lights, Leslie found the light emitted by the sun 12,000 times more powerful than that of a wax candle; that is to say, if a portion of the luminous solar matter, rather less than half an inch in diameter, were transmitted to our planet, it would throw forth a light equal to the effect of 12,000 candles.

It has been objected that the instrument now described is only a species of thermometer, and not strictly a photometer; since it measures heat, and not light. To this objection Sir J. Leslie replies by asking, "What does the thermometer itself indicate except *expansion?* As heat is measured by the expansion it occasions, so light is determined by the intensity of the heat which in every supposition invariably accompanies it. What other mode, after all, could be imagined for detecting the presence of light? How can an unknown quantity be expounded but in terms of one already known?" (*Ency. Brit.*, art. CLIMATE.)

It must be admitted, however, that the same quantity of light emitted by terrestrial bodies of different kinds is not always accompanied with the same degree of heat. Thus, phosphorus burns in oxygen gas with intense splendour, and yet gives out far less heat than the comparatively dull combustion of hydrogen in the same gas; and the unfitness of this instrument for comparing the intensities of lights from different sources has been pointed out by Arago, who proved that it rises when exposed to the light of the sun, falls when exposed to the light of a common fire, and under the light of an Argand lamp remains stationary. (*Humboldt's Kosmos*, vol. iii. 1851.) See *Leslie's Experimental Inquiry into the Nature and Propagation of Heat*, 1804.

PHRA'GMOCONE. (Gr. φςαγμος, *a partition*; κωνος, *a cone.*) The essential part of the complex-shell of the Belemnite, consisting of a straight cone divided by numerous transverse partitions perforated by a marginal siphon. From the time of Llwyd conchologists have called this part the "alveolus," a term which is now more properly restricted to the socket of the sheath lodging the "phragmocone." Belemnites are chiefly distinguished by modifications of the "sheath" or "dart;" but the phragmocone is the constant and true characteristic of this extinct group of Cephalopods, which chiefly flourished from the epoch of the Muschelkalk to that of the Maestricht chalk.

PHTHORE. (Gr. φθοςος, *pernicious.*) A name given by some of the French chemists to *Fluorine.*

PHYLLIRE'INE. A bitter crystalline principle contained in the *Phyllirea latifolia.*

PHY'MA. (Gr. φυω, *I produce.*) A term applied by the ancient physicians to scrofulous tumours. In modern medical language it signifies a tubercle on any external part of the body.

PHYSE'TER. (Gr. φυσητης, *a blow-pipe.*) The generic name of the cachalot, or sperm whale.

PHY'SICAL SCIENCE. This term has been applied, arbitrarily, to signify the Science of Inorganic Bodies, as contradistinguished from that of Organised Beings. In this sense it includes the study of the external appearances and elementary principles, as well as the properties of inorganic matter.

PHYTE'LEPHAS. Vegetable Ivory. (Gr. φυτον, *a plant*; ελεφας, *an elephant.*) A genus of plants inhabiting America. Its fruit is of great size, and contains a milk which hardens into a substance resembling ivory.

Of this hardened albumen, buttons, boxes, and other articles are turned. It is the *Caleza de Negro*, or *Taqua plant*.

PHYTO'TOMY. (Gr. φυτον, *a plant;* τεμνω, *I cut.*) Vegetable anatomy.

PIAU'ZITE. A fusible resin-like substance found in the brown-coal at Piauze, near Neustadt in Carniola.

PI'CKERINGITE. A magnesian alum occurring in white silky fibres at Iquique in Peru.

PICRAMY'LE. (Gr. πικρος, *bitter;* υλη, *principle.*) A radical hydrocarbon = $C_{14}H_6$. The name has reference to the composition of bitter almond oil, which is $C_{14}H_6O_2$, and therefore a *binoxide of Picramyle.*

PICROGLY'CION. (Gr. πικρος, *bitter*, and γλυκυς, *sweet.*) An extractive matter of a bitter and sweet taste, obtained from the stalks of the *Solanum dulcamara*.

PI'CROLITE. (Gr. πικρος, and λιθος, *a stone.*) A name given by some mineralogists to fibrous serpentine.

PI'CROPHA'RMACOLITE. (Gr. πικρος, φαρμακον, *poison*, and λιθος, *a stone.*) A native arseniate of lime and magnesia from Riechelsdorf in Hessia.

PICROPHYLLITE. (Gr. πικρος, and φυλλον, *a leaf.*) A species of serpentine in dark green foliated masses.

PI'CROSMINE. (Gr. πικρος, and οζειν, *to smell.*) A species of steatite said to yield a *bitter odour* when breathed upon.

PILE, GALVANIC. *See* Voltaic Electricity.

PILLOWS. In Machinery, are the bearings on which gudgeons and journals rest. They are usually fixed in blocks of cast iron, whence the term *Pillow Block*, and sometimes, corruptly, *Plumber Block*.

PIMA'RIC ACID. The purified resin of the *Pinus maritima*: it forms a white crystalline mass. When subjected to dry distillation it yields an oil which has been called *Pimarone*.

PIME'LIC ACID. (Gr. πιμελη, *fat.*) One of the products of the action of nitric acid on fatty bodies.

PI'NGUITE. (Lat. pinguis, *fat.*) A greasy feeling silicate of iron, of a dark green colour, found at Wolkenstein in Saxony, and in the Harz.

PI'NIC ACID. (Lat. pinus, *the fir tree.*) The principal resinous constituent of common resin or colophony.

PIPEFISH. The vernacular name of the fishes of the genus *Syngnathus*.

PI'SSOPHANE. (Gr. πισσα, *pitch.*) A substance chiefly composed of sulphate of alumina and iron, found in the decomposing alum slate of Saalfeld and Reichenbach in Saxony. It resembles pitch in fracture and colour.

PI'STACITE. A green silicate of alumina, lime, and iron. It is a variety of epidote, and occurs embedded in many crystalline rocks. The finest crystals are from Arendahl, and from several parts of the Alps.

PISTO'MESITE. A crystallised carbonate of iron and magnesia from Saltzburg.

PITCH. In wheel work, signifies the distance between the centres of two contiguous teeth. *Pitch Line* is the circle, concentric with the circumference, which passes through all the centres of the teeth.

PITTIZITE. In Mineralogy, a variety of bog iron ore found near Limoges in France.

PLA'GIONITE. A sulphuret of lead and antimony from Wolfsberg in the Harz.

PLA'KODINE. (Gr. πλαξ, *a tabular surface.*) A native arsenuret of nickel found near Müsen in Siegen in tabular crystals.

PLA'SMA. (Gr.) The fluid of the blood in which the red particles are suspended, to which its colour is due: it consists of serum, holding fibrine in solution. It is sometimes called "Liquor sanguinis."

PLA'TTNERITE. A native oxide of lead from Leadhills in Scotland.

PLE'XUS. (Lat. *woven.*) In Anatomy, the term is substantively applied to those portions of nerves which interweave and interchange fasciculi, appearing to anastomose with each other, as, *e. g.*, in the arm-pit, forming the "axillary" or "brachial plexus," and in the loins, forming the "lumbar plexus." As nerves approach their final distribution in the several tissues, the minute fibres commonly form delicate plexuses, called the "terminal plexuses."

PLICIDE'NTINE. (Lat. plica, *a fold;* dens, *a tooth.*) That modification of dentine in which the substance is folded, as it were, on a series of vertical vascular plates, which radiate from the central axis of the pulp, and which is accompanied by a fluted character of the exterior of the tooth: the basal part of the teeth of the wolf-fish, of the *Lepidosteus oxyurus*, and of the *Ichthyosaurus*, affords examples of plicidentine.

PLI'NTHITE. A hydrated silicate of alumina and iron from Antrim in Ireland.

PLU'MBIC ACID. The *Peroxide of lead* = PbO_2. It combines with certain bases, forming compounds which have been called *plumbates*.

PLUMBOCA'LCITE. (Lat. plumbum, *lead*, and calx, *chalk.*) A mixed carbonate of lime and lead from Wanlock Head, in Scotland.

PLU'MBUM CORNEUM. (Lat.) Horn lead. The old chemical name of fused chloride of lead.

PLUMOSE ALUM. (Lat. pluma, *a feather.*) A name formerly given to the silky amianthine crystals occasionally observed on alumslate. It is a *sulphate of alumina and iron*.

PLU'MOSITE. (Lat. pluma, *a feather.*) Capillary or plumose sulphuret of antimony, chiefly found in the Harz and Hungarian mines.

PNEUMATO'METER. (Gr. πνευμα, *air*, and μετρον, *measure.*) A gasometer constructed for the purpose of measuring the quantity of air taken into the lungs and again given out, at each inspiration and expiration.

PNIGA'LIUM. (Gr. πνιγω, *I suffocate.*) A name given by some medical authors to the *Nightmare*, from the sense of suffocation which it induces.

POE'NAMU. A variety of jade or nephrite used in New Zealand for the manufacture of axes and other weapons.

PO'LAR CLOCK. An optical apparatus invented by Professor Wheatstone, whereby the hour of the day is found from the polarization of solar light.

Light reflected from the atmosphere, like other reflected light, is polarized in a certain plane; and it is found that the light reflected from any particular point of the sky is polarized in the plane passing through that point, through the sun, and the eye of the observer. Suppose the point of the sky under observation to be the pole, then the plane in question is one which passes (sensibly) through the axis of the earth's rotation, and consequently the angle which it makes with the meridian is an hour angle; if, then, the situation of this plane be determined, the hour of the day, or time from true noon, is determined also.

Mr. Wheatstone's method of determining the plane of polarization consists in attaching to the top of an upright pillar a glass plate, held by a brass ring, and directed perpendicularly to the earth's axis, the lower half of the ring being divided into twelve equal parts (which may be again subdivided) to represent the hours. A conical tube is fitted into the brass ring, so that its axis is parallel to that of the earth. The upper and wide end of the tube is closed by a plate of glass having a star of selenite on it, and a Nichol's prism is attached to the lower end. The principal sections of the thin plates of selenite which form the star are all parallel, and inclined at an angle of 45° to the plane of polarization of the prism, and so placed that the lamellæ simultaneously appear colourless. In order to make the observation the tube is turned till the central portion of the star exhibits the maximum of red colour, when a black line drawn on the glass plate in the direction of a principal section of the lamellæ and serving as an index, gives the position of the plane of polarization of the reflected light, and consequently indicates the hour. Instead of this apparatus, Soleil proposed to use a polariscope containing two plates of quartz of opposite rotation, in which case the situation of the plane of polarization becomes known by the equality of colour.

The polariscope has some advantages over the sun dial, inasmuch as it may be used some time before sunrise and after sunset, and even when the sky is in some measure clouded, but the practical use of the instrument appears to be subject to many considerable difficulties. (*Annual Report on the Progress of Chemistry, &c.* vol. iii. part 1.)

POLA'RISCOPE. Any apparatus or instrument by means of which it can be ascertained whether light is in its ordinary state, or has been polarized. This may be done in various ways. The polariscope proposed by Arago is formed of a tube closed at one extremity by a plate of rock crystal cut perpendicularly to the optical axis, and about five millimetres (or a fifth of an inch) in thickness, and having at the other end, where the eye is applied, a prism possessing the property of double refraction placed transversely to the axis of the tube. A beam of polarized light, after passing through the plate, is decomposed by the prism into two others which are polarized at right angles to each other, and exhibit the complementary colours, varying with the position of the prism. *See* Polarization of Light, in Dict.

POLA'RIZATION OF LIGHT. The phenomena of polarization are arranged under the heads *plane polarization*, *circular polarization*, and *elliptic polarization*. For the first, see Polarization, in Dict.

Circular Polarization is produced when light is twice totally reflected from the second surfaces of bodies at their angle of maximum polarization. It may also be produced, as was discovered by Arago, by the passage of light through rock crystal; or, as discovered by Biot and Seebeck, through certain fluids, as oil of turpentine, oil of laurel, solution of sugar, &c.

Elliptic Polarization, is produced by reflexion from the polished surfaces of metals at angles included between 70° 45′ and 78° 30′; gold having the least and tin the

greatest polarizing angles. This property was discovered by Sir David Brewster.

PO'LIANITE. A crystallised peroxide of manganese from Bohemia.

PO'LISHING SLATE. *Polierschiefer* of the German mineralogists. A light slaty substance occurring abundantly at Bilin in Bohemia: it consists of the siliceous bucklers of microscopic animals.

POLLUX. Among the abundant absurdities of mineralogical nomenclature, is the application of the names Castor and Pollux to two varieties of felspar found in the granite of Elba.

POLY'BASITE. (Gr. πολυς, *many*, and βασις, *support.*) A native sulphuret of silver, copper, arsenic, and antimony, found in the mines of Saxony, Hungary, and Mexico.

POLYCHROMA'TIC ACID. (Gr. πολυς, and χρωμα, *colour.*) A compound resulting from the action of nitric acid upon aloes. When used as a dye-stuff it yields a great variety of colours.

POLYDI'PSIA. (Gr. πολυς, and διψη, *thirst.*) Excessive thirst.

POLYHY'DRITE. (Gr. πολυς, and ὑδωρ, *water.*) A hydrated silicate of iron from Breitenbrun, in Saxony. It seems to be the same as the *Hisingerite* of Berzelius found in Sweden.

PO'LYKRASE. (Gr. πολυς, and κρασις, *combination.*) A rare mineral occurring in black six-sided tables: it contains titanic and tantalic acids, zirconia, yttria, alumina, magnesia, lime, and the oxides of iron, cerium, and uranium. It is found at Hitterö, in Norway.

POLYSPHÆ'RITE. A reniform variety of chlorophosphate of lead from Freiberg, containing also phosphate of lime.

POLY'XENE. (Gr. πολυς, and ξενος, *stranger.*) A name given by Hausmann to the ore of platinum, as indicating the many new metals associated with it.

POO'NAHLITE. A species of zoolite from Poonah, in Hindostan.

PO'RTAL. (Lat. porto, *I carry.*) In Anatomy, is applied to a system of veins that ramify like arteries, and send the blood from trunks to branches in the substance of the liver. The portal system is derived in mammals from the veins of the abdominal organs of digestion, which form a common trunk, called "Vena portæ." This subordinate kind of circulation in the liver is called the "portal circulation," and the blood it transmits is called the "portal blood." The blood of the portal vein differs from other venous blood in being of less specific gravity, darker, and incapable of being rendered bright by the contact of salt or oxygen; in containing only about half the ordinary quantity of fibrine, and in containing less albumen, but more red globules, and nearly twice the usual amount of fatty matter.

POSO'LOGY. (Gr. ποσον, *quantity*, and λογος, *description.*) In Medicine, that which relates to the doses or quantities in which medicines should be administered.

POST MORTEM. (Lat. *after death.*) In Anatomy, the technical phrase signifying the inspection and examination of the dead body, in order to determine the cause of death: it is also applied to the appearances presented, and more especially to some phenomena which are constantly noticed shortly after death. Thus, the muscles retain their property of contracting under the influence of stimuli applied to them, or to their nerves, for some time after death; and when they have lost this irritability, they spontaneously pass into a state of contraction, producing a general stiffening of the body, which is called "post-mortem rigidity," or "rigor mortis."

POT-METAL. An alloy of copper and lead.

POUDRE'TTE. (Fr.) A manure composed of night-soil mixed up with clay, and formed into cakes.

PRA'SEOLITE. A species of tourmalin from Norway.

PREDA'ZZITE. A magnesian marble, or dolomite, which forms mountain masses at Predazzo, in the Tyrol.

PREMO'LAR. (Lat. præ, *before*, molaris, *grinding tooth.*) In Anatomy, the name of those permanent teeth in the Diphyodont mammals that displace and succeed the deciduous teeth vertically: they are situated before the molars; and, being in many cases of more simple structure, they have been termed "false molars," and in Human Anatomy "bicuspides." The premolars never exceed four in number on each side of both jaws.

PRIMING AND LAGGING. The alternate acceleration and retardation of the times of high water, caused by the combined action of the sun and moon. *See* LAGGING.

PRINCE'S METAL. Prince Rupert's metal. The same as pinchbeck. An alloy of copper and zinc.

PROCŒ'LIAN. (Gr. προ, *before;* κοιλος, *hollow.*) In Anatomy, those vertebræ are so called which have a cavity or cup at the fore part of the body, and a ball at the back part. The term is also applied to the group of animals—a certain family of Reptiles, *e. g.*, which manifest this vertebral character. It is found in most existing Saurians, but not in any extinct species of earlier date than the cretaceous period.

PROLETAI'RE. (Lat. proles, *offspring.*) A term that has come into common use in the social discussions of late years, signifying that class of the community whose labour is their only capital. As its origin indicates, it was applied to those members of a community whose social duties were limited to furnishing children to defend the state, and whose social rights were necessarily small. The word plays a considerable part in all the writings of the communists and socialists both of France and Germany.

PROSY'LLOGISM. In Logic, a word sometimes used to signify a second syllogism, proving a former one; at other times in the same sense as Enthymeme, viz. a syllogism of which one premise is suppressed.

PRO'TEINE. (Gr. πρωτειον, *the chief place.*) The azotised substance which forms the basis of albumen, fibrine, and caseine, in which proximate principles it is combined with small proportions of sulphur and phosphorus. Different formulæ have been assigned to proteine: that of Mulder is $C_{40}\ H_{30}\ O_{12}\ N_5$.

PRO'TEOLITE. (Gr. πρωτος, *first*, and λιθος, *a stone.*) The slaty rock immediately recumbent upon granite.

PRO'TOZENE. (Gr. πρωτος, and ξενος, *a stranger.*) Talcose granite. A mixture of felspar, quartz, and talc, or chlorite. It decomposes into china clay or porcelain earth.

PSELLI'SMUS. (Gr. ψελλιζω, *I stammer.*) An imperfect articulation. Stuttering.

PSEU'DÆSTHE'SIA. (Gr. ψευδης, *false*, and αισθανομαι, *I feel.*) Imaginary or false feeling.

PSEU'DOMA'LACHITE. (Gr. ψευδος, and μαλακος, *soft.*) Native phosphate of copper.

PSEUDOMO'RPHOUS CRYSTALS. (Gr. ψευδος, and μορφη, *form.*) Substances found in crystalline forms not belonging to them, and being, as it were, casts of other crystals.

PSEUDOSCOPE. (Gr. ψευδος, and σκοπεω, *I view.*) A name given by Professor Wheatstone to the stereoscope when employed to produce what he calls "conversions of relief." These conversions may be produced in three different ways:—1st, by transposing the pictures from one to the other; 2ndly, by reflecting each picture separately, without transposition; and, 3rdly, by inverting the pictures to each eye separately. The converse figure differs from the normal figure in this circumstance, that those points which appear most distant in the latter are the nearest in the former, and vice versâ. The *pseudoscope* consists of two reflecting prisms placed in a frame, with adjustments, so that when applied to the eyes, each eye may separately see the reflected image of the projection which usually falls on that eye. The instrument being directed to an object, and adjusted so that the object shall appear of its proper size, and at its usual distance, the distances of all other objects are inverted; all nearer objects appear more distant, and all more distant objects nearer, and this constitutes the "conversion of relief." The inside of a teacup appears a solid convex body. A china vase ornamented with coloured flowers in relief, appears to be a vertical section of the interior of the vase, with painted hollow impressions of the flowers. A small terrestrial globe appears a concave hemisphere; when the globe is turned on its axis, the appearance and disappearance of different portions of the map on its concave surface has a very singular effect. A bust regarded in front becomes a deep hollow mask. When regarded in profile the appearance is equally striking. A framed picture hung against a wall appears as if imbedded in a cavity made in the wall. (See *Athenæum* for 1852, Jan. 24, and STEREOSCOPE in SUPP.)

PSILA'NTHROPISTS. (Gr. ψιλος, *mere*, and ανθρωπος, *man.*) A name given to a peculiar sect of Unitarians who believe that Jesus was the son of Joseph, and in whose creed the resurrection holds a higher place than the crucifixion.

PSILOME'LAN. (Gr. ψιλος, *mere*, and μελας, *black.*) In Mineralogy, black hæmatitic ore of iron.

PSOROPHTHA'LMIA. (Gr. ψωρα, *the itch;* οφθαλμος, *the eye.*) An inflammation and ulceration of the eyelids attended by an itching sensation.

PTYALI'NE. (Gr. πτυαλον, *saliva.*) A supposed peculiar animal matter obtained from saliva. It is insoluble in alcohol, and is said to be analogous to the vegetable substance termed diastase.

PULSE GLASS. A tube of about a quarter of an inch diameter and five or six inches long, with a bulb at each end, and about half filled with spirit of wine or water, care having been taken to expel the whole of the air previously to sealing the tube. When held in an inclined position, one of the bulbs being grasped

in the hand, the expansion of the included vapour causes the liquid to rise and fall in the tube, or to *pulsate*.

PU'NCTUM CÆCUM. (Lat.) That part of the retina of the eye immediately about the spot at which the optic nerve unites with it is found experimentally to be totally insensible to the stimulus of light, and hence it has been called by writers on Optics the *Punctum Cæcum*.

PURREE, or INDIAN YELLOW. A yellow colouring matter imported from India and China. Its origin has not been accurately ascertained, but it is supposed to be a vegetable juice mixed with magnesia.

PUSCHKINITE. A variety of Epidote from Siberia.

PUZZOLA'NO. A volcanic rock, which yields an excellent water-cement. It occurs at Puzzuoli, near Naples.

PYRARGI'LLITE. (Gr. πυρ, *fire*, and αργιλλος, *pure clay*.) A hydrated silicate of alumina, found in the granite of Finnland.

PYRA'RGYRITE. (Gr. πυρ, and αργυρος, *silver*.) The red or ruby silver ore; it is either a sulphuret of silver and antimony, or a sulphuret of silver and arsenic. The finest specimens are from Andreasberg, in the Harz, and from Joachimsthal in Bohemia.

PYRE'NEITE. A species of garnet found in the limestone of the Pic d'Erselids near Barége, in the Pyrenees.

PYROPHI'LLITE. A hydrated silicate of alumina and magnesia which exfoliates before the blowpipe, found in the Ural, and formerly considered as *talc*.

PYROPHY'SALITE. (Gr. πυρ, *fire*, and φυσαλος, *a toad*.) A mineralogical synonym of the common topaz, found in veins and blocks near Fahlun. A crystal in the College of Mines at Stockholm weighs 80 lbs.

PYRO'SKLERITE. (Gr. πυρ, and σκληρος, *hard*.) A green hydrated silicate of magnesia and alumina coloured by iron and chromium, from Elba.

PYRRHOSI'DERITE. (Gr. πυῤῥος, *brown*, and σιδηρος, *iron*.) A brown hydrous peroxide of iron.

PY'RRHOTINE. (Gr. πυῤῥος, *brown*.) Magnetic iron ore.

PYRU'VIC ACID. (Gr. πυρ, *fire*, and Lat. uva, *a grape*.) An acid discovered by Berzelius amongst the products of the destructive distillation of racemic and of tartaric acid. It had been before observed by Pelouze, who mistook it for acetic acid.

Q.

QUAS. A fermented liquor used in Russia, and prepared from a mixture of meal and malt.

QUI'NCEITE. A hydrated silicate of magnesia tinged red by oxide of iron, found near Quincey, in France.

QUI'NOIDINE. (From Quinin.) An alkaloid said to accompany cinchonia and quinia in certain varieties of *cinchona*.

R.

RAPHA'NIA. (Lat. Raphanus, *the radish*.) A disease said to be produced by eating the seeds of a species of raphanus; it is attended by convulsive motions of the limbs, vomiting, and diarrhœa.

RA'PHELITE. A species of hornblende from Perth, in Upper Canada.

RATAFI'A. A term applied to certain liqueurs or drams, derived like the word *ratify* from *ratum* and *fio*, to make firm, or *confirm*. By ratafia, therefore, was originally meant a liquid drank at the *ratification* of an agreement. (PEREIRA, *on Food and Diet*.)

RE'AGENT. In Chemistry, bodies which serve to detect the presence of others; tests.

RECE'IVER. In Chemistry, generally means a globular vessel applied to a retort in which the *distillate* or product of distillation is collected or received. The bell-glass placed upon the plate of an air-pump is also called a receiver. *See* RETORT, in DICT.

RED FIRE. A pyrotechnical compound which burns with a beautiful red or pink flame. It consists of nitrate of strontia, mixed with charcoal and a little sulphur and chlorate of potassa.

RE'DRUTHITE. The vitreous sulphuret of copper, magnificent crystallised specimens of which have been obtained from the mines near Redruth in Cornwall.

REFLEX FUNCTION, in Physiology. *See* AUTOMATIC, MOTORY, SENSORY.

REFLEX ZENITH TUBE. An instrument recently invented by the Astronomer Royal, and erected at the Greenwich Observatory, for measuring the zenith distances of stars very near the zenith. It consists mainly of an object-glass of 5 inches diameter and 10 ft. focal length; of a micrometer firmly attached to the cell of the object-glass; and of a trough of mercury placed beneath the object-glass at a distance of nearly half its focal length. The cell of the object-glass is fixed in a tube sliding in another tube fastened to the flooring of the small chamber in which the instrument is erected, the mercury being a short distance beneath the flooring. By this apparatus the parallel rays proceeding from a star very near the zenith are, while in a converging state, reflected from the mercury, so as actually to converge to a focus and form an image at a short distance above the object-glass; and it is ingeniously contrived that the point of convergence shall be in the same line (measured parallel to the diameter of the object-glass) as its focal centre. By this means any inaccuracy which would arise from a small error of level of the plane of the micrometer is avoided. A micrometer is mounted upon the cell which carries the object-glass, which has a series of wires stretched across its side bars, and whose screw acts against the standards carrying the bars, the wires being placed at intervals nearly equivalent to double the distance of γ Draconis from the zenith of Greenwich. For viewing the images of the star and the wires together, a compound 4-glass eye-piece is used, consisting of two distinct parts, the first part consisting of a first lens for receiving the rays from the object-glass, and a glass reflecting prism for turning them into a horizontal direction, the prism having one side ground to a spherical surface, so as to produce the effect of the second glass of the eye-piece, and to avoid unnecessary loss of light. This part is fixed in a tube carried between the bars of the micrometer. The second part consists of the third and fourth glasses of the eye-piece mounted in a tube carried horizontally by a fixed support, so as to allow the head of the observer to avoid interference with the rays after passing through the object-glass. The cell of the object-glass is made to revolve, carrying with it the micrometer, for the purpose of making observations in reversed positions. The micrometer is also double, carrying screws and divided heads on each side of the object-glass, and it is so arranged that by the action of one of the screws the micrometer wires are carried without disturbance of the reading of the head attached to the other screw.

REMI'SSION. In Medicine, the abatement of a disorder, or regular mitigation of symptoms, as opposed to *intermission*, in which the symptoms of disease for a time entirely disappear. *See* REMITTENT FEVER, in DICT.

RE'SINITE, or RETINITE. A substance intermediate between resin and asphalt. *See* RETINASPHALTUM, in DICT.

RE'STIFORM. (Lat. restis, *a rope*, and forma.) In Anatomy the term is applied to certain rope-like columns or tracts, behind the "lateral tracts" of the medulla oblongata. The "restiform tract" is continuous below with the posterior columns of the myelon, while above, its fibres may be traced transversely through the pores into the cerebellum. If the restiform tracts be irritated the most acute suffering is produced.

REVE'RBERATORY FURNACE. A furnace in which the flame is made to pass over a bridge, and then beat down again upon a hearth or surface, on which the materials to be heated are placed.

RHABA'RBARINE. The colouring principle of rhubarb.

RHÆ'TIZITE. A mineralogical synonym of the cyanite of the Tyrol.

RHEO'METER. (Gr. ῥεω, *I flow*; μετρον, *measure*.) A term proposed by Peclet as a synonym for *galvanometer*, and generally adopted by the French writers on physics. Professor Wheatstone, in an ingenious paper entitled "An Account of several new Instruments and Processes for determining the Constants of a Voltaic Circuit," published in the *Philosophical Transactions* for 1843, uses the term, in a general sense, to designate any instrument for measuring the force of an electric current, without reference to its particular construction. Mr. Wheatstone also uses the following similar terms in describing apparatus employed in investigations on the same subject:—

Rheomotor (Lat. moveo, *I move*), any apparatus which originates an electric current.

Rheoscope (Gr. σκοπεω, *I view*), an instrument for ascertaining merely the existence of a current.

Rheostat (Gr. ιστημι, *I place*), an instrument for adjusting or regulating the circuit, so that any constant degree of force may be obtained.

Rheotome (Gr. τεμνω, *I cut*), an instrument which periodically interrupts an electric current.

Rheotrope (Gr. τρεπω, *I turn*), an instrument which alternately inverts the current.

RHEOPHORE. (Gr. ῥεω, *I flow*, and φορεω, *I carry*.) A term employed by Ampere to designate the connecting wire of a voltaic apparatus, as being the carrier or transmitter of the current.

RHODA'NIC ACID. (Gr. ῥοδον, *a rose*.) A chemical synonym of sulphocyanic acid. It produces a red colour with persalts of iron.

RHODIZO'NIC ACID. A substance formed by

passing dry carbonic oxide over highly heated potassium, and acting on the product by water. A red powder separates which is rhodizonate of potassa, from which rhodizonic acid may be separated by a mixture of sulphuric acid and alcohol. Its formula is said to be $C_7 O_7$, 3 HO.

RHO'DIZITE. (Gr. ῥοδον, *a rose.*) A species of boracite, which, when heated before the blowpipe, colours the flame first green, but afterwards red.

RHO'DOCHROME. (Gr. ῥοδον, *a rose*, and χρωμα, *colour.*) A hydrated silicate of magnesia and alumina, containing a little chromic oxide, and of a red colour when in fine splinters. It has been found in Siberia, also near Baltimore, and in Tino in Greece.

RHO'DONITE. (Gr. ῥοδον, *a rose.*) A silicate of manganese.

RHYTHM. (Gr. ῥυθμος. *rhyme.*) In Physiology, the more or less regular succession of the contractions of certain automatic muscles. In the heart the motion commences in the venæ cavæ, and proceeds through the auricles and ventricles, and then, after an interval, is resumed in the venæ cavæ. In the intestine the movement travels in a vermicular manner from above downwards; and a second movement, beginning at the upper part of the intestine before the first has completed its course, affects the parts in the same order. These movements are called "rhythmic;" those of the intestinal tube are also called "peristaltic."

RI'CINOSTE'ARIC ACID. One of the acids resulting from the saponification of castor oil.

RIFACIMENTO. (Ital. *re-establishment.*) A term in common literary use applied to any work or treatise, the materials of which have neither been derived from original research, nor have been collected for the first time.

RIGOR MORTIS. (Lat.) In Physiology, the general stiffening of the body produced by the simultaneous contraction of all the muscles of the trunk after death. The muscular coat of the arteries also contracts after death on division and mechanical irritation, on the application of cold, and under the stimulus of electricity.

RIPIDOLITE. A mineral resembling Chlorite.

RISUS SARDONICUS. (Lat. *sardonic laugh.*) So called as having been produced by eating a species of ranunculus growing about certain springs in Sardinia. A convulsive grin, giving a peculiarly horrible expression to the countenance, chiefly observed in cases of tetanus and inflammation of the diaphragm.

ROCHE ALUM. Alum deprived of part of its water of crystallisation by heat. The term is also sometimes applied to the so-called *Roman Alum*, made from the alum ore of the Solfaterra, near Naples.

ROCKSOAP. An earthy silicate of alumina. It is used for crayons, and also for washing cloth.

ROCKWOOD. The common name for ligniform asbestus.

ROME'ITE. A native antimoniate of lime found in the manganese mines of St. Marcel, in Piedmont, and named in honour of the celebrated crystallographer Romé de l'Isle.

RO'SENITE. A sulphuret of lead and antimony from Wolfsberg in the Harz. Named in honour of H. Rose, the analytical mineralogist.

RO'SITE. (Eng. *rose.*) A mineral of a red colour in small grains embedded in limestone, from Sweden; it appears to be silicate of alumina tinged red by manganese. It has also been called *Rosellanite.*

RUBI'NIC ACID. An acid formed by exposing a solution of catechuic acid in carbonate of potassa to the action of air.

RU'FINE. (Lat. rufus, *red*) A red substance formed by the action of sulphuric acid on salicine.

RUTHE'NIUM. A metal closely resembling iridium, with which it is associated in the residue from crude platinum insoluble in aqua regia. Its properties require further investigation. (CLAUS. *Annalen der Chem. und Pharm.*, lix. 234.)

RUTI'NIC ACID. An acid contained in the leaves of rue.

S.

SA'CCHARITE. (Lat. saccharum.) A mineral of the felspar family, found in veins in serpentine, in the chrysoprasm mines near Frankenstein, in Silesia.

SACCHARO'METER. (Lat. saccharum, Gr. μετρον.) An improved construction of the saccharometer was exhibited at the London Exposition of Industry by M. Duboscq-Soleil. A double gauge is formed by a rotating polarising plate of quartz and Iceland spar, of which two semicircles, placed in juxtaposition, and viewed through a telescope of low magnifying power, are brought into exact coincidence of colour, by turning the spar. In this situation the images are viewed through an empty tube, closed at both ends with glass. The saccharine juice is poured in and the quality of colour is disturbed; the semicircles, which no longer match, are readjusted, by sliding upon each other two achromatised prisms of Iceland spar, so as to leave a variable difference of thickness estimated in parts of a finely divided scale, which gives numerical evidence of the quantity of saccharine matter present.

SAL ALEMBROTH. The hydrargo-chloride of ammonium. A compound of sal ammoniac and corrosive sublimate.

SA'LAMSTONE. The common name of the oriental sapphire.

SAL DE DUOBUS. (Lat.) An ancient chemical name applied to sulphate of potassa.

SALICY'LIC ACID. An acid obtained by the action of fused potassa on salicine: it may also be obtained from various other sources. The formula of the salicylic acid is $C_{14} H_5 O_5 + HO$.

SAL MIRABILE. (Lat.) Glauber's salt. Sulphate of soda.

SAL PERLATUM. (Lat.) A term applied by old chemical writers to the rhombic phosphate of soda.

SAL PRUNE'LLA. Nitrate of potassa fused into cakes or balls. The latter were sometimes coloured blue.

SA'MARSKITE. A granular mineral found in the Ilmen mountains near Miask. It contains uranium and tungstic acid.

SA'NDERS WOOD. The wood of the *Pterocarpus Santalinus*, a large tree growing upon the Coromandel coast and in other parts of India, especially Ceylon. It furnishes a deep red resinous colouring matter.

SANDYX. (Gr. Σανδυξ.) An old alchemical term applied to red lead prepared by calcining carbonate of lead.

SA'NTONINE. A crystalline principle contained in the *Artemisia Santonica*, the buds or broken peduncles of which plant are used in pharmacy under the name of *worm seed: Semen Cinæ*, or *Contra.* The composition assigned to santonine is $C_{30} H_{18} O_5$.

SA'RCOSINE. (Gr. σαρξ, *flesh.*) A basic substance obtained by boiling kreatine with hydrate of baryta. Its formula is $C_6 H_7 O_4 N$.

SARGA'SSO. *Fucus natans* or Gulf Weed, spread over a large part of the Atlantic. Its abundance has led to the Portuguese expression *Mar de Sargasso*, or Weedy Sea.

SA'TELLITE. The recent discovery of an eighth satellite in the system of Saturn may be regarded as the natural consequence of the increased optical power of the instruments now applied to astronomical observations, but it was by a singular chance that the discovery was made both in England and America on the very same day, — the 19th of September, 1848.

In order to avoid the confusion which has arisen from the practice of designating the satellites of Saturn by numbers, applied sometimes with reference to the order of discovery and sometimes to the order of distance, Sir John Herschel proposed to distinguish the individuals of this system by names, and in conformity with the nomenclature adopted by him (the names of the Titanian divinities), both discoverers of the new satellite gave it the name of Hyperion. Commencing with the one nearest the planet, and taking them in the order of distance, the names of the eight satellites at present known are as follows.—

Mimas, Enceladus, Tethys, Dione,
Rhea, Titan, Hyperion, Iapetus.

Of these bodies Titan is by far the largest, and supposed to be nearly equal in size to the planet Mars. Mimas and Enceladus are the two discovered by Sir W. Herschel, interior to the ring, and so small that they can be seen with great difficulty even in the best telescopes. Hyperion is probably not greater than Mimas, but more easily seen on account of its greater distance from the planet. Prior to its discovery the interval between Titan and Iapetus was so great as to destroy the analogy which seemed to prevail in the other cases, and to leave, as it were, a large gap in the system, similar to that in the solar system between Mars and Jupiter before the discovery of the small planets. From this circumstance, and also from the smallness of Hyperion, Sir J. Herschel has surmised the probability of other minute satellites revolving at the same mean distance.

Of the six satellites of Uranus seen or suspected by Sir William Herschel, the existence of two only has been confirmed by the observations of other astronomers. Some others have been seen by Lassell and by Otto Struve; but none of them appear to be identical with those observed by Sir W. Herschel. The remaining two are still doubtful.

One satellite of Neptune has been repeatedly observed, both by Lassell and O. Struve. The existence of a second, suspected by Lassell, has not yet been verified.

SATURA'TION. In Chemistry, a fluid is said to be saturated with a substance when it holds as much of it in solution as it can take up and retain: we thus speak

of *saturated solutions* of saline, and other bodies. The term *saturation* is also especially applied to the combination of acids and alkaline or other basic bodies, in such definite proportions as neutralise each other; thus we say that sulphuric acid is saturated by potassa, when neither acid nor alkaline properties are predominant: hence, also, the resulting sulphate of potassa is called a *neutral salt*. An excess of acid would be termed *supersaturation*.

SATURATION, FRACTION OF. The term *Fraction of Saturation* is used to denote the ratio of the elastic force of the vapour actually existing in the atmosphere, to the elastic force of as much vapour as atmospheric air is capable of containing in an equal volume and at the same temperature, or as would *saturate* the air.

SCA'LPRIFORM. (Lat. scalprum, *a knife*.) Certain teeth are so called, which have a cutting edge, preserved by a partial deposition of the enamel on one side: such scalpriform teeth are large, long, and curved, and are well exemplified in the incisors of the Rodent order.

SCA'RBROITE. Hydrated silicate of alumina from the vicinity of Scarborough.

SCE'LOTYRBE. (Gr. σκελος, *the leg*, and τυρβη, *disturbance*.) A disease described by Galen, in which a man is incapable of walking straight forward, and drags the foot: it is generally regarded as a species of Chorea, or St. Vitus's dance.

SCHE'RERITE. A mineral hydrocarbon found in beds of brown coal in Switzerland.

SCHRO'TTERITE. A hydrated silicate of alumina from Freienstein in Styria.

SCHU'LZITE. An antimonial sulphuret of lead from Gallicia in Spain.

SCHWEINFURTH GREEN. A compound of arsenious acid and oxide of copper, much resembling Scheele's Green.

SCLE'ROGEN. The ligneous matter deposited in the cells of plants.

SCO'LEZITE. A species of zeolite.

SCOU'RING DROPS. The essential oils of lemon and of bergamotte are sold under this name, for the purpose of removing grease stains from silk dresses. They are generally adulterated with oil of turpentine.

SCREW PROPELLER. An instrument for the propulsion of vessels, consisting of two or more twisted blades, like the vanes of a windmill, set on an axis running parallel with the keel, and revolving beneath the water at the stern. The screw propeller is driven by a steam engine situated within the vessel, and by its revolution in the water it carries the vessel forward in the manner a cork-screw is drawn forward when penetrating a cork, or a bolt when turned round in a stationary nut. The water in which the vessel floats forms the nut of the screw propeller; and when the propeller is turned round, therefore, the vessel is screwed on. To enable the water to act as the nut of the screw, the thread traced in the water requires to be very much deeper than if it were traced in metal or wood, and the pressing surface of the screw requires to be large, to prevent the thread from being stripped or broken by the reacting force. Accordingly, screw propellers are made with a small central body and deep thread; they are also made as large in diameter as possible, reaching, usually, from the keel to near the surface of the water.

History of the Screw Propeller. — It appears probable that the screw propeller is as old as the windmill; and a windmill of the construction now usually employed is represented in the 77th proposition of Hero's Spiritalia, a work written 130 years before the Christian era. In China screw propellers are said to have been employed from a very early date as an arrangement for sculling vessels; and a screw is a continuous sculling machine, in which the necessity of a reciprocating motion is superseded by giving a complete revolution to the propelling blade. Captain Basil Hall, in his account of his voyage to Loo Choo, states that the Coreans scull their ships instead of rowing them; and, from what he saw of the operation, he is inclined to give the preference to that mode of propulsion. The galleys of the Greeks and Romans were also propelled by an action of the oars more nearly resembling sculling than rowing, as was first pointed out by Robert Hooke in 1684; and Hooke also showed that this mode of action would be exceedingly efficient. In a work entitled *Philosophical Collections*, printed for Richard Chiswell, printer to the Royal Society, 1681, there is a paper by Hooke on Horizontal Windmills, containing various suggestions of great originality and importance. Hooke says that he does not consider horizontal windmills to be as efficient as vertical windmills; but if they are in any case employed, it will be advisable, he says, to make them on a certain construction, of which he gives a representation, and which is almost identical in its main features with the most improved species of feathering paddle wheel now employed in steam ships. Hooke adds, that wheels of this kind may be set to work advantageously, as water wheels in a river where no dam can be made, as may also the common vertical windmill with twisted arms. In this cursory suggestion we have the germ both of the screw propeller and feathering paddle wheel. Robertson Buchanan admits having taken the idea of his feathering wheel from the mechanism of orreries which was invented by Hooke; and the same considerations which make the screw and feathering wheel eligible instruments when driven by the water equally hold when the water is driven by them.

On the 14th of October, 1683, Hooke showed to the Royal Society an instrument he had invented for measuring the velocity of the wind. It consisted of four vanes, like the vanes of a windmill, set upon an axis, and the vanes were so constructed that they could be set at any angle that was desired. On the 28th of November, in the same year, Hooke showed to the Royal Society an instrument he had contrived, and had shown to some of the members twenty years before, for measuring the way of a ship through the water. The prime mover of this instrument was a screw turned by the water, and the instrument not merely took cognizance of the progress of the vessel through the water, but also of the lee way. The plan of making gearing in steps, as is now usually done in such screw vessels as make use of gearing, is also an invention of Hooke's. Wheels made upon this principle are divided in the direction of their breadth into a number of parallel wheels, which are set a little in advance of one another, so that the teeth of each do not come in the same line. The benefit of this practice is that the teeth, though necessarily very thick to give adequate strength, work as smoothly as if they were thin and small, or as if the space between the teeth were only a fractional part of its actual amount.

In the *Recueil de Machines approuvées par l'Academie, depuis* 1727 *jusqu'au* 1731, there is a machine described, which was invented by M. Du Quet, for dragging up barges against a current in a river by the aid of a screw driven by the water, and by the screw thus driven a rope, dragging the barges, is to be wound up. This screw, which is a helical blade wound upon an axis, is only partially immerged in the water, and it would be a much less effectual instrument than the screw of a windmill form previously recommended by Hooke. In Bouguer's *Traité du Navire*, published in Paris in 1746, an arrangement of revolving oars, resembling the vanes of a windmill, is mentioned as having been proposed for the propulsion of vessels; but this expedient, it is stated, had not been found to possess sufficient force. In 1752 Daniel Bernouilli obtained the prize offered by the French Academy of Sciences for the communication of the best project for impelling vessels without the aid of the wind. Bernouilli's apparatus consisted of an iron axle, 14 feet long and 2 inches thick, set upon each side of the vessel beneath the water. Each axle was to carry eight wheels, six feet diameter, set at equal distances from one another, and each wheel was to have eight arms or spokes, to the extremity of each of which a sheet-iron plane 16 inches square, and inclined so as to form an angle of 60° with the axle or keel of the vessel, was to be affixed. Bernouilli's plan appears to have been contrived to meet Bouguer's objection, and it would probably answer for towing, but the revolution of such a large number of wheels in the water would in all cases of considerable speed occasion a serious loss of power from friction and other analogous causes.

In Emerson's *Principles of Mechanics*, published in 1754, we have an explanation of the mode of constructing screws with an expanding or increasing pitch. Emerson describes an arrangement of screw set vertically in a well or stationary cylinder, as an instrument for rendering available a fall of water in giving motion to mills. The water is admitted at the top of the cylinder and escapes at its base, and in its descent it turns round the screw by which the cylinder is filled up. Emerson explains, that at the top of the cylinder the blade of the screw must have very little inclination with the axis, but at the bottom of the cylinder the blade of the screw must have a considerable inclination with the axis. Blades set in a conical pit or vessel, and driven round by the gravity of water, have long been in use in France, under the name of Danaïdes, or *roues à poires*; and in some cases the blades were merely plane surfaces suitably inclined, while in other cases they were spiral or screw-formed. Instruments of this kind are described by Belidor in his *Architecture Hydraulique*.

In 1768 a work on the Archimedean screw was published at Paris by M. Paucton; and it is suggested that a ptérophore, composed of the circumvolution of the thread of a screw round a cylinder, should be placed on each side of a vessel to propel her through the water, or one only may be used at the fore part. These screws, it is stated, may be either wholly or partially immersed. In 1776 a submarine vessel was invented by D. Bushnell, an American, which was to be raised upward or

sunk downward in the water by means of an inclined blade or oar affixed to the top and operating in the manner of a screw, and forced forward or backward in the water by another similar blade affixed to the bow. This vessel was to carry a powder magazine, which was to be screwed to the bottom of an enemy's ship to blow her up. It was the original of Fulton's torpedo.

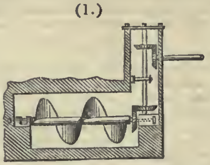
In 1784 Joseph Bramah, of London, engineer, obtained a patent for propelling vessels by means of a wheel with inclined fans or wings, similar to the fly of a smoke-jack or the vertical sails of a windmill. This wheel was to be fixed to an axis passing out at the stern of the vessel, and was to revolve beneath the water with a stuffing box, or proper packing surrounding the shaft, where it pierces the vessel, to prevent the water from entering. In 1794 William Lyttleton, a merchant of London, obtained a patent for an instrument which he called an "aquatic propeller," and which consisted of a single convolution of a three-threaded screw. The thread of a screw is the projecting part of it, and a screw may have one, two, three, or any other number of threads. A string wound round a cylinder represents the thread of a screw: and if one string only be wound round it, the screw will be a screw of one thread; if two strings be wound round it, so as equally to divide the space, the screw will be a screw of two threads; and so of any number. If, instead of a string, a thin ribbon of iron be wound edgeways upon the cylinder, and be soldered thereto, then a slice cut off the end of this screw will have two projecting arms or portions of this ribbon, if the screw be one of two threads; three projecting arms, if of three threads; and so of any other number. In any screw propeller, therefore, the number of threads is the same as the number of arms. The pitch of the screw is the distance from one thread of the screw to the next thread measured on the axis, supposing the screw to be continued through a whole convolution. A spiral stair is virtually a screw; and the pitch is the vertical distance from any one step of the stair to the step immediately over head.

In 1799 Edward Shorter, of London, mechanic, obtained a patent for propelling vessels, and among the expedients he employed is one termed a "perpetual sculling machine," consisting of a screw immerged in the water at the stern of the vessel. The shaft, which gives motion to the screw, passes through the stern of the vessel above the level of the water, and is armed at its extremity with one of Hooke's universal joints, from whence a pole extends obliquely into the water with the screw attached to its extremity. The end of the pole is prevented from sinking too deeply in the water by a buoy which supports it at the proper elevation, and guy ropes are applied, by means of which the pole and screw may be moved to the one side or the other, so that the vessel may be steered, or assisted in her steerage, thereby. Between 1800 and 1836 various arrangements of screw propellers were proposed by Dallery, Stevens, O'Reilly, James, Trevithick, Boswell, Millington, Scott, Whytock, Delisle, Bourdon, Dollman, Perkins, Brown, Tredgold, Maceroni, Cummerow, Smith, Church, Copley, Ovinel, Peltier, Salichon, Poole, Woodcroft, Sauvage, Emerson, Burke, Theal, Smith, and Fitzpatrick. The forms of these screws are very various, but in most cases they consist of helical blades, like the vanes of a windmill, revolving beneath the water at the stern, or of a helical feather coiled round an axis, in the manner of an Archimedean screw. In some cases the pitch of the screw is intended to be uniform, and in other cases increasing, the uniform pitch being a straight line wound upon a cylinder, and the increasing pitch being a curved line wound upon a cylinder, or a straight line wound upon a cone or spire. Bourdon, in 1824, formed his screw with an increasing pitch, and placed it in the dead wood of the vessel. Tredgold, in his work upon the Steam Engine, published in 1827, recommended that screws should be made with an increasing pitch. Peltier, in 1830, proposed to make his screw with an increasing pitch, and Woodcroft proposed the same thing in 1832. Marestier, in 1824, in a work published by direction of the French government, giving an account of steam navigation in America, described various arrangements of screw propellers which had been tried in that country, but none of those expedients had come into practical operation. Lyttleton in 1794, Shorter in 1802, Stevens in 1804, Bourdon in 1824, and several others at different times, had practically tried the effect of propelling vessels by means of a screw. But these experiments led to no useful result, and in 1836 there was no vessel propelled by a screw in existence. In that year patents for propelling vessels by a screw were taken out by F. P. Smith and Captain John Ericsson; and to these two persons the successful introduction of the screw as a propeller must be attributed. Ericsson, not meeting with the encouragement in this country that he expected, went to America, where he soon after constructed the war steamer Princeton, and about two hundred screw vessels have since been built in America. Smith, as soon as his early trials had demonstrated the efficacy of the screw as a propeller, built the Archimedes, and soon afterwards his propeller was applied to the war steamer Rattler. It has subsequently been applied to about fifty war steamers and a very large number of merchant steamers. In by far the greater proportion of these vessels the screw is only applied as an auxiliary to the sails, and at present this appears to be its most valuable application.

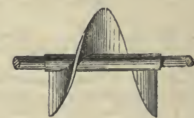
It would swell these remarks beyond the limits to which they must be restricted to attempt any enumeration of the various modifications in the form of the screw, and in the mode of its application, which have been made or proposed since the time it has been practically introduced as an available propeller. In this country vessels are, for the most part, fitted with Smith's screw of two or three threads. In America, and in France, vessels are mostly fitted with Ericsson's screw of four or six threads. The average efficiency of both is about the same, but screws of few threads appear to be best adapted for sharp and swift vessels, or which are much immersed in the water; whereas in the case of heavy vessels of shallow draught screws of many threads appear to be the most suitable. For vessels with auxiliary power, of good form and considerable immersion, a screw with three blades appears to be, upon the whole, the best propeller that can be employed.

In Smith's earlier experiments upon the screw propeller he employed a single-threaded screw of two convolutions, such as that represented in *fig.* 1. During one of his trials, however, the screw having come in contact with some object in the water, about half of it was broken away, and the vessel was found in consequence to realise a higher speed than before. The Archimedes was originally fitted with a single-threaded screw of one convolution, such as that represented in *fig.* 2.; and it

(1.)



(2.)



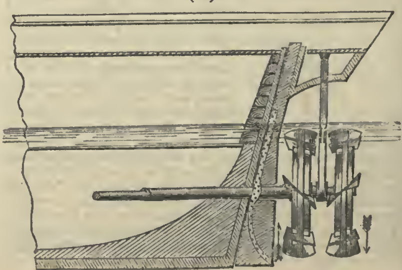
was with a screw of this kind that the efficiency of the screw as a propeller was originally demonstrated. She was subsequently fitted with a double-threaded screw of half a convolution, which gave the same amount of propelling surface, and diminished the uneasy motion at the stern. This screw is represented in *fig.* 3. The Rattler was fitted with a screw of this kind, but its length was subsequently reduced to one-sixth of a convolution, which made its length just one-third of its original length, and the best results were obtained with this proportion. This amended screw of the Rattler is shown in perspective in *fig.* 4.

(3.)

(4.)

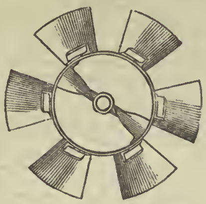
Ericsson, in his original form of propeller, employed two wheels armed with helical blades and revolving in opposite directions. The object of this arrangement was to neutralise any tendency which one wheel might have to turn the vessel from her appointed course. The second wheel, however, was soon discarded, as it was found that it was not required. *Fig.* 5. represents Ericsson's original arrange-

(5.)



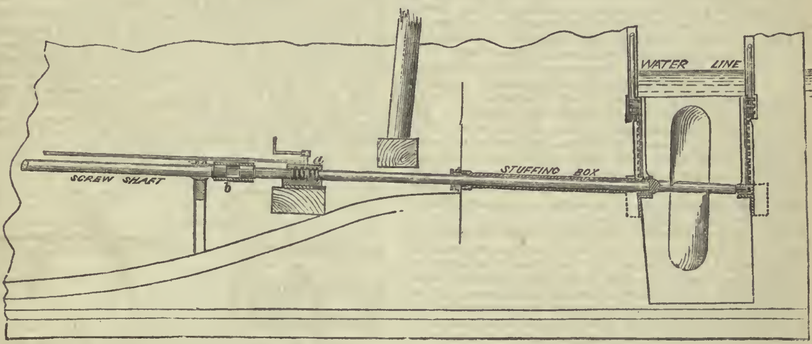
ment of screw propeller, and *fig.* 6. is the propeller of the Princeton, which is the form he now usually employs.

(6.)



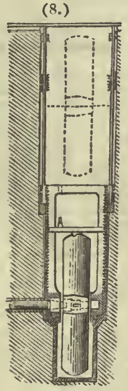
Description of the mode of applying the Screw Propeller. — The most approved method of introducing the screw propeller into a vessel will be seen by a reference to *fig.* 7., which is a section of the stern portion of H. M. S. Wasp. The screw is set in a hole or opening in the dead wood behind the stern post, and before the rudder post. It is hung upon a short shaft, which is carried by a metal frame with a rack on each side, and in these racks endless screws work, which, being put into revolution, raise the frame, lifting the propeller out of the water, so as to enable the screw to be repaired if required, or a new one introduced without putting the vessel into dock. Before, however, the frame can be raised, the shaft, passing through the ship, and which communicates with the engine, has to be pulled on end, so as to disengage it from the boss of the short shaft, which supports the screw. This is accomplished by the handle *a*, by means of which an end motion is given to an adjoining bearing, in which work a number of collars formed on the shaft, the brass of the bearing being suitably grooved to receive these collars. At *b* a vacant space is left between the end of the shaft which communicates with the engine, and the end of the shaft which communicates with the screw, so as to enable the shaft communicating with the screw to be drawn on end without disturbing the other shaft; and a short pipe fixed to the one shaft, but sliding on

(7.)



the other, is so applied that, notwithstanding the end play, the force of torsion will be communicated from the one shaft to the other. *Figs.* 8. and 9. represent the screw propeller and the apparatus for raising it out of the water, as applied in Her Majesty's steam frigate Ajax. By a reference to these figures the configuration of the screw usually employed for the service of the navy, and the mode of raising it out of the water, will be readily understood. A catch represented as engaging the centre of the screw is put down only when the screw requires to be raised out of the water, and its use is to retain the blades in a vertical position during that operation.

(8.)

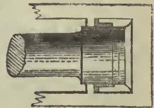


(9.)

The screw shaft at the point where it passes through the stern of the vessel is kept tight by means of a stuffing-box, consisting of a long pipe fitted tightly into the hull of the vessel. Through this pipe the screw shaft passes, and the space between the shaft and the pipe is kept tight by means of a plaited rope of soft hemp forced tightly into a recess provided for the purpose by means of screws. It is very desirable that the shaft should fit so accurately into this pipe as to be exempt from all side play, which, if it exists, will have the effect of communicating a disagreeable motion to the stern of the vessel. In wooden vessels the pipe should be made of brass; and it has been found advantageous in such cases to cover with brass that part of the shaft which revolves within the pipe, so as to obviate corrosion from the sea-water. In all cases the extremity of the vessel in advance of the screw should be brought to as fine a line as possible, and the hole in the dead wood in which the screw revolves should be considerably larger than the screw itself. The screw in its revolution carries with it a coating of water, and if this coating be partially stripped off at every revolution from the too near proximity of the stern part of the vessel, a shock will be communicated at every revolution, from the impact of the water against the side of the dead wood, and a part of the engine power will be also dissipated without effect.

Modes of receiving the Thrust of the Screw. — As the screw by its revolution is forced forward in the water, carrying the vessel with it, the screw shaft, it is clear, must have to sustain a forward thrust, and it is this thrust in fact which propels the vessel. The severity of this forward thrust, combined with the velocity of rotation which the screw shaft requires to maintain, was the occasion, in the earlier screw vessels, of considerable inconvenience, in consequence of the friction produced; and several cases have occurred where the end of the shaft became white hot, and actually welded itself to the steel plate against which it pressed, although a stream of water was all the while running upon the surfaces in contact. Various expedients have since that time been proposed for receiving the thrust, of which one was to let the end of the shaft enter, in the manner of a piston, a tight cylinder of oil, so that it would be against a liquid only that the end of the shaft would press. Another expedient was to place a large collar upon the shaft, which should press against a number of balls or small rollers resembling the rollers of a swivelling bridge. Neither of these plans, however, have come into practical use; but one of two other modes is now generally followed. Either the thrust is received upon a number of collars, as represented in *fig.* 7., before described, or else it is received upon a series of discs applied to the end of the shaft, and resting in a cistern of oil, as represented in *fig.* 10. The cistern is usually cast upon the base plate or some other solid part of the engine, and its end is sufficiently strong to bear the thrust of the screw. Interposed, however, between the end of the cistern and the end of the shaft are two, three, or more discs of metal, usually about two inches thick, and of the same diameter as the shaft itself. A bolt passes through their centres to keep them in a line, but they

(10.)



are each free to revolve upon this bolt; and where the shaft passes out of the cistern a collar of leather is applied, to prevent the oil from escaping. It will be obvious from such an arrangement that if the end of the shaft where it presses upon the discs begins to heat from undue friction, it will revolve with somewhat more difficulty, and will consequently carry the first disc round with it. The rubbing surfaces, therefore, are no longer the end of the shaft and the first disc, but the first disc and the second disc. In fact, the rubbing surface, instead of being confined to one disc, is distributed over several. Those surfaces which begin to heat, and consequently to stick, will cease to rub, whereby they will speedily become cool again, and their efficiency will thereby be speedily restored.

Best Proportions of Screw. — For mercantile purposes screws with three blades are, on the whole, to be preferred. The diameter of the screw should be as large as it can be conveniently got, and when the area of the screw's disc — that is, the area of the circle described by the extremity of the arms of the screw — has one square foot of area for every $2\frac{1}{2}$ square feet in the area of the immerged midship section of the vessel, a very efficient performance is obtained. The pitch of the screw should be equal to the diameter of the screw, or a little more, and the length of the screw fore and aft should be that answering to one-sixth of a convolution. Thus in the case of a screw twelve feet in diameter, the pitch would be twelve or fourteen feet, and the length of the screw measured along the axis would be about two feet.

Best Forms of Screw. — Screws are commonly made with a uniform pitch, and with the blades standing at right angles with the axis. A slightly progressive increase in the pitch, however, say to the extent of 5 per cent., appears to be advisable — that is, the pitch of the screw at its leading end should be 5 per cent. less than at its following end. The pitch at the centre should also be 10 per cent. less than the pitch at the circumference, for the centre should merely screw through the water without seeking to produce any reacting force, which, from the great obliquity of the blades at the centre, could not be done with advantage. Finally, the blades of the screw should be bent a little astern, so as to produce a tendency in the particles of water they force backwards to converge to a point. This tendency will balance the divergent tendency produced by the centrifugal action of the screw in its revolution, and the two forces, by balancing one another, will cause the water to be projected backwards from the screw in a cylindrical column. With the ordinary screw the water projected backwards assumes the figure of the frustum of a cone, and some portion of the power is lost thereby.

Positive and negative Slip of the Screw. — When a vessel is propelled by oars, paddles, or any other instrument which acts upon the water, it is obvious, that since the water is not a solid body which can resist without disturbance the application of force, there will be a certain amount of recession in the water, or, in other words, the water will be moved to a certain extent backwards, while the vessel is forced to a certain extent forwards. This backward movement of the water is what is termed *Slip*, and in its results it is analogous to the loss of power and speed which a locomotive experiences when the wheels slip upon the rails. This slip exists in the case of the screw as well as in the case of the paddle or other species of propeller; and when the engines of a steam vessel are set in motion while the vessel is at anchor or moored in a river, the whole power of the engines is wasted in slip, or in moving the water without moving the vessel. The ordinary amount of slip in paddle vessels is about one-third of the whole distance travelled, or, in other words, the vessel would go one-third faster with the same number of revolutions if the wheels geared into an iron rack instead of gearing into water. In well-constructed paddle vessels the slip is only 10 per cent., or, in other words, the vessel would only go one-tenth faster with the same number of revolutions if the screw worked in an iron nut instead of working in water. Since, therefore, all the power expended in producing slip is lost, and since there is less slip with the screw than the paddle, there is an apparent superiority in the screw from this cause. In some screw vessels, however, the apparent slip is nothing at all, and in others it is less than nothing, or, in other words, the vessel is propelled through the water by the screw alone at a greater velocity than if the screw worked in a solid nut with the same number of revolutions. In the early history of the screw propeller this apparent paradox provoked much incredulity, but the phenomenon is now understood, and is not difficult of explanation.

When a vessel passes through the water, the friction of the bottom and the sides puts a column of water in motion which proceeds in the direction of the vessel. Sea-weeds and other light objects adhering to a vessel have been observed to stand out straight from her side when the vessel was moving through the water with a considerable velocity, whereby it is clear that a film of water must be moving with the vessel. The vacuity also which the motion of the vessel through the water tends to produce at the stern causes a flow of water towards the stern in order to fill it up. It follows, therefore, that a vessel, in passing through the water, puts in motion a stream or current which follows in her track; and that this is no hypothetical supposition is proved by the fact that a boat will often follow a vessel without being towed by a rope, and that when a slow steamer gets into a swift one's wake the slow steamer will not fall into the distance, but will be towed by the current which the leading steamer creates. Now in a screw vessel the screw works in this current; and if from the form of the stern or other causes the current runs at a considerable velocity, and if from the large dimensions of the screw or otherwise the actual slip of the screw be small, then it will often follow that the slip of the screw will *appear* to be less than nothing, or negative, if the comparison be made not with the current, but with the stationary water at the ship's side. The screw must at all times have slip *relatively with the water in which it works;* but if that water is itself in motion, it is not surprising that the vessel should travel through a greater distance than what answers to the pitch and revolutions of the screw, any more than that a paddle vessel in descending a river with a strong current should pass through a greater distance than what answers to the diameter and revolutions of the wheel, if the distance travelled be measured on the river bank. A log placed where the screw revolves will always show that the screw advances with a greater velocity than the vessel as measured at that point, or, in other words, that the screw passes through the current with a greater velocity than the vessel passes through the current, though of course the speed of the vessel and of the current together may be greater than the speed of the screw alone.

Measure of the Thrust upon the Screw Shaft, and Amount of Power lost by Slip. — In some vessels a dynamometer has been applied to the end of the screw shaft, whereby it has become possible to measure accurately the amount of forward pressure exerted by the screw. In the Rattler, a vessel of 888 tons burden, this pressure amounted, on an average, to about four tons. This pressure, multiplied by the space passed through by the vessel per minute, and divided by 33,000, will manifestly give the force in actual horse power that is instrumental in the propulsion of the vessel, and the power thus computed amounts, on an average, to about half or two-thirds the power developed in the cylinders. It hence appears, that in screw vessels such as the Rattler from one-third to one-half of the engine power is wasted in slip and in the friction or other resistances caused by the revolution of the screw in the water. With the paddle wheel the loss from these causes is nearly the same, and the screw and paddle consequently produce about the same speed by the application of the same amount of power.

Relative Efficiency of the Screw and Paddles. — To determine the relative efficiency of the screw and paddle as a propeller, two vessels, the Rattler and the Alecto, were constructed of about the same power, 200 horses, and of nearly the same size and form; but the Rattler was a screw vessel, and the Alecto a paddle vessel. The Rattler, it was found, had, in nearly all cases, somewhat the advantage in point of speed, but the engines of the Rattler also exerted somewhat more power. Subsequently two other vessels, the Niger and Basilisk, were constructed of 1072 tons, and 400 horse power, the Niger being a screw vessel, and the Basilisk a paddle vessel, and the following were the results obtained: — In deep immersions the screw vessel had an advantage of $1\frac{1}{2}$ per cent. over the paddle vessel, but with medium immersions the paddle vessel had an advantage of $1\frac{3}{4}$ per cent. over the screw vessel, and in light immersions the paddle vessel had an advantage of $4\frac{3}{4}$ per cent. over the screw vessel. The slip of the screw was 24 per cent. Upon the whole, therefore, the screw seems to have somewhat the advantage when the vessel is deep, and the paddle seems to have somewhat the advantage when the vessel is at a light or medium immersion.

Screw Vessels not adapted to go Head to Wind. — The experiments with the Rattler and Alecto established one important fact in connection with screw vessels, viz. that they are ill-adapted to advance against a head wind. For, although both vessels attained the same speed of 4 knots against a strong head wind, yet, in the case of the Alecto, this performance was attained with a velocity of the engine of 12 strokes per minute; whereas, in the Rattler, it was only attained with a velocity of the engine of 22 strokes per minute. It follows, therefore, that a screw vessel in proceeding head to wind will require 1·8 times, or nearly twice the quantity of fuel to do the same amount of work. The screw, in fact, revolves at nearly the same velocity whether the wind is adverse or favourable, or whether the vessel

is lying at anchor; and this is a serious defect in the case of vessels intended to encounter adverse winds. In the case of vessels, however, which use the screw only as a resource in calms, or as an auxiliary to the sails, this disadvantage will not be experienced, since such vessels have no pretensions to the capability of proceeding in direct opposition to a strong head wind.

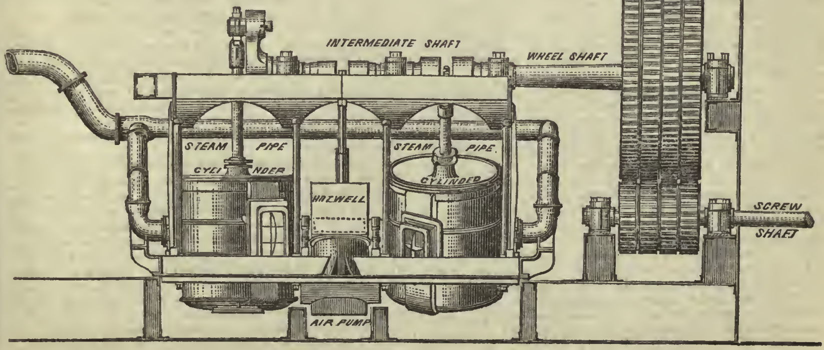
Paddle and Screw Vessels tied Stern to Stern.—In all cases where screw and paddle vessels of equal power and size have been tied stern to stern, the screw vessel has preponderated, and towed the paddle vessel so soon as the engines were set on. When the Rattler and Alecto were tied together in this manner, the Alecto's engines were set on first, and she was allowed to tow the Rattler at the rate of 2 knots an hour. The Rattler's engines were then set on. In five minutes the two vessels became completely stationary. The Rattler then began to move ahead, and towed the Alecto against the whole force of her engines, at the rate of 2·8 knots per hour. In like manner the Niger towed the Basilisk astern, in opposition to the force of her engines, at the rate of 1·1 knots per hour. The natural inference from this experiment would be that the screw is more suitable for towing than the paddle; yet this inference is not confirmed by experiment. For, when the Niger and Basilisk were each set to tow the other alternately, in the usual manner in which a steamer tows a ship, it was found that the Niger towed the Basilisk at a speed of 5·63 knots, with 593·9 horse power, and that the Basilisk towed the Niger at the rate of 6 knots, with 572·3 horse power. The paddle vessel, therefore, accomplished in towing the largest speed with the least power. It has also been found that when a paddle and screw vessel set stern to stern push one another instead of pulling one another, the paddle vessel preponderates, whereas, if they pull, the screw vessel preponderates. These circumstances seem to show that the power of a screw vessel to tow a paddle vessel astern, when the two are tied together, does not arise from any superior tractive efficacy of the screw itself, but is due to the centrifugal action of the screw, which raises the level of the water at the stern, so that the vessel gravitates down an inclined plane.

Cause of the serrated Outline of the Dynamometer Diagram.—In those screw vessels which have had a dynamometer applied to the end of the shaft the thrust of the screw was made to act upon a spring, and a pencil in connexion with the shaft marked a line upon a revolving cylinder, which line was either high up on the cylinder, or low down, as the thrust of the screw increased or diminished. The line thus traced, instead of being tolerably uniform and straight, was found to be serrated, like the teeth of a saw; and, on further investigation, it was discovered that every time the screw, in its revolution, brought the blades into the vertical position, and therefore into a line with the stern post, at that moment the thrust was increased. This phenomenon appears to be due to the circumstance of the water immediately behind the stern post being carried forward with nearly the same velocity as the vessel itself; and when the screw comes into that dead water, as it is termed, it is no longer a reaction answering to the *difference* of speed of the screw and vessel that it has to encounter, but a reaction answering to nearly the *whole* speed of the vessel. If such a reaction had to be encountered through the whole revolution of the screw, the velocity of its rotation would be necessarily diminished until the reacting pressure produced was balanced by the pressure on the pistons of the engine. But the momentum of the machinery and of the screw itself momentarily carries up the thrust to a higher point than that due to the pressure on the pistons. If a screw vessel be reversed until she attains full speed astern, and be then suddenly changed to full speed ahead, it will be found that a dynamometer diagram taken at that point at which the vessel is stationary in the water, from the effort to overcome her own momentum, will have a straight, and not a serrated line.

Importance of making the Stern of Screw Vessels very sharp and fine.—The preceding remarks will have very clearly indicated the importance of making screw vessels as sharp as possible at the stern; but the following facts may be stated in corroboration of the propriety of such a configuration:—In 1846 the Dwarf, a screw steam vessel, with a fine run, was filled out in the stern by the application of three successive layers of planking, so as to alter the shape to that of a vessel with a full run. Prior to the alteration the speed of the vessel was 9·1 knots per hour, the engines making 32 revolutions per minute. The effect of the filling was to reduce the speed to 3·25 knots per hour, with a speed of the engine of 24 revolutions per minute. One layer of filling was then taken off, and the speed rose to 5·75 knots per hour, the engines making 26·5 revolutions per minute. When the whole of the filling was removed the speed rose to 9 knots, as before. Care was of course taken in this experiment to bring the filling into conformity with the lines of the vessel, so that there should be no roughness or abruptness to aggravate the evils of a full run. Again, the Sharpshooter and Rifleman were sister vessels of 486 tons, and 200 horse power, but the Rifleman was made with a full run, and the Sharpshooter with a fine run. The speed of the Rifleman was found on trial to be 7·9 knots, and of the Sharpshooter 9·9 knots. The Minx and Teazer were sister vessels of about 300 tons and 100 horse power, but the Teazer was made with a full run, and the Minx with a fine run. The speed of the Teazer was found to be 6·3 knots, and of the Minx 7·8 knots. The sterns of both the Rifleman and Teazer were sharpened subsequently to these trials, and the 100 horse engines of the Teazer were at the same time put into the Rifleman, while new engines of 40 horse power were put into the Teazer. Both vessels went faster than before. The Rifleman, when sharpened at the stern, attained a speed of 8 knots with engines of 100 horse power, whereas she had before only attained a speed of 7·8 knots with engines of 200 horse power. The Teazer, when sharpened at the stern, attained a speed of 7·685 knots with engines of 40 horse power, whereas she had before only attained a speed of 6·3 knots with engines of 100 horse power. The engines of the Teazer when transferred to the Rifleman drove that vessel nearly 2 knots an hour faster than they had previously driven the smaller vessel, an amelioration consequent altogether upon the sharpened form of the stern.

Engines for driving the Screw.—It will be obvious, on looking to the pitch of an ordinary screw, and the speed with which the vessel passes through the water, that the screw must revolve with a considerable velocity. For example, if a vessel be driven 10 miles an hour, or 880 feet per minute, by a screw of 12 feet pitch, then the screw must make somewhere more than the twelfth part of 880, or 73 revolutions in the minute. This is a much higher speed than marine engines have been heretofore accustomed to travel at, and two methods of obtaining the necessary velocity of rotation have been adopted. In the one the construction and

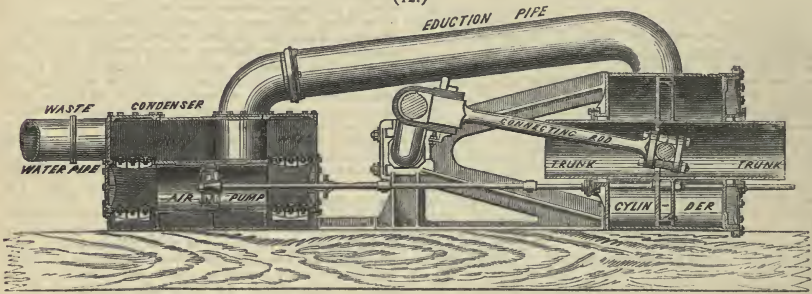
(11.)



speed of the ordinary engine have been retained without material alteration, and the required velocity of revolution has been given to the screw shaft by means of intervening gearing. In the other case a new arrangement of engine has been introduced which is capable of moving with a much greater velocity than ordinary engines, and the engine and screw shaft are directly connected with one another. *Fig.* 11. represents a pair of geared screw engines, being the engines constructed by Messrs. John Penn and Son for the Great Britain. These engines are on the oscillating principle, which Messrs. Penn have rendered so celebrated, and they are almost identical in construction with the paddle engines made by Messrs. Penn for the Sphinx and other vessels. The Great Britain is of 3500 tons burthen, and her displacement, at 16 feet draught of water, is 2970 tons. The diameter of cylinder is 82½ inches, length of stroke 6 feet, nominal power 500 horses, diameter of screw 15½ feet, pitch of screw 19 feet, length of screw 3 feet 2 inches. The screw has three arms or blades. The multiple of the gearing is 3 to 1, and there are 17½ square feet of heating surface in the boiler for each nominal horse power of the engine. The crank shaft, being put in motion by the engine, carries round the great cog wheel or aggregation of cog wheels affixed to its extremity, and these wheels acting on suitable pinions on the screw shaft cause the screw to make three revolutions for every revolution performed by the engine.

Fig. 12. is a representation of a pair of direct-action screw engines, being the engines constructed by Messrs.

(12.)



John Penn and Son for H. M.'s screw frigates Arrogant and Encounter. Here the cylinders lie in a horizontal position, and are traversed through the centre by a pipe or trunk, upon which the piston is cast. The central trunk is circular, and it projects through both the top and bottom of the cylinder, the points of penetration being made tight by suitable packing. One end of the connecting rod is attached to the centre of the trunk, while the other end engages the crank, which turns round the screw shaft. The air-pump, which also lies in a horizontal position, is double-acting, and is situated within the condenser. A large pipe, called the eduction pipe, leads the steam from the cylinder to the condenser, where it is condensed by a jet of cold water, and the hot water thence resulting is ejected by the air-pump through the waste water pipe, and passes overboard. In the figure only one cylinder and one air-pump is represented, but it will be understood that there are two cylinders and two air-pumps. The valves by which the water is admitted to the air-pump from the condenser, and passes again from the air-pump into the hot well and waste pipe, consist of several discs of indian-rubber, kept down by a central bolt so as to cover radial slits or orifices in a perforated plate. These valves are found to operate without noise or shock, notwithstanding the high speed at which the engine must work in order to give motion to the screw without intervening gearing. The diameter of the cylinder in the Arrogant and Encounter is 60 inches, and the diameter of the trunk 24 inches, which, being deducted, leaves an available area of piston equal to that of a piston 55 inches in diameter. In the Arrogant the length of stroke is 3 feet, and in the Encounter 2 feet 3 inches. The nominal power of both engines is 360 horse. The diameter of the screw of the Arrogant is 15 feet 6 inches, and the diameter of the screw of the Encounter is 12 feet. The pitch of both is 15 feet, and the length 2 feet 6 inches. The Arrogant is a vessel of 1872 tons burden, and the Encounter of 953 tons. Both the engines and boilers are kept below the water-line, so as to be out of the reach of shot.

The forms of engine, both geared and direct-acting, for giving motion to the screw, are too numerous to be here described. But in most war vessels the cylinders are placed upon their sides, so as to keep the engines below the water-line. In merchant vessels a form of engine like the land beam engine, with the cylinder at the one end of a beam and the connecting rod at the other — the connecting rod extending downwards from the end of the beam to give motion to the crank — is frequently employed. In other cases the cylinder is inverted, and a connecting rod proceeds from the end of the piston rod to turn the crank, the end of the piston rod being, of course, steadied by suitable guides. Upon the whole, a construction of engine resembling that of the Arrogant and Encounter appears to be the best for driving the screw, but perhaps it might be preferable if the trunk were put into the air pump instead of into the cylinder. The condenser also might be dispensed with, and the condensation be performed in the air pump, — the flow of water *to* which and *from* which might be governed by a slide valve of a construction similar to that employed to regulate the admission and escape of the steam from the cylinder. It appears probable that slide valves will come into use for regulating the flow of water to and from pumps of every kind; but in the case of ordinary pumps for raising water those valves need not be like common slide valves, — which, in fact, do not seem well adapted to give sufficient area for such purposes, but they may consist of short wide cylinders with gridiron orifices revolving slowly at the top and bottom of the pump.

Screw Vessels with Auxiliary Power. — We have already stated that screw vessels, intended to go head to wind and to contend against head seas, are not so efficient as paddle vessels, inasmuch as they require more coal to do the same work. Under the conjoint influence of sails and steam, however, they are under most circumstances as efficient, and, if deeply laden, are more efficient. A screw vessel, being divested of paddle boxes, partakes more of the character of a sailing ship; nevertheless, from the experiments with the Niger and Basilisk, it does not appear that a screw vessel is more efficient under sails than a paddle vessel, although such a result might naturally be expected. The advantages incident, therefore, to the use of screw vessels with auxiliary power do not result from any superiority of the screw as a propeller, nor from the increased facilities which it presents for the application of sails, but are to be ascribed to the large employment in screw vessels of wind power, which costs nothing, instead of steam power, which costs much, and also to the maintenance of lower rates of speed than are thought necessary in paddle vessels. The screw, indeed, is a less cumbrous propeller than the paddle, and, in consequence of the high speed of engine which it permits, a very considerable engine power will go into a small compass. Upon the whole, therefore, the screw for all purposes of auxiliary propulsion is much to be preferred; nevertheless, it is right to understand that its superior eligibility is not due to any greater efficiency than the paddle as a propeller, either in a calm or under sail, but only to the greater convenience in the application of auxiliary steam power which its employment affords.

Comparative Expense of conveying Merchandize in a Paddle Vessel of full Power, and in a Screw Vessel of auxiliary Power. — For the purposes of this comparison, we may take a paddle vessel of 1000 tons burden and 350 horses power, and a screw vessel of 300 tons (old measurement) and 50 horses power—each performing a voyage of 500 miles. The paddle vessel would perform the voyage in about 45½ hours, carrying 400 tons of cargo, exclusive of her machinery and coals. The screw vessel would perform the voyage in about 62 hours, carrying 400 tons of cargo, exclusive of her machinery and coals. Each vessel would make one double trip weekly, or 104 single trips per annum. The first cost of the paddle vessel

would be about 40,000*l.*; the first cost of the screw vessel would be about 10,000*l.* In the paddle vessel the wages and the scale of the expenses altogether would be larger than in the screw vessel, which would partake more of the nature of a coasting ship. The following is an approximate estimate of the expense of each:—

PADDLE VESSEL.

	Per Annum. £	Per Trip. £ s.
Wear and tear 10 per cent. on 40,000*l.*	4,000	96 3
Depreciation 5 per cent.	2,000	
Insurance 5 per cent.	2,000	
Interest 5 per cent.	2,000	
	10,000	

	Per Month. £ s.	Per Trip. £ s.
Commander 25*l.* per month, and 6*s.* per day victualling	33 8	26 11
Two mates, first 7*l.* and second 4*l.* per month, and 3*s.* 4*d.* per day	22 4	
Two quarter-masters 3*l* per month, and 1*s.* 6*d.* per day victualling	10 4	
Ten seamen 2*l.* 10*s.* per month, and 1*s.* 6*d.* per day victualling	46 0	
Carpenter 5*l.* per month, and 1*s.* 6*d.* per day victualling	7 2	
Three apprentices 16*s.* per month each, and 1*s.* 6*d.* per day	8 14	
Eleven firemen and trimmers 3*l.* per month, and 1*s.* 6*d.* per day	56 2	
Two engineers, first 12*l.* per month, second 8*l.*, and 3*s.* 6*d.* per day	28 16	
Wages and victualling per month	212 10	

SCREW VESSEL.

	Per Annum. £	Per Trip. £ s. d.
Wear and tear 10 per cent. on 10,000*l.*	1,000	24 0 9¼
Depreciation 5 per cent.	500	
Insurance 5 per cent.	500	
Interest 5 per cent.	500	
	2,500	

	Per Month. £ s. d.	Per Trip. £ s. d.
Captain 16*l.* per month, and 5*s.* per day victualling	23 0 0	11 6 9
Mate 4*l.* per month, and 3*s.* 6*d.* per day	8 18 6	
Six seamen 2*l.* 10*s.* per month, and 1*s.* 6*d.* per day	27 12 0	
One apprentice 16*s.* per month, and 1*s.* 6*d.* per day	2 18 0	
One engineer 8*l.* per month, and 3*s.* 6*d.* per day	12 18 6	
Three firemen and coal trimmers 3*l.* per month and 1*s.* 6*d.* per day	15 6 0	
Wages and victualling per month	90 13 0	

PADDLE VESSEL.

	Per Trip £ s. d.
Wear and tear, depreciation, &c.	96 3 0
Wages and victualling	26 11 3
Coal, 60 tons at 15*s.*	45 0 0
Oil and tallow	5 0 0
Port charges, light dues, &c.	19 0 0
Sundry ships stores	7 0 0
Expense per trip of paddle vessel	198 14 3

SCREW VESSEL.

	Per Trip. £ s. d.
Wear and tear, depreciation, &c.	24 0 9¼
Wages and victualling	11 6 9
Coal, 15 tons at 15*s.*	11 5 0
Oil and tallow	1 0 0
Port charges, light dues, &c.	8 0 0
Sundry ships stores	5 0 0
Expense per trip of screw vessel	60 12 6¼

Thus it appears that it will cost 198*l.* 14*s.* 3*d.* to transport 400 tons of merchandize through a distance of 500 miles with a full-powered paddle vessel, and that it will cost only 60*l.* 12*s.* 6½*d.* to transport the same merchandize through the same distance with a screw vessel of auxiliary power. The average speed of the paddle vessel would be 11 miles per hour, and the average speed of the screw vessel would be 8 miles per hour.

Comparative Cost of carrying Merchandize in Screw Vessels and in Sailing Ships.— By carrying an investigation similar to the foregoing into the case of sailing ships, so as to determine the cost of conveying a given quantity of merchandize per annum through any given voyage by their instrumentality, as compared with the cost of carrying the same merchandize through the same voyage by the instrumentality of screw vessels, it will be found that the screw vessels will do the work at the least expense, or, in other words, that a given sum of money, if invested in screw vessels, will yield larger returns than the same sum of money invested in sailing ships, and this irrespective altogether of any benefit or preference which may fairly be expected from the increased speed. Mr. Laming states, in his evidence before the committee of the House of Lords on the slave trade, that he had had the management of a line of sailing vessels between London and Rotterdam which were at length superseded by screw vessels, after having been in existence for 25 years; that, taking the three sailing vessels, the Hope, the London, and the Alkmaar, by which, before the establishment of the screw vessels, the communication had been maintained, the average cost of carrying a ton of merchandize, from one terminus to the other, was 1*l.* 12*s.* 5½*d.* With the screw vessels, however, the City of London and the City of Rotterdam, the average cost of conveying the same quantity of merchandize through the same distance was, on an average of ten voyages, only 19*s.* 6*d.*; so that the screw vessels not merely maintained a superior speed, but did the same work at about one-third less expense.

Conditions to be observed in the Construction of Screw Vessels.— The whole of the superior eligibility of screw vessels for the conveyance of merchandize, whether compared with paddle vessels or sailing ships, is not due to the action of the screw itself or to the use of steam power. Much, probably most, of it arises from the superior form of vessel which has been simultaneously introduced, and by which the sails have been rendered much more efficient than heretofore in urging the vessel through the water. And the main conditions necessary to the satisfactory performance of screw vessels lie in making the form of the vessel sharp and fine, in applying a large amount of sail power, and in keeping the screw well immersed in the water. Screw vessels should be broad at the water line, so as to enable them to bear the pressure of a large amount of sail and the sails should be as flat as possible, and be laced to the spars, so as to enable the vessel to go as near as possible to the wind. The rigging of all vessels is still in a most defective state. It is without any provision whatever for using up the power of the wind in an effectual manner, and a large proportion of that power is consequently lost. Under suitable arrangements vessels would be able to sail directly against the wind, instead of having to tack, as is at present the practice; and there is every reason to believe that before many years, expedients for this purpose, and for obtaining from a given force of wind and area of sail a much larger propelling effect, will be practically applied.

For further information respecting the screw propeller, see a *Treatise on the Screw Propeller*, by John Bourne, C. E., from which the engravings and most of the information given in this article have been extracted.

SEED LAC. The substance called Gum Lac in a granulated form. *See* LAC, in DICT.

SELBITE. A name given to native carbonate of silver.

SE'NSORY. The term appears to have been first applied by Hartley to those nerves which convey a stimulus to the neural axis or nervous centres with which they are connected, in contradistinction to the nerves that convey a stimulus from the neural axis to the muscles. "The actions of sneezing, swallowing, coughing, hiccoughing, vomiting, and expelling the fæces and urine" are to be deduced "from those vibrations which first ascend up the sensory nerves and then are detached down the motory nerves, which communicate with these by some common trunk, plexus, or ganglion." — *On Man*, vol. i. p. 97. This class of motions or vibrations, now called "reflex," Hartley distinguishes from those produced by the transmission of the sensory vibrations to the brain, where they produce "sensation," and excite "volition;" and the nerves producing the "first and fourth classes of motory vibrations of Hartley's system" have been recently asserted to be anatomically distinct from those that produce sensational and volitional vibrations. The distinction has not been recognised, and anatomists apply the term "sensory" to those parts of the neural axis with which the sensory nerves are connected, as, *e.g.* the posterior columns of the myelon, the optic lobes, the thalami and the corpora striata, which are termed "sensory ganglions."

SE'RUM. (Lat. *whey.*) In Anatomy the constituent of the plasma, or liquor sanguinis, which remains after the separation and coagulation of the fibrin. Serum contains a quantity of albumen, and coagulates at a temperature of from 150° to 170°.

SE'THITES or SETHIANS. In Ecclesiastical History, a branch of the Ophites, a sect of the family of the Gnostics. They are said to have believed that Seth, the son of Adam, appeared again in the person of the Messiah. (*Mosh.* vol. i. cent. 2.)

SE'VERITE. A hydrated silicate of alumina found in nodules in the gravel of St. Sever in France.

SHA'LLOT. The *Allium Ascalonicum* of Linnæus. It possesses the flavour of garlic, but less pungent.

SHEAR STEEL. A kind of steel made by welding several bars together, and again drawing them out. It

is used for clothiers' *shears*, and many other cutting instruments. *See* STEEL, in DICT.

SHELL LIMESTONE. *See* GEOLOGY.

SHOEMAKERS' BLACK. *Atramentum sutorium.* A name given by Pliny to sulphate of iron, or green vitriol, from the circumstance of its being used to rub over tanned leather, to which it communicates a black dye.

SI'BBENS. A disease endemic in some of the western parts of Scotland, somewhat resembling the yaws, and propagated by direct application of the contagious matter.

SI'DERITE. (Gr. σιδηρος, *iron.*) Sparry iron ore. Native carbonate of iron.

SIDE'ROSCOPE. (Gr. σιδηρος, *iron*; σκοπεω, *I view.*) An instrument for detecting minute degrees of magnetism in substances usually supposed to be non-magnetic, — the name having reference to the hypothesis that the traces of magnetism so detected are due to the presence of atoms of iron. The apparatus proposed by Lebaillif, in which the object is accomplished by means of a very delicate combination of magnetic needles, is described by Pouillet, *Elemens de Physique*, and by Sir D. Brewster, *Treatise on Magnetism*, in the *Encyclopedia Britannica*.

SIGAU'LTIAN OPERATION. The division of the *symphysis pubis*, for the purpose of increasing the capacity of the pelvis in cases of impracticable labour. It was first performed by a French surgeon of the name of Sigault, but is now discarded.

SIGNATURE. In Printing, a letter or letters of the alphabet placed at the bottom of the first page of each sheet of a book, to denote the order of the sheets, and to guide the bookbinder in folding and arranging them. Sometimes figures are used, but seldom, except in America.

SILICATES. (Lat. silex.) Compounds of silica with certain bases: thus we have silicates of lime, magnesia, oxide of iron, &c. amongst minerals; and silicate of *lead* is an important ingredient in flint glass.

SI'LICITE. (Lat. silex.) A silicate of alumina and lime from Antrim in Ireland.

SI'LVANITE. Auriferous and argentiferous ore of Tellurium.

SILVER GLANCE. A mineralogical synonym of the vitreous sulphuret of silver.

SI'LVIC ACID. A name applied to that portion of common rosin or colophony, which is most readily soluble in cold alcohol. Its combinations with salifiable bases have been termed *silvates*. It is crystallisable, and its alcoholic solution reddens litmus.

SI'NOPITE. The *Sinopian earth* of the ancients. A hydrated silicate of alumina and iron from Asia Minor.

SITO'LOGY. (Gr. σιτος, *aliment*; λογος, *a discourse.*) *Dietetics*, or the doctrine of aliments.

SKU'TTERUDITE. The arsenuret of cobalt found in mica slate at Skutterud, near Modum in Norway.

SLATE SPAR. A variety of calcareous spar of a shining white pearly lustre and greasy feel, found at Wicklow in Ireland, in Glentilt in Scotland, and in Norway.

SLEET. Rain mixed with hail or snow in small particles. It falls during gales or in squally weather, and chiefly in spring and autumn, when the temperature of the air at a small height above the earth is below the freezing point. M. Kaemptz considers gusts of wind to be a necessary condition for the formation of sleet.

SLIDE-REST. An apparatus adapted to a turning-lathe for carrying the tool, and which by means of screws is made to move or *slide* along the frame of the lathe so as to bring the tool successively to the different parts of the work. The advantages obtained by the slide-rest are extremely important, particularly in reference to the construction of machinery, where extreme accuracy is requisite, both in respect of the size and form of the work. The tool being fixed to the rest, and adjusted by screws, its distance from the axis about which the work revolves can be regulated with the utmost precision, while a degree of steadiness is secured which is altogether unattainable when the tool is simply held in the hand.

SLO'TTING MACHINE. A machine for grooving metal surfaces.

SMALL WARES. A commercial term applied to tape, bindings, braid, and other textile articles of that kind.

SMA'RAGDITE. (Gr. σμαραγδος, *emerald.*) A variety of hornblende.

SMILA'CINE. (Lat. smilax.) A crystallisable principle obtained from Sarsaparilla root.

SMI'THSONITE. A variety of calamine, or native carbonate of zinc, from Somersetshire and Derbyshire, analysed by Smithson.

SNAKE WEED. The great Bistort, *Polygonum bistorta.* The root is *twice bent* on itself, hence the name. This root contains starch, which renders it nutritive; hence, in Siberia, it is roasted and eaten.

SO'CIALISM. The science of reconstructing society on entirely new bases, or the substitution of the principle of association for that of competition in every branch of human industry. *See* RIGHT OF PROPERTY and SAINT SIMONIANS in DICT. The best account of the innumerable modifications of which this principle has been made susceptible, from Rousseau down to Proudhon, will be found in Karl Grün's work entitled "Soziale Bewegung."

SOLA'NO. A hot wind, or species of sirocco, prevailing at certain seasons, in Spain and Portugal.

SOLAR PHOSPHORI. Substances which are seen to be luminous in a dark place after having been exposed to light.

SO'LVENT. In Chemistry, the liquid in which a solid is dissolved. The substance dissolved is sometimes distinguished as the *solvend*.

SO'MERVILLITE. A mineral found in the ejected blocks on Vesuvius, named after Mrs. Somerville.

SORDAWA'LITE. A mineral of the hornblende family, being a silicate of alumina, iron, and magnesia, with about 3 per cent. of phosphoric acid. It occurs in thin veins in the trap rocks of Sordawala in Finland.

SOU'JEE. A species of Semolina; it is a granular preparation of wheat deprived of bran.

SOURKROUT, or SAUERKRAUT. Fermented cabbage. The plants are collected in autumn, divided, the stalks removed, and the leaves cut into slices, a layer of which is placed in a vat alternating with a layer of salt till the vessel is full, when it is subjected to the action of heavy weights placed on the whole. At the end of about six weeks, when the acetous fermentation is complete, it is considered fit for use. The method of cooking it in Germany is simply to stew it in its own juice with bacon, pork, or other fat meat: dill, caraway seed, and other carminatives, are occasionally added. Sauerkraut is not fitted for persons troubled with acidity of stomach; it has a slight relaxing effect on the bowels. As an antiscorbutic it has long been celebrated, and was highly spoken of by Captain Cook. (PEREIRA *on Diet.*)

SOWANS, or SOWINS. The husk and some adhering starch separated from oats in the manufacture of oatmeal are sold, says Dr. Christison, under the inconsistent name of *seeds*; these, if infused in hot water and allowed to become sourish, yield, on expression, a mucilaginous liquid, which, on being sufficiently concentrated, forms a firm jelly, known by the name of Sowins. A similar preparation from groats or oatmeal is called *flummery*.

SPANISH CHALK. A variety of steatite or silicate of magnesia. It is also called *French chalk*.

SPECIFIC HEAT. In Physics, denotes the ratio of the quantity of heat entering into or passing out of a given weight of any substance, to the change of temperature thereby produced. For instance, if the unit of heat be assumed to be that quantity of heat which is necessary to melt a pound of ice at the temperature of 32° of Fahrenheit, then assuming n to denote the number of pounds of ice necessary to cool down a body whose weight is one pound from t to t', the specific heat of the body is $n \div (t-t')$. Hence if $t-t'=1°$, the specific heat is denoted simply by n.

It is found by experiment that, provided a body does not change its state (as from solid to liquid), the above ratio remains constant, or nearly so, through a considerable range of temperature; but it varies greatly in respect of different substances. Thus a pound of water absorbs thirty times more heat than a pound of mercury in being heated the same number of degrees, and consequently, the specific heat of water is thirty times greater than that of mercury. It is usual to express the specific heats of different substances in terms of that of water assumed equal to 1000; the specific heat of mercury thus becomes 33.

SPEISS. An impure arsenuret of nickel, obtained from the ores of cobalt and nickel in smalt-works.

SPELDINGS. A Scotch term for dried and salted whitings.

SPERMATO'A. (Gr. σπερμα, *seed*; ωον, *egg*). The cells which stand in the relation of nuclei to the sperm cells, and of developmental cells to the spermatozoa. Sometimes the sperm-cell contains a single spermatoon, sometimes several spermatoa, in which case the resulting spermatozoa often unite together and form a fasciculus, as, *e.g.* in the sparrow.

SPERMATO'PHORA. (Gr. σπερμα, and φερω, *to carry.*) In Anatomy, cases of albuminous matter, in which the bundles of spermatozoa are packed: they are largest and most complex in the Cephalopods.

SPERMATOZO'A. (Gr. σπερμα, and ζωον, *animal.*) The filamentary bodies developed in the semen, and consisting of an enlarged extremity called "body," and a vibratile filamentary appendage, called "tail." Spermatozoa consist of an amber-coloured, highly refracting homogeneous substance, like the hyaline nucleus of cells, and are formal modifications of the nucleus of the spermatoon. They are essential to impregnation.

SPERM-CELL. In Anatomy, the cells contained in the liquor seminis, in which are formed the spermatoa, or cells of development of the spermatozoa.

SPHE'ROSIDE'RITE. (Gr. σφαιρα, *a globe*, and σιδηρος, *iron.*) A name given by Hausmann to a granular variety of spathose carbonate of iron.

SPIKENARD. The spikenard of the ancients appears to have been the *Nardostachys satamansi*, the root of which is highly esteemed at the present day throughout the East as a perfume, and as a stimulant medicine. The plant is a native of the mountainous parts of the north of India.

SPINAL CHORD or CORD. *See* MYELON.

SPINAL MARROW. The division of the neural axis lodged in the vertebral column of the trunk. *See* MYELON.

SPIRÆ'A ULMARIA. (Lat.) Meadow Sweet. The essential oil of this plant has been produced artificially by the oxidizement of salicine, and has been termed *spiroylous acid*. Its chemical formula is $C_{14}\ H_5\ O_3 + H\ O$.

SPUNK. A species of Agaric or fungus; the *Polyporus*, or *Boletus igniarius;* called also Touchwood. Cut into thin slices and beaten till soft, it has been used as a styptic to check hæmorrhage; it is also used, when soaked in a solution of nitre, for kindling matches and tobacco, under the name of *amadou*, or *German tinder*.

SPURGE, or SPURGE OLIVE. The *Daphne Mezereon*. All parts of this plant, but especially the fruit and the bark, are very acrid and poisonous; it is used as a sudorific and alterative in medicine, and is sometimes applied externally as an irritant.

SQUA'LUS. (Lat.) In Ichthyology, the Linnæan generic designation of the shark tribe.

SQUIRTING CUCUMBER. The *Momordica elaterium.* When the fruit or *pepo* is ripe it separates from the stalk and expels its seeds and a thin mucous juice with considerable violence through the remaining aperture. The acrid purgative, known in pharmacy under the name of *elaterium*, is deposited by this juice.

STANDARD MEASURES OF LENGTH. A standard-bar measurer of very refined construction was produced by Messrs. Whitworth and Co. at the Great Exhibition of 1851. The machine consists of a metal frame, at each end of which is placed a micrometer. These micrometers, by means of a combination of screws and wheels, will measure small differences of length corresponding respectively to the one-millionth and the one-five-thousandth part of an inch. The bar to be measured is carried in a steel groove on the upper part of the frame, a parallel-sided piece of metal at the right-hand end forming a perfectly flat contact for measurement, and the other end abutting against the left-hand micrometer.

The determination of the exact contact for the measure of length can be made either by a *gravitation test* or a *galvanic test*. In the former the experimenter moves the end of the screw of the right-hand micrometer through one division of the head, corresponding to one-millionth of an inch, and, carefully raising the contact-piece, lets it fall by its own gravity; and he repeats this operation till the approach of the screw prevents the contact-piece from descending. In the galvanic test, a small battery composed of a piece of copper and zinc soldered together and immersed in rain water, is connected with the micrometer, and also with a delicate galvanometer by means of covered wires, the bar to be measured being insulated from the machine. The contact is in this case indicated on completing the circuit by the deflexion of the needle of the galvanometer.

STAR. The recent researches of Sir J. Herschel, Argelander, Struve, Peters, and others, have led to some very remarkable views relative to the distances, magnitudes and number of the stars, and their distribution in space.

Distance.—Although it is a very improbable supposition that all the stars are of the same size, it is equally improbable that their real magnitudes are in any way dependent on their distance from the sun; but unless this latter supposition be made, we must conclude that *on the average* (putting individual cases out of view), the most distant will be those which have the smallest apparent magnitude.

Argelander, of Bonn, has given a catalogue of the stars visible to the naked eye, in which they are divided into six orders of magnitude; the faintest stars, or those just perceptible by the naked eye, being considered as the smallest of the sixth magnitude. If we suppose six concentric spheres to be described about the sun, with radii such that the first contains all the stars of the first magnitude, the second all those of the first and second magnitude, the third all those of the three first magnitudes, and so on; and if we also suppose the *mean* distance of the stars of the first magnitude to be unity, then, according to the computation of Struve (founded necessarily on certain hypothetical assumptions respecting the distribution of the stars in space), the mean distance of the stars of the different orders of magnitude, and the radii of the spheres circumscribing them, as above supposed, are as follows: —

Magnitudes.	Mean Distance.	Radius of Sphere.
1	1·0000	1·2638
2	1·8031	2·1408
3	2·7639	3·1961
4	3·9057	4·4374
5	5·4545	6·2093
6	7·7258	8·8726

For stars of the three next magnitudes, the data for computing the relative distances have been furnished by Bessel's zone observations. Struve finds the radii of the circumscribing spheres to be as follows: For those of the seventh magnitude 14·4365 units; for those of the eighth 24·8445; of the ninth 37·7364; and lastly, he concludes that the smallest stars observed by Sir William Herschel with his twenty-foot reflector are at an average distance of 227·8 units, or 25·67 times more distant than the smallest stars visible to the naked eye. (*E'tudes d'Astronomie Stellaire*, p. 81.)

It is usual to express these almost inconceivable distances in terms of the time which light—propagated at the rate of 192,000 miles in a second—takes to traverse them. The average parallax of stars of the first magnitude has been computed by Peters to be 0″·209. (*See* PARALLAX, in SUPPL.) Now if a star has a parallax of 1″, its distance is 206,265 times the distance of the sun from the earth (for radius : sin. 1″=206265 : 1), and the time which light takes to traverse this distance is about 3 years and 83 days, or $3\frac{1}{4}$ years; therefore the time which light takes to come from a star whose parallax is 0″·209,—that is, to traverse a distance equal to the average mean distance of a star of the first magnitude, which has been assumed as the unit of the above scale,—is 15·4 years; to come from the remotest star of the sixth magnitude, 137 years; from the remotest of the ninth magnitude, 580 years; and from the remotest star visible in Herschel's twenty-foot reflector, 3500 years. (*E'tudes*, p. 106.)

Number of visible Stars.—As no limit can be set to the distance to which the stars may extend in space, the number of visible stars is limited only by the powers of the telescope. But the direct enumeration is beyond human power, and in order to obtain an approximation, it is necessary to have recourse to hypothetical considerations. By a very ingenious investigation, founded on the numbers ascertained by Sir W. Herschel to exist within certain limited spaces, Struve has attempted to compute the whole number in the heavens within the range of the twenty-foot reflector, which, as stated above, is 227·8 times that of the distance of stars of the first magnitude. He first establishes a law of diminution depending on the angular distance from the plane of the galactic circle (*see* GALAXY), and having ascertained the mean number visible in a field of the telescope in that plane, he finds, by a process of integration, the whole number in the celestial vault to be 20,374,034, or upwards of twenty millions. Whether this number be near or far from the truth, it must be taken as the most probable estimate yet made. (*E'tudes*, p. 72.)

If we confine our attention to stars visible to the naked eye, the number may be estimated with greater precision. The number of stars of the several magnitudes, in the northern hemisphere, contained in Argelander's catalogue, is as under: —

Magnitudes	1	2	3	4	5	6
Stars in each	9	34	96	214	550	1439
Sums	9	43	139	353	903	2342

Assuming the *density* to be the same in the southern hemisphere as in the northern, the catalogue should contain 4684 stars. It is estimated by Struve, that the number entered in the catalogue is to the whole number existing (and visible to the naked eye) within a given space, in the ratio of 8136 to 10,000. Hence the whole number of stars which can be seen with the naked eye is 5757, or less than 6000. Sir J. Herschel remarks that the whole number of stars already registered, down to the *seventh* magnitude inclusive, amounts to from 12,000 to 15,000.

Apparent Magnitudes.—The method of estimating the apparent magnitudes usually adopted is by a scale of brightnesses decreasing in geometrical progression, each term being half of the preceding, or at least having a fixed ratio to it. Sir J. Herschel proposes and recommends the adoption of a scale decreasing as the squares of the terms of an harmonic progression, namely, the series 1, $\frac{1}{4}$, $\frac{1}{9}$, $\frac{1}{16}$, $\frac{1}{25}$, &c. This scale is not a purely photometric one, like the former, but involves the physical idea of supposing the scale of magnitudes to correspond to the appearance of a first magnitude star removed successively to twice, three times, four times, &c. its original or standard distance; so that upon the supposition of an equality among the real lights of the stars, the nominal magnitude would be a sort of index to the presumable distance.

Real Magnitudes.—The only means we have of obtaining any indication respecting the real magnitudes of the

stars is by means of the quantity of light received from them. Sir J. Herschel compared the light of α *Centauri* directly with the moon, and from several experiments, made with attention to all the circumstances required to be taken account of, found that the mean quantity of light sent to the earth by a full moon exceeds that sent by α *Centauri* in the proportion of 27,408 to 1. Dr. Wollaston (*Phil. Trans.* 1829) found the proportion of the sun's light to that of the full moon to be that of 801,072 to 1. Combining these results, it appears that the light sent to us by the sun is to that sent by α *Centauri* as 21,955,000,000, or about twenty-two thousand millions to one. Hence, and from the parallax assigned to that star (0″·913), it is easy to conclude that its intrinsic splendour, as compared with that of the sun, is in the proportion of 2·3247 to 1. The light of Sirius is four times that of α *Centauri*, and its parallax is only 0″·230, if so much; its intrinsic splendour, therefore, according to these determinations, must be above sixty-three times (63·02) that of our sun. (Herschel, *Outlines of Astronomy*, p. 553.)

STAR ANISE. The fruit of *Illicium anisatum*, an evergreen growing in Japan and Cochin China: the seeds have the odour of common anise, and yield, when distilled with water, an oil sometimes called *Oleum badiani*, which is used by liqueur makers.

STA'VESACRE. The *Delphinium staphysagria.* The seeds of this plant are emetic and purgative, in consequence of the presence of *Delphinia*, a very acrid bitter principle, which, in the dose of a few grains, excites a sense of heat and tingling in various parts of the body. The disease in which it has been chiefly successful is neuralgia, in which it has been applied externally in the form of ointment.

STEAM HAMMER, for pile-driving. An ingenious machine invented by Mr. Nasmyth, now in general use in government and other large works. "It consists of a steam cylinder, closed at the bottom, but with openings in the top to allow the passage of air; a piston works in it, having its rod passing through a steam-tight aperture in the bottom. To the piston the monkey or driver, which weighs 2½ tons, is attached, and is thus suspended. The machine is worked by high-pressure steam, which being admitted at the bottom of the cylinder by the induction-pipe, raises the piston, and, with it, the monkey attached to it. The instant it arrives at the height required, it closes the induction-pipe, and, opening the eduction-pipe (also at the bottom of the cylinder), the steam escapes, and the piston, with the monkey attached to its rod, falls freely on the head of the pile. A large heavy cap of iron, with a hole to allow the head of the pile to pass through, slides between the upright standards, and guides the direction of the pile. The monkey and cylinder also follow the course of the pile, guided by the same uprights, between which they slide."

The saving of labour effected by this contrivance is very great. A stage, which carries the machine, boiler, workmen, and every thing necessary, moves along a railway. Having driven one pile, the machine moves onward the regulated distance; it then picks the next pile out of the water, hoists it high in the air, drops it into its exact place, then covers it with the great cap; the monkey immediately acts, giving at the rate of seventy-five blows in a minute. The whole operation of raising a pile from the raft, putting it in its place, and driving it to the required depth, occupies generally from two to four minutes. By the old method of pile driving, a comparatively light weight (about 12 cwt.) is made to fall from a great height, and the blows succeed at intervals of about five minutes. By the new machine a very heavy weight (about 50 cwt.) falls through a height of only three feet, and the blows are repeated seventy-five times in a minute.

The principle of this invention may be said to consist in the employment of a heavy weight moved with a small velocity, instead of a light weight moved with a great velocity. In a paper communicated to the British Association for 1841, Dr. Greene gave the following instance of the state of the heads of two piles, as driven by the two methods:—

"One was 56 feet long, driven by a monkey of 12 cwt. falling from a great height, and making only one blow in five minutes, and requiring twenty hours to drive it; this, though protected by a hoop of iron, was so split and shattered on the head, that it would require to be re-headed, to drive it any further. The other, though 60 feet long, was not even supported by an iron hoop, and the head is as smooth as if it were dressed off with a new plane. It was driven with a hammer of 50 cwt., and only three feet fall, making seventy-five blows in a minute, and was put into its place and finished in four and a half minutes."

STEI'NMANNITE. One of the mineralogical synonyms of the double sulphuret of lead and antimony.

STE'LLITE. A variety of zeolite crystallised in delicate rhombic prisms grouped in concentric stars, from Kilsyth, Scotland.

STEPHANITE. A mineralogical synonym of one of the varieties of brittle sulphuret of silver.

STEREO-ELECTRIC CURRENT. (Gr. στερεος, *solid.*) A term applied to the *thermo-electric* current which ensues when certain metals are brought into contact at different temperatures; it implies the production of a current of electricity in *solid bodies*, as opposed to the voltaic or *hydro-electric* current, in which fluids are essential.

STE'REOSCOPE. (Gr. στερεος, *solid;* σκοπεω, *I view.*) The name given by Professor Wheatstone to an instrument or apparatus proposed by him, and described in a paper on the Physiology of Vision, published in the *Philosophical Transactions* for 1838, for the purpose of exhibiting the effect of simultaneously presenting to each eye the projection of a solid body on a plane surface as it appears to that eye. To render this clear, it may be necessary to observe, that when a body of three dimensions is placed so near the eyes that, on looking at it, the optic axes must converge, a different perspective representation of it is seen by each eye; the body being, in fact, thus seen from two points of sight, at a distance from each other equal to the distance between the centres of the pupils, and the pictures of it projected on the two retinæ being consequently dissimilar. Supposing, then, two perspective drawings, on a plane surface, to have been made of an object as it is seen by each eye respectively; in order to try the experiment, it is necessary that the pictures be placed so that each can be seen by one eye only, and that the rays of light from the corresponding points of the two pictures fall on similar points of both retinæ, or enter the eyes in the same directions as the rays from the corresponding points of the original object. By reason of the small distance between the two eyes, this, manifestly, cannot be done without altering the direction of the rays. For this purpose Professor Wheatstone employed two small plane mirrors, about four inches square, adjusted at right angles to each other, so as to form two adjacent sides of a cube, the faces being outwards. The edge where the two planes meet being brought close to the face of the observer, and the mirrors being placed symmetrically with respect to the direction of the visual rays, it is evident that if the two pictures be respectively placed before the mirrors symmetrically, and at equal distances, rays of light proceeding from them in opposite directions, and falling on the mirrors, will be reflected at right angles to their former directions, and become parallel. The right eye will see only the reflexion of the picture on the right hand side, and the left eye that on the left hand side; but on regarding both simultaneously, the mind readily unites the two images, and instead of the two plane pictures, an object of three dimensions makes its appearance, the exact counterpart of that from which the pictures were drawn, standing out, as it were, in relief between the planes of the two mirrors.

In the Report of the British Association for the Advancement of Science, for 1849, Sir David Brewster states, that having had occasion to make numerous experiments on this subject, he was led to construct the stereoscope in several new forms. Of these forms, the most generally useful is the *Lenticular Stereoscope.* This instrument consists of two semilenses placed at such a distance that each eye sees the picture of a drawing opposite to it, through the margin of the semilens, or through points of it equidistant from the margin. The distance of the two portions of the lens through which we look must be equal to the distance of the centres of the pupils, which, at an average, is two and a half inches. By this method the images are not only united, but magnified at the same time, which is in many cases advantageous.

STERNBERGITE. The flexible sulphuret of silver and iron, named by Haidinger in honour of Count Sternberg. It occurs in Bohemia and Hungary.

STILBENE. (στιλβω, *I shine.*) A peculiar hydrocarbon, which crystallises in scales of a pearly lustre.

STILBITE. A pearly variety of zeolite.

STILPNOSIDERITE. (στιλπνος, *lucens;* σιδηρος, *iron.*) A native oxide of iron.

STIMMI. An ancient name of the sulphuret of antimony.

STIR-ABOUT. A moderately consistent mixture of oatmeal and water boiled, and generally eaten with cold milk, called Porridge in Scotland. When mixed with the thin liquor of boiled meat, or the water in which cabbage or kale has been boiled, it is called *beef brose*, or *kale brose*. (PEREIRA *on Diet.*)

STONE BLUE. A compound the basis of which is usually an impure starch, or mixture of starch and gluten, being the starchmakers' refuse, coloured either by indigo or Prussian blue. It is used in the laundry to cover the yellow tint of linen.

STRAWBERRY. The fruit of *Fragaria vesca.* Strawberries contain a very small quantity of nutritive matter. The grains or seed-like pericarps are not digestible, and sometimes excite intestinal irritation; so

that some physicians have directed their patients to suck strawberries through muslin.

STRETCHING MACHINE. Calicoes, and other similar textile fabrics, are prepared for the market by being stretched in a proper machine, which lays all their warp and woof yarns in parallel positions, and extends their width after the shrinkage occasioned by bleaching, dyeing, &c.

STROGA'NOWITE. (Named after Count Stroganoff.) A mineral found in loose blocks in the Slüdänka, a river of Dauria, of a greyish white colour, and slightly effervescent with acids; it is a silicate of alumina, soda, and lime, combined apparently with carbonate of lime.

STROMEY'ERITE. A mineral so named by Haidinger, after the Hanoverian chemist Stromeyer, who analysed it; it is a double sulphuret of silver and copper.

STRO'MNITE. A sulphate of baryta and carbonate of strontia: probably a mixture merely of the sulphate and carbonate, found at Stromness in Orkney. It occurs in yellowish-white translucent masses, with a slight pearly lustre, and crystalline cleavage.

STRU'THEINE. (Gr. στρουθος, *a kind of herb.*) A bitter acrid principle obtained from the root of *Gypsophila struthium.* It appears to be identical with *saponine*, obtained from the *Saponaria officinalis*, or soapwort.

STRU'VITE. A name (in honour of Struve) given to the crystallised ammonio-magnesian phosphate, found in peat earth, in digging the foundation of a church at Hamburgh.

STY'PHNIC ACID. (Gr. στυφνος, *astringent.*) An astringent acid compound obtained by the action of nitric acid upon certain gum resins. It is also called *Nitrostyphnic acid.*

STYRO'LE. (Gr. στυραξ.) An oily hydro-carbon obtained by distilling liquid storax. It is perfectly liquid, but has the curious property of becoming a soft viscid transparent solid when heated. In this state it has been called *metastyrole.* The formula of styrole is $C_{16}\ H_8$.

SUBSTITU'TION. In Chemistry, this term is applied to such results of affinity as are dependent upon the substitution of one or more atoms or equivalents of a simple or compound body, for the same number of atoms of another body. Thus, in the decomposition of water, which ensues when zinc is made to act upon dilute sulphuric acid, an atom of zinc is *substituted for* (or replaces) an atom of hydrogen, the latter being expelled. These changes are clearly shown by the aid of formulæ. Thus, in the above case,

$$H + S\,O_4 \text{ becomes } Zn + S\,O_4.$$

Another illustrative case of substitution occurs in the conversion of acetic into chloracetic acid, in which the 3 atoms of hydrogen belonging to the acetic acid are substituted by 3 atoms of chlorine:

$$\underbrace{C_4\ \ H_3\ \ O_3}_{\text{Acetic acid}} \text{ becoming } \underbrace{C_4\ \ \ Cl_3\ \ \ O_3}_{\text{Chloracetic acid.}}$$

In the same way in the formation of nitric ether, an atom of nitric acid is substituted for an atom of water:

$$\underbrace{C_4\,H_5\,O + H\,O}_{\text{Alcohol.}} \text{ becoming } \underbrace{C_4\,H_5\,O + N\,O_5}_{\text{Nitric ether.}}$$

SU'CCORY. Called also *Chicory*. The *Chicorium intibus* (*wild endive*). The root of this plant, which resembles a carrot, when cut into slices, dried, roasted, and ground into powder, is used for the adulteration of ground coffee. It has a somewhat burned flavour, a very little resembling that of coffee, but it yields a large quantity of a rich brown infusion, or decoction, with water. To detect the adulteration, sprinkle the suspected article upon the surface of some water in a jar or tumbler: if genuine coffee, it remains for a long time floating, scarcely tinging the water, and appearing greasy, or not easily wetted; whereas, if succory powder be present, it communicates a deep reddish-brown tint to the water, and portions of it soon sink to the bottom.

SUDORI'PAROUS GLANDS. (Lat. sudor, *sweat;* pario, *I produce.*) In Anatomy, the secreting organs of the sweat, which consist of a slender elongated blind glandular tube, coiled into a lobular form and imbedded in the subcutaneous fat, and continued thence in a spiral course to the cuticle, where it opens by an oblique pore.

SU'LFAMIDE. A crystallised compound obtained by the action of anhydrous sulphuric acid on ammonia. The compound resulting from the analogous combination of dry sulphurous acid on ammonia has been termed *Sulfimide.*

SULPHURA'TION. The process by which certain silk, cotton, and woollen goods are subjected to the fumes of burning sulphur, or sulphurous acid, for the purpose of decolouring or bleaching. The rooms or chambers in which the operation is conducted are often of considerable dimensions, and fitted with poles and frames, on which the blankets, shawls, and similar articles may be suspended. The straw used in the manufacture of hats is similarly bleached or sulphured.

SU'NSTONE. A resplendent variety of felspar, found in Norway and elsewhere. The play of colour which it exhibits arises from minute lamellar crystals of iron-glance which are embedded in it.

SUPRARE'NAL BODIES. (Lat. supra, and ren, *a kidney.*) In Anatomy, the flattened bodies situated on the upper part of the kidneys in man, and at the forepart in brutes: they are well supplied with blood-vessels and nerves, and are composed principally of simple or closed vesicles, resembling the secreting glands, except that they have no ducts. They are of disproportionately large size and the fœtal state in man and quadrumana.

SU'RINAMINE. A crystallisable principle obtained from the bark of the *Geoffroya Surinamensis*, or *Surinam bark.*

SWEETBREAD. The thymus gland of the calf is employed as food, under this name; it contains about 70 parts of water, and 30 of nutritious matter, chiefly of an albuminous character. "A fresh sweetbread when plainly cooked (by boiling) and moderately seasoned, forms a very agreeable and suitable dish, for the convalescent; but, when highly dressed, is improper both for dyspeptics and invalids." (PEREIRA *on Diet.*)

SYE'POORITE. A sulphuret of cobalt, found in primary rocks at Syepoor, near Rajpootanah, in North-west India. It is said that the Indian jewellers use it to give a rose colour to gold.

SYMBOLS, CHEMICAL. A chemical symbol is the representation of one atom or equivalent of each elementary substance by the capital initial letter or letters of its Latin name, it being necessary where the names of two or more elements begin with the same letter to add a second, in a smaller character, for the purpose of distinguishing between them. Thus, C, Cl, Ca, Cd, Co, Cu, Ce, Cr, are the symbols of Carbon, Chlorine, Calcium, Cadmium, Cobalt, Copper (Cuprum), Cerium, and Chromium, H and Hg are the symbols of Hydrogen and of Mercury (Hydrargyrum), O and Os of Oxygen and of Osmium, and so on. The following table enumerates, in alphabetical order, the simple or elementary substances, with their annexed symbols, and equivalents or atomic weights; that is, the respective *weights* of each of the elementary bodies which each symbol is assumed to represent upon the *hydrogen* scale, or in reference to hydrogen as unity:

	Atomic Weight.	Symbol.
Aluminum	14	Al.
Antimony (Stibium)	129	Sb.
Arsenic	75	As.
Barium	69	Ba.
Bismuth	106	Bi.
Boron	11	B.
Bromine	78	Br.
Cadmium	56	Cd.
Calcium	20	Ca.
Carbon	6	C.
Cerium	46	Ce.
Chlorine	36	Cl.
Chromium	28	Cr.
Cobalt	30	Co.
Copper (Cuprum)	32	Cu.
Didymium ?		Di.
Fluorine	19	F.
Glucinum	17	G.
Gold	200	Au.
Hydrogen	1	H.
Iodine	126	I.
Iridium	99	Ir.
Iron (Ferrum)	28	Fe.
Lanthanum	36	Ln.
Lead (Plumbum)	104	Pb.
Lithium	7	Li.
Magnesium	12	Mg.
Manganese	28	Mn.
Mercury (Hydrargyrum)	100	Hg.
Molybdenum	48	Mo.
Nickel	29	Ni.
Niobium ?		Nb.
Nitrogen	14	N.
Osmium	100	Os.
Oxygen	8	O.
Palladium	54	Pd.
Pelopium ?		Pe.
Phosphorus	32	P.
Platinum	99	Pt.
Potassium (Kalium)	40	K.
Rhodium	52	R.
Ruthenium	52	Ru.
Selenium	40	Se.
Silicium	15	Si.
Silver (Argentum)	108	Ag.
Sodium (Natrium)	24	Na.
Strontium	44	Sr.

	Atomic Weight.	Symbol.
Sulphur - - -	16	S.
Tantalum (or Columbium) -	185	Ta.
Tellurium - - -	64	Te.
Thorium - - -	60	Th.
Tin (Stannum) - -	59	Sn.
Titanium - - -	24	Ti.
Uranium - - -	60	U.
Vanadium - - -	68	V.
Wolframium (or Tungston) -	95	W.
Yttrium - - -	32	Y.
Zinc - - - -	32	Zn.
Zirconium - - -	23	Zr.

It will be understood that the above symbols represent a single atom or equivalent of each of the simple bodies, in reference to Hydrogen as *unity*. Thus, H represents 1 part by weight of Hydrogen; O, 8 parts by weight of Oxygen; S 16 of Sulphur; Hg, 100 of Mercury, and so on. It is evident, however, that, as far as the equivalents are concerned, other numbers or weights, bearing the same relations to each other, might be adopted: thus, upon the *oxygen* scale, oxygen is represented as = 100; in which case hydrogen is 12·50, sulphur 200, mercury 1250, and so on. But we shall confine ourselves exclusively to the hydrogen scale, which is now in most general use, and in all respects preferable to the more complicated numbers which the oxygen scale necessarily involves.

When two or more equivalents of one elementary substance are to be indicated, figures are placed either before or after the symbol. Thus, 2 equivalents (or *atoms*, for we use the terms synonymously) of iron may be represented by 2 Fe, or by Fe 2; in the former case a large, in the latter a small numeral being generally adopted. It is often customary to place this small numeral somewhat above or below the symbol, as Fe^2 or Fe_2, but there are inconveniences and no advantages attending this arrangement; and they give to these chemical symbols something of the character of algebraic symbols, with which they have little in common. Some writers have expressed two atoms of an element by drawing a line through its symbol; thus, 2 atoms of hydrogen are represented by $\not{H}$; 2 of sulphur, by $\not{S}$, &c.; but such abbreviations are inconvenient.

By a proper collocation of symbols, the *formulæ of compounds* are easily represented; thus, Cu O represents an atom of copper and an atom of oxygen in combination, that is, *protoxide of copper;* Fe O, protoxide of iron, &c. Sulphuric acid, which is a compound of 1 atom of sulphur with 3 atoms of oxygen, is represented by $S\ O_3$, and sulphate of protoxide of iron by $Fe\ O + S\ O_3$; or, more commonly, the symbol + is omitted in such cases, and a comma substituted, as $Fe\ O, S\ O_3$. It will be observed that this formula has reference to the assumed *proximate* constituents of the salt in question, and that if its ultimate elements only were intended to be indicated, the formula would stand thus, $Fe\ S\ O_4$. In many instances the plus sign and the comma are conveniently available in the same formula; thus, the double sulphate of potassa and oxide of iron may be written as follows: $K\ O, S\ O_3 + Fe\ O, S\ O_3$. Here the comma may be assumed as indicating a more intimate or higher order of combination than the plus sign, namely, that of the oxide and acid in each salt, while the union of the salts with each other is represented by the sign +.

In the preceding formulæ the figures only affect the symbol to which they are immediately appended. When they are intended to apply to the *entire compound*, they precede the symbol of the compound, and it is in such cases clearer to use large figures: thus, $3\ S\ O_3$ represents three atoms or equivalents of sulphuric acid, and 2 Cu O, two atoms of protoxide of copper. A salt containing *two* atoms of oxide of copper and *one* of sulphuric acid would be written as follows: $2\ Cu\ O, S\ O_3$, or $2\ Cu\ O, + S\ O_3$: in these cases the intervening comma or *plus* sign prevents the extension of the influence of the figure 2 beyond the oxide of copper, and if our object were to imply *two atoms of sulphate of copper*, we should inclose all that is to be affected by the figure 2 within brackets, and write it thus: $2\ [Cu\ O, S\ O_3]$. To give one other instance: $Pb\ O, Cr\ O_3$ is the neutral chromate of lead; and $3\ [Pb\ O, Cr\ O_3]$ is *three* atoms of the same neutral chromate; but $2\ Pb\ O, Cr\ O_3$ is the *dichromate* or subchromate of lead, and $3\ [2\ Pb\ O, Cr\ O_3]$ is three atoms of the same dichromate. $K\ O, 2\ Cr\ O_3$ is the *bichromate* of potassa, and $4\ [K\ O, 2\ Cr\ O_3]$ four atoms of the same, &c.

The following are more complicated illustrations of the application of these symbolic notations: $K\ O, S\ O_3 + Al_2\ O_3, 3\ S\ O_3 + 24\ H\ O$ represents the constitution of crystals of common alum; they include an atom of sulphate of potassa, an atom of sulphate of alumina, and 24 atoms of water of crystallisation: an atom of alumina includes 2 atoms of *aluminum* and 3 of oxygen, and its *sulphate*, as it exists in alum, is constituted of 1 atom of alumina and 3 of sulphuric acid. In *iron alum* the alumina is replaced by its *isomorphous substitute*, peroxide of iron; and the formula of this salt is

$$K\ O, S\ O_3 + Fe_2\ O_3, 3\ S\ O_3 + 24\ H\ O.$$

It is obvious that the atomic or equivalent weights of compounds are in all cases to be deduced from their symbols. Thus, the symbol of potassa K O indicates its equivalent to be 48, for the equivalent of K is 40, and that of oxygen 8. And again; $S\ O_3$, the symbol of sulphuric acid, is equal to 40 of that acid; for S is = 16 sulphur, and O_3, $8 \times 3 = 24$ of oxygen; and $16 + 24 = 40$. Hence also, $K\ O, S\ O_3$, is one atom, or equivalent of sulphate of potassa, or 88 parts by weight.

In the construction of chemical formulæ the arrangement of the symbols should not be arbitrary, but such that the *basic* or electro-positive elements should precede the *acid* or the electro-negative elements: hence sulphate of potassa is written $K\ O, S\ O_3$, and not $S\ O_3, K\ O$; and chloride of sodium is represented by Na Cl, and not Cl Na. In this way, also, much useful information respecting the real or theoretical constitution of compounds may be expressed in the due arrangement of their formulæ: thus, $H\ O, S\ O_3$ represents hydrated sulphuric acid of the specific gravity of 1·84, or common oil of vitriol, which may be called a *sulphate of water:* the acid of the specific gravity of 1·78 contains 2 atoms of water to 1 of anhydrous sulphuric acid, and might therefore be represented as $2\ H\ O, S\ O_3$; but if we give to it the formula $H\ O, S\ O_3 + H\ O$, we indicate that 1 atom of water only is combined as a *base*, with the anhydrous acid, and that the second atom of water is in combination with the sulphate of water, constituting, as it were, water of crystallisation.

In cases where complicated formulæ are to be expressed, and more especially in the combinations with which the mineralogist has to deal, the above symbolic notation may become inconveniently long, and, accordingly, various abbreviations have been suggested, but the evil of them is their frequent indistinctness, and the confusion which results from slight and almost unavoidable typographical errors. The equivalent of oxygen in oxides and acids is thus frequently represented by a point placed over the symbol of the element with which the oxygen is combined. The following, for instance, are the several combinations of nitrogen with oxygen, represented in ordinary and in abbreviated notation:—

Nitrous oxide - -	N O	$\dot{N}$
Nitric acid - - -	$N\ O_2$	$\ddot{N}$
Hyponitrous acid - -	$N\ O_3$	$\dddot{N}$
Nitrous acid - -	$N\ O_4$	$\ddddot{N}$
Nitric acid - - -	$N\ O_5$	$\overset{\cdot\cdot\cdot\cdot\cdot}{N}$.

Mineralogists also sometimes represent the atom of sulphur by substituting a dash over the symbol of the element with which it is combined, in place of using the letter S in the usual way; thus they indicate the three sulphurets of arsenic:—

$As\ S_2$	by	$\overset{\prime\prime}{As}$
$As\ S_3$	„	$\overset{\prime\prime\prime}{As}$
$As\ S_5$	„	$\overset{\prime\prime\prime\prime\prime}{As}$.

Certain compound bodies, more especially where they perform the part of elementary substances, are sometimes conveniently represented by their initial letter or letters, as if they were simple bodies. For instance, Cyanogen, which is a compound of 2 atoms of carbon with 1 of nitrogen, is indicated by Cy, instead of $C_2\ N$; and Ethyle, which is a compound of 4 atoms of carbon and 5 of hydrogen, by E instead of $C_4\ H_5$. And, lastly, certain organic bases and organic acids are similarly expressed by one or more initial letters, with the plus or minus sign attached; thus, instead of giving the composition of Morphia, Cinchonia, &c. at length, they are represented by $\underline{\overset{+}{\text{Mor}}}$, $\underline{\overset{+}{\text{Cin}}}$, &c., and Acetic, Tartaric, and other acids, by $\overline{\text{A}}$, $\overline{\text{Tar}}$, &c. But these and similar abbreviations are only admissible where a frequent repetition of the extended symbol is required, and where the indication of the elementary components is immaterial.

SYNAPTA'SE. (Gr. συναπτω, *to be present.*) A term applied by Robiquet to the *emulsine* or *vegetable caseine* of the almond, in consequence of its necessary *presence* in the conversion of *amygdaline* into hydrocyanic acid and bitter almond oil.

SYRINGI'NE. A crystallisable bitter principle obtained from the leaves of the lilac tree (*Syringa vulgaris*). It has also been called *lilacine.*

SYSTE'MIC. In Physiology, is applied to designate the circulation of the general system, beginning at the left ventricle and aorta, and ending at the venæ cavæ and right auricle, as contradistinguished from the circulation through the lungs, which is called "pulmonic." They have also been termed the greater and lesser circulations. The parts concerned in these circulations have also received the same names: thus the left ventricle is called the "systemic" one.

T.

TABOO. A word used by the South Sea islanders to denote something sacred, or set aside for particular uses or persons.

TA'CHYLITE. (Gr. *ταχυς*, *rapid*.) A very fusible alumino-silicate of protoxide of iron, occurring in certain basaltic rocks. Its name has reference to its rapid fusibility.

TAFFO. A manure made in China, composed of night soil mixed up with clay and formed into cakes which are dried in the sun.

TA'GILITE. A native phosphate of copper from Nischne-Tagilsk, in Siberia.

TA'LBOT. A hunting dog, between the hound and beagle.

TA'LBOTYPE. A name given certain photographic pictures in honour of the inventor of the process, Mr. W. A. Fox Talbot. *See* PHOTOGRAPHY, in DICT.

TANGHICI'NE. A crystallisable neutral principle said to possess narcotic properties, extracted from the kernel or seed of the *Tanghinia venenifera*, a native of Madagascar. This seed, which is said to be a deadly poison, was formerly used in Madagascar to ascertain the guilt of suspected persons, as a kind of ordeal, those who withstood it being deemed innocent. The extract of the seed has been called *Tanginine*.

TANSY. *Tanacetum vulgare*. The herb and flowers of this plant, used sometimes as a kind of medicinal pot-herb, have a disagreeable though somewhat aromatic odour, and a strong nauseous bitter taste. A small portion is sometimes added to omelets, and we have heard of *Tansy puddings*.

TARA'XACINE. A crystallisable bitter principle contained in the juice of the root of dandelion (*Leontodon taraxacum*).

TA'RNOWITZITE. A carbonate of lime, or species of arragonite, containing a small proportion of carbonate of lead, found at Tarnowitz, in Upper Silesia.

TAU'RINE. A crystalline substance containing a large proportion of sulphur, and obtained from bile. Its formula is $C_4\ H_7\ O_6\ S_2\ N$.

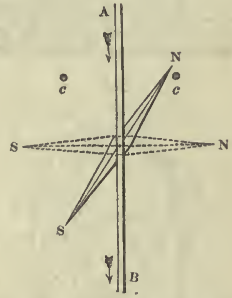
TE'BETH. The tenth month of the Jewish ecclesiastical year, and fourth of the civil year. It corresponds to December.

TE'KORETINE. A crystalline resinous product obtained from turf.

TELEGRAPH. The Electric, or, as it ought more properly to be called, the ELECTROMAGNETIC TELEGRAPH, has now superseded all other means of telegraphic communication. We purpose, therefore, here briefly to describe the *principle* upon which these instruments are constructed, referring for minute details to the various works which have been published, and to the specifications of the many patents which have been issued upon the subject. The mutual relation of electric and magnetic currents will be evident from what has been stated elsewhere under the heads ELECTROMAGNETISM and GALVANOMETER, so that it will only be necessary to recapitulate such circumstances as have especial relation to telegraphic purposes.

When a current of voltaic electricity is traversing a metallic wire, a magnetic current is at the same time established, at right angles to, and as it were revolving about the electric current, as its axis; and if the pole of a magnet be supposed capable of freely moving in any direction, the tendency of such pole would be to revolve about the wire in question, or rather, about the electric current which that wire carries. If a common magnetic needle, turning horizontally upon a point or pivot, be brought near the voltaic current, or to the wire conveying that current, the magnet will accordingly be deflected from its meridian. Supposing, for instance, the magnetic needle in its natural position, and pointing therefore north and south, to be approached by a wire transmitting the volta-electric current, held above, and parallel to the needle, the deflection of the needle will take place either to the right or left, or to the north or south, the direction of the deflection depending upon that of the electric current; and accordingly the tendency of the magnetic needle will be to place itself at *right angles* to the wire conveying the electric current. It is obvious, therefore, that the electric and magnetic forces may so far be said *to deflect each other*, and upon this principle the various forms of the galvanometer are constructed. Now, in reference to the application of such principle to telegraphic purposes, another form of apparatus must be adopted, in which the magnetic needle and deflecting current, instead of being placed horizontally, as in the galvanometer, are placed *vertically*, or perpendicularly, as in the annexed diagram, where A B represents a wire having a magnetised steel needle placed immediately behind it, and so adjusted as to hang vertically when at rest. If an electric current be now made to descend from A to B through such wire, the needle will be deflected into the position N S; that is, its north

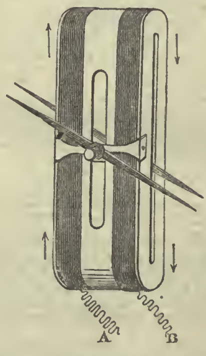
(1.)



pole will turn to the right as you stand before it; and on increasing the force of the electric current, the deflection of the needle might be so far increased as to cause it to place itself at *right angles* to the electric current, as shown by the dotted figure; but this may be prevented by the small studs *c c*, by which such extreme deflection is limited. If we now suppose the wire to be continued on, and bent into the shape of the letter U, the current still passing onwards, that is, down the limb A B and up B C (as indicated by the darts), then the portion of the current B C would also act upon the needle, and proportionately increase the deflection. If we now change the direction of the electric current, so as to send it down C and up A, then also will the direction of the deviation of the magnetic needle be changed, and its north pole, instead of pointing to the right, will point to the left. And if, by repeated convolutions of the wire, the electric current be made to pass many times around the magnetic needle, the deflection would be still further increased, so that, by the adoption of this latter expedient, or the use of a *coil* instead of a single wire, the effect of the electric current may be so *multiplied* as to produce a considerable deflection by a comparatively feeble current. This is, in fact, the principle of the *galvanometric multiplier*, and is the form of apparatus used in the electric telegraph, as now most commonly constructed. The construction of this *coil* is shown in the annexed wood-cut It consists of a polished wooden

(2.)

(3.)

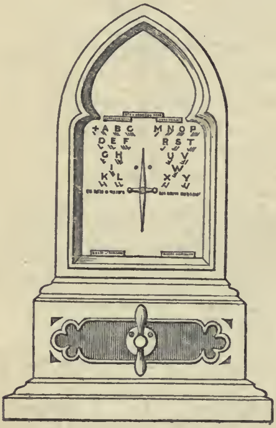


or ivory frame, round which are bound some hundred feet of fine copper wire, covered with silk, which, being a nonconductor, prevents the lateral passage or transfer of electricity from wire to wire, so that the current, entering at A, passes through the whole length of the coil, and goes out at B. Two magnetic needles are fixed

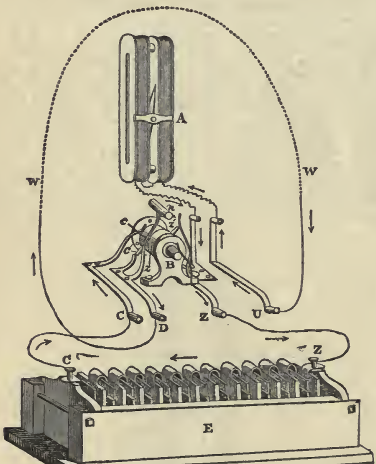
upon an axis which passes through the frame, one within, and the other without the coil, the poles of which needles are in opposition to each other, by which they are rendered *astatic*, that is, they are not affected by the magnetism of the earth. This coil is so placed at the back of the dial plate of the telegraph, shown in the next diagrams, as to allow the outer needle to traverse right and left upon the dial plate.

Having said thus much of the *principle* upon which the usual form of the electro-magnetic telegraph is constructed, we may now further explain the details of its simplest form, in which *one* indicating needle only is employed, and which therefore is usually called the *Single needle instrument*. A front and back view of this telegraph is given in the following cuts, the battery being represented annexed to the latter, and the circuit through

(4.)



(5.)



the galvanometric coil A being completed by the wire W W. The following description of the *working* of the instrument is abridged from Mr. C. V. Walker's "Electric Telegraph Manipulation," to which we may here refer the reader for a variety of details respecting its construction and uses, which would have been irrelevant in this article.

The instrument has a twofold character: it is either *passive*, or ready for *receiving* signals *from* another instrument; or it is *active*, or ready for *transmitting* signals *to* another instrument. By describing first how it is fitted for *receiving* signals, and then how it is arranged for *transmitting* them, we shall be better able to analyse it, and comprehend its structure. The frame of the coil A is screwed upon the face of the instrument, which face is a brass plate varnished on the inner side. Looking at the coil, a short wire from its *right-hand end* comes to a screw terminal, which, by a slip of brass, is connected with another terminal U. The *left-hand end* of the coil comes also to a terminal, from which a slip of brass descends to a brass plate, here partly hidden; but its form may be seen from a similar plate, visible on the left side. These twin plates are in metallic connection by means of the two upright *springs*, shown in the cut. The *springs* are of steel, and press strongly on two points in a short insulated brass rod *n*, which is screwed into the framework of the instrument. The left-hand plate is connected with the terminal D, also by a slip of brass. If, now, the two terminals U and D are connected by a wire W W, the circuit will be complete, as follows: from the terminal U into the coil at the right-hand side; out of the coil, at the left side, downwards to the right-hand plate; up the right-hand steel spring, across the brass rod *n*, to the left-hand steel spring; downward, by this spring, to the left-hand plate, thence by the slip of brass to the terminal D, and thence by the wire W W to the terminal U, whence we started. If, now, the wire from U went up the line of railway, and the wire from D down the line, and the circuit were in some way kept complete on the large scale, as it has been here described on the small scale, any electric current passing along the wire from a distant station would traverse this coil in its course, and would *deflect the needle*, and so make a signal.

So far for receiving a signal; now for sending one. Were we to go out on the open railway, taking with us a battery, and to cut any one of the wires, and place its two ends, thus obtained, upon the two terminal ends of the battery, a current would pass along the line, and the needles on that line would be deflected; and if we changed hands, so as to reverse the connections, and consequently to reverse also the direction of the electric current, the deflections of the needles would be reversed. The same would happen were we to cut a wire inside the office, or inside the telegraph, and to treat it in a similar way. Now, in every apparatus contrived for transmitting signals, we have a *place corresponding to such a cut wire;* and, near this place, are the poles of the battery, mounted and moveable, so that they may be readily applied in the breach, one way or the other as required. The place here (*fig.* 5.) is the *top of the springs*. They are not *joined* to the brass rod *n*, but *press hard* upon it, and can readily be raised; and when either of them is raised, the circuit is broken. Now near this place is a contrivance, by which the poles of the battery may make a breach in the circuit, and be applied in the breach in either direction. The drum B is of box-wood, the ends *c* and *z* being capped with brass, and insulated from each other by the wood left between them. The drum is moveable by a handle in front of the instrument, visible in *fig.* 4. A stout steel wire, *c′*, is screwed beneath into the *c* end of the drum; and a similar wire, *z′*, is screwed above into the *z* end. These two wires are the poles of the battery, *z′* being connected with the zinc end, and *c′* with the copper, thus: — from the copper end of the battery a wire is led to the terminal C; thence a slip of brass leads to a curved brass spring which presses on the drum at *c;* from the zinc end of the battery a wire goes to the terminal Z, and thence a slip of brass leads to a similar curved spring, pressing on the continuation of the *z* end of the drum, as shown in the figure. Whenever, therefore, the drum is moved, the steel wire *z′* will lift up one or other of the upright steel springs; it is now lifting up the right-hand one, and so breaks the circuit; but, by a little further motion of the drum, the wire *c′* will press upon the boss below, as shown in the figure, and thus there will be a battery-pole on each side of the breach, and a signal will be made on this, and on all instruments connected with it. And, from the peculiar arrangement of the drum, the motion can be changed as rapidly as the hand can move. I have shown the battery connections exactly as they occur in practice; and the connections are such that if the right-hand spring is moved off, the needle moves to the right, and if the left to the left. The needle on the face of the instrument always has its north end upward, and the needle within the coil its north end downward, so that, by the law elsewhere stated (*fig.* 1.), if we look at the face of an instrument, and see the top end of the needle move to the right, we may be sure that in the half of the coil nearest to us the current is *ascending*.

Now, as regards the *front* of the instrument, upon which the alphabet is engraved right and left of the needle, it will be obvious, from what has been said above, that the manipulator has it in his power to cause the dial-needle to vibrate or deflect to the right or left, as he directs the electric current one way or other through the coil, and this direction of the electric current is commanded in the way above described, by turning the handle at the lower part of the instrument to the right or left;

when this handle is *vertical*, the current is altogether cut off.

The letters of the alphabet, and a few other signals, are indicated by the number of *beats* made by the needle, some of these beats being to the left and some to the right, the general rule being, that in the letters placed to the *left* of the needle the *last* beat to make any given letter is a *left-hand* beat, whatever other beats may enter into the production of the letter; thus, L requires four beats, and they are right, left, right, *left*, finishing with the *left;* so, again, the letters placed on the *right* of the needle finish with a *right-hand* beat, as, for instance, W, which is composed of four beats, three to the *left*, and the *fourth* to the *right*. The system upon which this single instrument alphabet is formed is sufficiently simple. The symbol of each letter is placed underneath it, and consists of one or more diagonal lines sloping either to the right or left, some of which are full length, and others half length; the direction of the diagonal is the direction of the deflection or beat, a deflection being made for each diagonal, the deflection corresponding to the *half length* being made *first*. D, for instance, is thus represented \/, and is made by a beat to the right, followed by a beat to the left; R is represented by √, and is made by a beat to the left, followed by a beat to the right; H is \\/, two to the right and two to the left, W is ///, three beats to the left and one to the right, and so on. The scheme of the code is, one, two, three, and four left-hand beats for the first four signals; then one right-hand and one, two, and three left-hand beats for the next in order; then two right-hand and one and two left for the next; then three right-hand and one left; then a left, a right, and a left; and lastly, right and left, right and left, \/\/, which reaches L, and comprises the first half of the series. The other half are the counterparts, with the beats reversed. To render this description more intelligible, we annex a separate representation of the dial alphabet, and a separate alphabet, in which the direction and number of beats for each letter is shown separately.

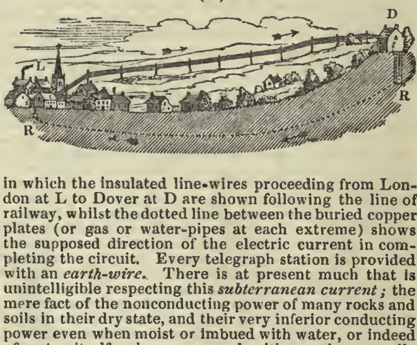
(6.)

In the preceding diagrams, the symbol like the Maltese cross ✠, indicated by one beat to the *left*, and which is termed *stop*, is used by the *sender* of a message, *at the end of every word*, and by the *reader* or receiver of the message, when he does *not understand* the previous word. On the other hand, a single beat to the *right* (indicating the letter M upon this form of the instrument) implies that he *does understand*. When, in this or other form of the needle-telegraph, *numbers* are to be transmitted, which, however, is very rarely necessary in the form of *numerals*, conventional letters and signals are settled upon for the purpose.

Our object here is, merely to render the principle of this form of the electric telegraph intelligible, and therefore we have selected the simplest instrument; but at all the principal stations a DOUBLE-NEEDLE INSTRUMENT is employed, and which may in fact be regarded as two single instruments capable of being worked separately or together. With this double telegraph the reading of the signals is much more rapid, but it has the inconvenience of requiring a separate line-wire for each needle; the signals also are different from those of the single instrument, but the *principle* is in both the same.

It is obvious, from the laws which govern the transmission of what we call the *electric current*, that when, by its means, a message is to be sent to any distant station, as, for instance, from London to Dover, there must be a means by which the current may return from Dover to London, and this was formerly effected by a separate wire; so that each single telegraph required two wires, one down the line to Dover, and one up the line to London, and a double-needle instrument could only be worked by four wires, by which much expense and occasional inconvenience was incurred. But, about the year 1837, it was discovered that the circuit might be completed, or at least that the return-wire might be superseded, by what has been called the *earth circuit*, so that, instead of using *two* lengths of wire, one only is employed for each needle, and the terminal or return-wire of the Dover instrument is connected with the gas and water-pipes of Dover, while the other terminal of the London instrument is similarly connected with the gas and water-mains of London, and, strange to say, it is found that this transit by the earth is more perfect, that is, presents less resistance to the passage of the electricity than if a return-wire had been used. In cases where there are no large subterranean metallic communications at hand, a hole is dug, in which a copper plate connected with the return-wire is buried, at a sufficient depth to be always in moist earth. The annexed cut will perhaps render this statement more intelligible,

(7.)



in which the insulated line-wires proceeding from London at L to Dover at D are shown following the line of railway, whilst the dotted line between the buried copper plates (or gas or water-pipes at each extreme) shows the supposed direction of the electric current in completing the circuit. Every telegraph station is provided with an *earth-wire*. There is at present much that is unintelligible respecting this *subterranean current;* the mere fact of the nonconducting power of many rocks and soils in their dry state, and their very inferior conducting power even when moist or imbued with water, or indeed of water itself, when compared with metal, are well-known facts, and yet, in the communication we have described, the circuit appears to be quite as complete as if a continuous wire had been used, or even more so. To get over this difficulty, some have discarded altogether the notion of *conduction* in these cases, and have regarded the earth as a reservoir in which positive and negative electricity are equally and indifferently lost, absorbed, or neutralised; the positive end of the battery freely giving off positive electricity to the earth at London, and the negative end giving off negative electricity to the earth at Dover, or *vice versâ*, as the case may be.

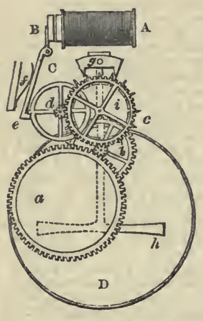
We have now endeavoured to render the principle upon which signals are communicable between distant stations by electromagnetic means intelligible, and have only noticed a few of the appendages, as they may be termed, to the talking part of the apparatus.

One of them, and an important one, is the *Alarum*, or *Bell-signal*, by which *audible* notice is given from station to station of their desire to talk to each other through the telegraph. These bell-signals may be either altogether independent of the telegraph, and rung by a separate wire, or they may be rung by the same wire which actuates the telegraph, and which in that case is so arranged that the electric current may be diverted through the bell-magnet, or through the telegraph, as occasion may require; and in this case, if we suppose the bell to be in the circuit, its *ringing* announces the wish of the distant station, say of Dover, to communicate with London; then London, on hearing the bell, turns on the current, to the bell at Dover, to announce that the signal has been successful; the current is then turned off the bells on to the needle-coils, and the message transmitted in the usual way. When sepa-

rate and independent wires and bells are employed, they are always in the circuit, and may be rung whenever required; for particular purposes the bells may serve as special signals, and when rung once, twice, thrice, and so on, may thus serve to announce something that has happened at the distant station.

These *alarums* are rung by means of an *electro-magnet*, that is, a short rod or core of *soft iron*, wound round with a sufficient length of silk-covered copper wire; this core becoming a powerful magnet whilst an electric current is traversing its copper coil, and returning again to its indifferent or normal state the moment that the electricity ceases to circulate. A side view of an *alarum* is given in the annexed diagram. A is the elec-

(8.)

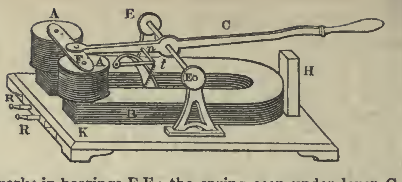


tro-magnet; in front of it is a soft iron keeper B. This keeper is attracted by the poles of the electro-magnet *every time* a current is made to circulate around it, and *as long* as it is in circulation; and attraction ceases the moment the current ceases. To prevent the keeper remaining attracted, which sometimes happens, even after the force ceases to circulate, it is prevented *actually touching* the pole of the magnet by two ivory studs, or sometimes merely by the intervention of a piece of paper; but it is so adjusted that, when in its state of rest, it shall be as near as convenient to the poles of the magnet. The rest of the figure represents the mechanism by which the bell is rung. The keeper B is mounted on the shorter arm of a lever C; the other end of the lever terminates in a catch *e*, which catches a pin in the circumference of the wheel *d*, and prevents it moving; *f* is a slender spring pressing against the long arm of the lever C, and by means of which the keeper is restored to its normal position when attraction ceases, and the catch *e* is made to act; *a* is a box containing the mainspring; *b*, a toothed-wheel connected with *a* by a pinion; *c*, a toothed-wheel having a pinion working in *b*; *d*, the wheel that carries the stop, and connected by its pinion with *c*; *g* is an escapement, working in pallets on the wheel *i*, which is on the same axis with the wheel *c*; *h* is the bell hammer: it is virtually a short pendulum, its connections and action being quite similar. When the voltaic current is made to pass along the wire of the coils A, the soft iron core is magnetised, and the keeper B is attracted; this raises the catch *e*, and so allows the wheel *d* to move. The machinery being thus liberated, the mainspring in the box *a*, which is kept wound up, sets it in motion, and the pendulum hammer *h* vibrates rapidly and strikes the bell D, which is shown also in section. When the magnetisation ceases, with the cessation of the current, the catch *e* is pressed into its place again by the reacting spring *f*, and the ringing terminates.

It will be seen, from this description, that the alarum is sounded by ordinary mechanism, and that the office of the voltaic force is merely to move a lever and liberate the machinery; whence it is obvious that there is little limit to the amount of noise which may be produced.

In some other forms of telegraph, the bell, instead of being sounded by the detachment of a common ringing scapement, is rung by the direct blows of a hammer attached to the keeper of the magnet itself; and there are several modifications of this contrivance, by which a single blow or a continuous ringing may be effected. For ringing bells at short distances, and in cases where a voltaic battery would be inconvenient, a current of magneto-electricity is substituted, which is most simply obtained by the following form of apparatus: — A A are coils (similar to the coils described); the two bars of iron which pass through the coils are connected by their upper ends to a strip of iron F, the lower ends rest on the magnet B; thus they form what is commonly termed a keeper, by connecting the two poles of the magnet; F is joined to a lever C, which is attached to a shaft that

(9.)



works in bearings E E; the spring seen under lever C is for forming a short circuit; N, a small ivory pin for insulating the wire *t*; R R, two terminals, where the wires coming from the coils terminate; H, a block for stopping the entire descent of lever; K is the stand, to which the whole apparatus is firmly fixed. As long as the iron bar remains on the magnet, no effect is produced; but sharply depressing the lever whereby the iron bars are detached from the magnet, a current of electricity is produced, passing through the coils and along the line to the bell.

TELESCOPE. In addition to the explanation of the general theory and mechanism of telescopes given in the body of the work, it is thought desirable to give specific accounts of some of those gigantic instruments whose establishment has done so much in the last few years to revolutionise certain preconceived notions in astronomy, and to supply information concerning the nature and existence of celestial objects which were before invisible. We propose then to confine ourselves to four of the largest telescopes now in existence, our space not admitting of much detail even for these. These telescopes are: the large reflecting telescope erected by Lord Rosse in the grounds of his residence at Birr Castle in Ireland; and the three large refracting telescopes at the Observatories of Pulkova near St. Petersburg; of Cambridge, Massachusetts, near Boston, U. S.; and of Cambridge in England.

Lord Rosse's 50 *ft. Reflecting Telescope.* — This enormous telescope, which has two object mirrors of 6 ft. diameter, and is 53 feet in focal length, was begun in 1842. The metal used for the specula is an alloy of tin and copper in atomic proportions, the weight of the copper being something more than double that of the tin. The weight of metal in one of the specula is $3\frac{1}{2}$ tons, and that of the other 4 tons. For fusing these immense masses of metal it was placed in three iron crucibles cast expressly for the purpose, each crucible weighing of itself about $1\frac{1}{2}$ tons. The crucibles were placed in as many furnaces, whose mouths were level with the ground, and with flues opening into one common stack or chimney. The metal for its complete fusion required to be kept in the furnace about twelve hours, and when it was in the state proper for casting, the crucibles were withdrawn from the furnaces by means of a powerful crane to the iron cradles of pouring frames arranged round the mould at intervals of ninety degrees.

The mould had for its base a framework of hoop iron six inches in depth, placed edgewise, packed in a strong frame, and supported by strong transverse bars beneath. The upper edges of these were ground into a slightly convex surface of about 108 feet radius, and thus formed the base of the mould; allowing the air to escape through the interstices, though, from the viscosity of the amalgam, no particle of *it* could escape through them. The metal also by being poured upon the iron became chilled immediately into a dense sheet of about half an inch thick, and thus secured one of the conditions which have been found to be most important, if not indispensable, in the casting of speculum metal. After becoming tolerably solid, the speculum was withdrawn to the annealing furnaces, where it remained for about sixteen weeks, when it was considered to be ready for the process of grinding and polishing.

A full account given by Lord Rosse of the polishing machinery will be found by those interested in this inquiry, in the *Phil. Trans.* for 1840. It is sufficient to state that the beam carrying the polisher is moved by a small steam engine, by which a rotatory motion round a vertical spindle is given to a crank, which by a connecting rod acts upon a sliding rod that moves the grinder or polisher backwards and forwards. By such means the polishers make strokes backwards and forwards very nearly in the manner in which the hand would make them, if the polishing were performed by hand, and at the same time another part of the machinery causes the frame carrying the speculum, and therefore the speculum itself, to revolve with a slow motion. We must remark further in connexion with this part of the subject, that it was necessary that the speculum should be cast and polished upon the same fixed frame (distinct from the rotatory frame before mentioned) that would support it when in the telescope. For this purpose the fixed frames are provided

with small wheels, by which, after being conveyed in a carriage to a railroad running into the lower part of the tube of the telescope, the speculum is deposited in its proper position for use.

For the support of the mirror in such a way as to avoid strain and flexure, a very ingenious system of levers is employed. This consists of a combination of three similar systems, resting on three points under the centres of gravity of the three equal sectors into which the speculum may be supposed to be divided. Each system consists of one triangle with its point of support directly under its centre of gravity, upon which it freely oscillates. This triangle carries at its angles three similar points of support for three other triangles, under their centres of gravity, and they again at their angles carry in a similar way cast-iron platforms formed of three ribs so as to make a kind of irregular open-work grating, supported under their centres of gravity. There are thus twenty-seven platforms, which are coated with greased cloth, and upon these the speculum is supported, each bearing $\frac{1}{27}$th part of the weight.

The above is the construction first adopted by Lord Rosse. But, as the surface of the speculum by the pressure on its edge at different elevations was found to be distorted, instead of the platforms in contact with the back before mentioned, there were adopted eighty-one brass balls capable of revolving freely, that is, three at the corners of each triangle, occupying the place of the platform in the former construction.

We now come to the mounting of this immense speculum. The tube of the telescope is made of wood, and is at the middle about 7 ft. in diameter; the interior exceeding 6 ft. in every part. This is fixed to a cube of 10 feet, which has folding doors in one of its sides for admission of the speculum, and which carries the fixed frame supporting the mirror on that side which is opposite to the mouth of the telescope. To this side of the cube is attached a universal joint by which the lower end of the telescope is connected with a fixed support, the joint being a few feet below the general surface of the ground.

On the east and west sides of the telescope are immense piers about 70 feet long and nearly 50 feet high, of which the eastern carries a large iron arc of a circle, in which moves a slider attached to a racked bar working by means of a pinion carried by the telescope tube, and the other carries the stairs and galleries necessary for the observers. Near the tops of the piers in the east and west plane passing through the universal joint are two cranes with pulleys, over which pass chains attached to the telescope, and to the ends of these chains, after they have passed through fixed pulleys in the walls, are attached the counterpoises, weighing about four tons each. There is also a contrivance connected with the chains for equalising the action of the counterpoise-weights in different positions of the telescope.

By means of the rack and pinion before mentioned, the observer is enabled, standing near the eye-end of the tube, to give a motion in hour angle of about half an hour on each side of the meridian position.

At the south end of the piers there are strong ladders, and upon these (assisted by counterpoises) there slides a stage upon which a small observing gallery travels backwards and forwards. For great elevations curved galleries are mounted upon the curved slope of the upper part of the western pier, carried by beams that run above and below pulleys fixed to the top of the pier; they are run out by rack and pinion work to approach the side of the telescope.

A quick motion in declination is given by the windlass below, and a slow motion is given by hand above for measurements: the quick motion in right ascension is given also below by a wheel turned by a workman, and the slow motion by hand above. The tube is slung by chains and is perfectly steady in a gale of wind.

The tube carries at the upper extremity the apparatus for the Newtonian small mirror, which is itself of considerable size and weight, the minor axis of its ellipse being about 6 inches; but Lord Rosse has made provision in the construction of his observing galleries for using it as a Herschelian telescope, if it is found necessary or desirable to obtain an increase of light.

In the use of this wonderful instrument Lord Rosse has hitherto chiefly confined himself to the observations of nebulæ. Many of these objects previously supposed to be unresolvable have been resolved by the powers of the telescope, and a great deal of most interesting information has been already gained respecting their structure. The figures of many of these are of a spiral form, something like the convolutions of some species of shells. 51 Messier and 99 Messier, of which drawings are given in the] *Phil. Trans.* for 1850, are very remarkable specimens of this class. The first, which is thickly studded with stars, has a large condensed mass in the centre with spiral curves of variable condensation radiating from it upon the general illuminated mass of the nebula. A large condensed mass exists at its right hand boundary. Messier 51, whose spiral formation was detected early in 1845, is of a different character, with but few detached stars, but the sweep of its spirals is exceedingly bold and interesting. Another class of nebulæ is the *annular*, of which several additional specimens have been detected. This class consists of nebulæ in the shape of a ring, and the most remarkable of them is that in Lyra, which the telescope has partially resolved.

For drawings of several other beautiful specimens, the reader may consult Lord Rosse's papers in the *Phil. Trans.* before quoted: enough has been said to show in some measure the powers of the telescope, and the grand future which it seems to open for astronomy.

Of *refracting* telescopes we give the first place to that at *Pulkova*. Its object-glass has a clear aperture of very nearly 15 inches, and its focal length is 22·5 feet. The length of that part of the tube between the object-glass and the declination axis is 13·7 feet, and that of the part between the eye-piece and the declination-axis is 9·2 feet. The tube is of wood; it is of a conical shape, and the exterior diameter at the extremities are 17·0 inches and 11·8 inches. The telescope is furnished with six eye-pieces, whose powers vary from 152 to 1218, and with other eye-pieces, twenty-one in number, belonging to the micrometrical apparatus, with powers as high as 2000.

The mounting is that known by the name of the Frauenhofer mounting, having the telescope on one side of the polar axis. The polar axis is nearly 4 feet in length and the diameter of the horary circle is 18 inches, and is divided to 40″ of time. Sidereal motion is given to the telescope by clock-work.

The instrument was constructed by Messrs. Merz and Mahler, and is in most respects similar to that erected at Cambridge, Massachusetts, near Boston, U. S., which we now proceed to describe.

The *Cambridge* telescope belongs to the observatory in connexion with the Harvard university. It has not been erected many years, but it has already earned considerable fame by the discovery of some comets, of the third ring and eighth satellite of Saturn, and by micrometrical observations of nebulæ of great excellence and importance.

The telescope and its equatorial mounting are the work of Messrs. Merz and Mahler of Munich. The extreme diameter of the object-glass is 15¾ English inches, the effective aperture barely 15 inches, and the focal length 22 ft. 6 in. The mounting, like the preceding telescope, is that known as Frauenhofer's, that is, the telescope is not in the plane of the polar axis, but on one side of it, supported near its centre at one extremity of the declination-axis, and counterpoised by a weight beyond the other extremity of the declination-axis. The declination-circle is 26 inches in diameter, and is read by four verniers to 4″ of arc; the hour circle is 18 inches in diameter, and is read by verniers to single seconds of time.

Sidereal motion is communicated to the telescope by clock-work, regulated by the friction of centrifugal balls.

It is furnished with nine eye-pieces, whose powers vary from 103 to 1118, and with a wire-micrometer eye-piece and position circle. The screw of the micrometer has been severely tested and found to be of sensibly equal value throughout its length.

The usual inconvenience attending the reversing of the telescope when an object arrives at the meridian is experienced, and the arrangement of the divisions of the hour circle and declination circle is complained of as awkward; the clock-work machinery is also disproportionate to the other parts of the instrument, and requires adjustment frequently; but the optical power of the telescope has excited universal admiration.

The whole aperture can be used without injury to the definition, and the disks of stars are remarkably small. In measuring double stars powers from 700 to 1200 have been habitually employed. On rare occasions, a power of 2000 has shown well the disks of Neptune and of the satellites of Jupiter.

With powers of 700 and 800, stars have been separated whose measured distance has proved to be 0″·3. The satellites of Neptune and the inner and eighth satellite of Saturn are seen steadily, as well as the edge of the ring at what is called its disappearance. — (*Description of the Observatory at Cambridge, Massachusetts, by William Cranch Bond.*)

The last telescope we propose to describe is that called the *Northumberland Telescope*, at the Observatory connected with our own university at Cambridge.

It was the gift of the late Duke of Northumberland when Chancellor of the University, and has acquired considerable fame from the successful search after the planet disturbing Uranus. Before the discovery of Neptune, at Berlin, it had been observed twice during

the sweep instituted for it, though it was not recognised till afterwards.

The object-glass, by Cauchoix of Paris, is of 11½ inches effective aperture, and the focal length is 19¼ feet. The mounting is that generally adopted with English equatorials, that is, the telescope is in the plane of the polar axis, and this prevents the disagreeable necessity of reversing the instrument when an object comes to the meridian.

The hour circle is 5½ feet in diameter, and is not permanently attached to the polar axis, but can be clamped to or released from the lower iron frame at pleasure. There is no declination circle, but its place is supplied by a declination sector, that is, a graduated arc carried by a flat brass bar nearly 6 feet in length, turning about a pin fixed in the telescope tube at the distance of rather more than 2½ feet from the axis of revolution of the telescope. This serves to measure small differences of declination. The instrument is provided with clockwork.

The whole of the mounting was performed under the direction of the Astronomer Royal, Mr. Airy. — (*Cambridge Observations; Airy's Description; Weale's London Exhibited in* 1851.)

TERA'TOLITE. (Gr. τερας, *a wonder*.) A species of clay found in the coal formation of Planitz, in Saxony. It is the *terra miraculosa* and *terra sigillata* of old pharmaceutical authors, and was celebrated for its supposed medical virtues.

TERCE-MAJOR. In Card-playing, a sequence of the three best cards.

TE'REBINE. A modified oil of turpentine.

TE'SSELITE. A species of *zeolite*, of a peculiar tesselated or mosaic-like structure, from Faroe.

TE'TANINE. The poisonous alkaloid *Strychnia* is sometimes described under this name.

THEBAI'A. A crystalline alkaloid contained in opium. It has also been termed *Paramorphia*. It exists in very small proportion.

THE'NARDITE. A native anhydrous sulphate of soda, found near Madrid, so named in honour of Thenard, the French chemist.

THENARD'S BLUE. A compound of a splendid blue colour, obtained by heating a mixture of phosphate of cobalt with pure alumina.

THEOBRO'MINE. A white bitter substance, contained in the chocolate nut (the fruit of the *Theobroma cacao*).

THERMONA'TRITE. A peculiar species of carbonate of soda, found in the Natron lakes at Lagunilla, in Columbia, in the Macarius desert in Lower Egypt, and in the steppes between the Ural and Altai, and is deposited from their water in the warm season. According to Haidinger, a saturated solution of carbonate of soda at a temperature between 80° and 100°, forms, on slow cooling, crystals of thermonatrite, which differ in form from those of the common carbonate, and contain less water of crystallisation.

THIEVES' VINEGAR. Called also Marseilles vinegar, and *Vinaigre des quatre voleurs*, is made by digesting rosemary tops, sage leaves, lavender flowers, and cloves, in vinegar: this useless preparation was once regarded as an effective antidote against the plague and other contagious diseases.

THRAU'LITE. (Gr. θραυω, *I break*.) A hydrated silicate of iron, which occurs, with magnetic pyrites, at Bodenmais, in Bavaria; it has a resinous fracture and is very brittle.

THRI'DACE. (Gr. θριδαξ, *lettuce*.) *Lettuce opium*, called also *Lactucarium*. It is the inspissated juice of the common lettuce, which is slightly sedative.

TIDE GAUGE. The chief improvements recently introduced into tide gauges are exhibited in that constructed by Hewitson, to which reference is made in the Dictionary. Great pains have been taken in every part of its construction to diminish friction as much as possible. The teeth of the wheels are carefully made, so that should the rise or fall of the tide amount to the fraction of an inch only, a simultaneous movement of the machine follows to that amount. It is furnished with a brass cylinder turning on axes of bell-metal revolving in Y's. The traversing bar carrying the registering pencil moves on steel friction rollers, concealed in the capitals of the brass supporting pillars. The machine is connected with an astronomical clock, which needs winding only once in 16 days, or in rather more than half a lunation, and thus produces, without any attention in this interval, a complete chart of tidal curves.

TI'KOR. A name applied in India to the fecula or starch of certain species of *Curcuma*.

TILE ORE. An impure oxide of copper of a brick-red colour.

TISSUE. In animals, the substance of which systems of organs are composed, as, *e. g.* bone, or "osseous tissue," in the osseous system; flesh, or "muscular tissue," in the muscular system; "neurine," or nervous tissue, in the nervous system; "dentine," or tooth-bone, in the dental system. The branch of Anatomy which treats of the tissues is termed "Histology."

TODDY. The sap or juice of the cocoa nut palm, which is collected in India by wounding the flower-stalk or spadix. Five or six pints are sometimes daily obtained from each tree, and it is in much request as a beverage, especially by European troops; but it requires to be drunk early in the day, and quite fresh, for it rapidly ferments, and acquires intoxicating powers.

TOLU'IDINE. An organic base obtained by the action of sulphuret of ammonium upon nitro-toluide: it is a yellow oil composed of $C_{14}\ H_9\ N$.

TOLUO'LE. An oily hydrocarbon obtained by distillation from Tolu balsam. Its composition is $C_{14}\ H_8$.

TO'MBAZITE. A mineralogical synonym of one of the native arsenurets of nickel.

TONE. In Physiology, a degree of firmness and tension in certain soft tissues, as contradistinguished from flabbiness: it is commonly applied to the muscles, in which the "tone" depends on a state of passive contraction, dependent on the connexion of their nerves with the myelon, and which is lost when that connexion, or the myelon itself, is destroyed.

TONKA, or TONQUIN BEAN. The fruit of the *Coumarouna*, or *Dipterix odorata*. It is used as a perfume, especially for snuff; its odour, resembling that of new hay, is derived from a concrete volatile oil which chemists have termed *Coumarin*, or *Tonka-Camphor*. A similar substance may also be extracted from the flowers of Melilot (*Melilotus officinalis*).

TOUCHWOOD. A term sometimes applied to the agaric of the oak (*Polyporus igniarius*).

TOUS LES MOIS. An article under this name is sold in London, as a substitute for *arrow root;* it is the starch of the *Canna coccinea*. Its particles are admirably suited as objects for the microscope, on account of their large size: in other respects they resemble the granules of potato-starch.

TRANSCENDENTAL. In Anatomy, the term has been applied to that branch which treats of the essential nature and homologies of the parts of the body, and the results of which study seem to be different from, or beyond, what would be suggested by the ideas of the parts derived from the outward senses; as when the human blade-bone, which to the eye is very different from a human rib, and which is quite distinct from the skull, is seen by the mind to be the rib of the occiput.

TRANSIT CIRCLE. A meridian instrument which combines the properties of the Transit Instrument and the Mural circle, that is, which can be employed for determining at the same transit of a celestial object, both its R. A. and its zenith distance. A remarkable instrument of this class was erected at Greenwich, by the Astronomer Royal, Mr. Airy, in the year 1850; and, from the beginning of the year 1851, all the meridian observations have been made with it. It consists mainly of a telescope of 12 feet focal length with an object-glass of 8 inches clear aperture, carrying on each side of its centre a circle of 6 feet diameter. The tube of the telescope is of iron cast in four pieces, viz. two immense cones at its eye end and object end, and a large central cube in two pieces, having attached to them in the same casts the pivots on which the telescope revolves. The cones weigh each about 1¾ cwt., and the central cube with its pivots weighs nearly 8 cwt. The two parts of the cube are bolted together on flanges with planed surfaces, as also are the cones to the central cube. The surfaces of the pivots were hardened after the casting, by chilling them, to a depth of about a quarter of an inch, and were afterwards ground and polished to a true cylindrical form after a great expenditure of time and labour. The circles are carried on cylindrical rims on the east and west sides of the central cube. The western circle has a *dished* surface of about 3 inches in breadth with its concavity westward, and carries two bands, one on its eastern and one on its western surface, the latter being divided to 5′ of space. The eastern divisions are merely given for the convenience of setting the instrument accurately to given objects by means of a pointer; but the western divisions are for the observations of zenith distance. For the reading of the circle six long microscopes or lunettes are fixed in the solid stone of the western pier, having their object-glasses arranged in a circle of about 5½ feet diameter on the inner or eastern surface, and their eye-pieces in a circle of about 2 feet in diameter at the back of the piers. The centres of these circles are in the same horizontal line with the centre of the telescope, and at the height of 5 feet from the floor. The microscopes, whose axes lie in a conical surface, are each 45 inches in length, and their axes are not quite perpendicular to the portions of the surface of the circle opposite to them, but are inclined in such a way that the light thrown through corresponding illuminating holes (cut in the pier) from a central gas lamp shall be reflected truly into them without the aid of specula. The error of collimation of the telescope is found by means of two 5 ft. telescopes, one to the north and the other to the

south of it, and the error of level is found by the observation of the reflected image of the central wire by means of Bohnenberger's eye-piece; by which means also, together with observations of stars by reflexion, the zenith point is found. An apparatus is provided by which the instrument can be lifted at pleasure out of its Y's, so as to be in the same state of strain when elevated as when resting in its Y's. The apparatus for carrying the mercury trough, which usually contains about 60 lbs. of mercury, is ingenious, and motions are readily given to it either in a north and south, or in an east and west direction.

For illumination of the wires with a dark field eight prisms are employed. Four of these are arranged symmetrically on the reflector, which is placed at the centre of the telescope as usual, but which is movable round an axis and can be acted upon by a rod passing through the tube of the telescope and having its end near the eye-piece; and four are arranged symmetrically in the plane of the wires in the eye-piece. By this means, when the field is dark, or the reflector is at right angles to the tube, the light after reflexion by the two sets of prisms is thrown across the field in the plane of the wires, and illuminates them abundantly for observation.

The casting and the engineering generally for this instrument was performed by Messrs. Ransomes and May of Ipswich, but the dividing of the circles, and all the optical part of it, was performed by Mr. Simms. The object-glass is also of his manufacture.

TRANSIT INSTRUMENT. Several improvements, both in application and in construction, have been within a few years made with regard to this admirable instrument. The principal new application of it is that by which it is made to determine the latitude of the place of observation, or the zenith distances of stars, by being placed at right angles to its ordinary position, that is, with its line of collimation lying in the plane of the prime vertical. A large instrument of this class has been recently erected at the observatory of Pulkova, and it serves to determine with admirable precision the zenith distances of stars which pass near the zenith of that observatory; and M. Struve considers its use to be of extreme importance in the ulterior investigations connected with aberration, precession, and nutation.

Mr. Simms produced at the Great Exhibition of 1851, a specimen of a *double transit instrument*, that is, of an instrument which might be used with equal facility when placed in the meridian and in the prime-vertical. This is effected by making the axis of the telescope itself convertible into a telescope by having an object-glass fitted into one of the pivots, and a sliding-tube carrying an adjustible cross of delicate spider-lines with a positive eye-piece at the other pivot. The adjustment of the axis-telescope is effected by a small collimator placed in a line with the axis. The axis is turned round, and the position of the wire-frame is shifted till the centre wire coincides with the mark equally well before and after reversion. If the meridian telescope be previously adjusted, it can be made use of for readily placing the axis telescope in its proper position for the determination of latitude by means of the transits of stars which pass the meridian near the zenith.

Another kind of transit instrument lately brought into use is the *diagonal* or *chamber transit*. The peculiarity of this instrument is, that the rays tending to form an image of a star after passing through the object-glass, do not proceed in a straight line through the tube in the usual way, but, being received upon a speculum or prism placed in the axis, are turned aside through one of the axes, which is perforated and provided with an eye-piece and a system of wires. By this means the inconvenience of placing the body in awkward positions for the observations of stars, so much felt in the use of small transits, is avoided, and the observer has no occasion to shift his position, whatever be the altitude of the star to be observed. Mr. Simms has succeeded in providing convenient means for the illumination of the field of view of the diagonal transit by the following method:— The back pivot being also perforated has a small convex lens set within it, and a larger convex lens is fixed within the axis at the back of the reflector, of such a size that one or more segments near the edges project beyond the edge of the reflector. The light of a lamp placed outside the pivot is condensed by the small lens, and the rays after crossing diverge upon the large lens at the back of the reflector, whose outer segments again condense it upon the field of view in sufficient quantity to produce a well illuminated field.

The last improvement we shall mention is the *prism illumination* of the field of view of transit instruments. It has always been a difficult problem for practical astronomers to provide for the observation of very faint objects, for which it is necessary to have the field of view dark and the wires illuminated. Various means, attended with only partial success, have been devised in different observatories, the most successful of which was till recently the application of the galvanic current. Mr. Airy applied for the first time the *prism-illumination* to the great transit-circle at Greenwich, in the year 1850, and this method, which is equally remarkable for its simplicity and facility of application, is now applied to small instruments, and will probably supersede all other methods. A pierced reflector is placed as usual in the central part of the axis of the telescope, but this, instead of being fixed, has a motion round an axis, so that it can be placed at any angle of inclination to the tube, being acted on by means of a rod projecting through the eye-end of the telescope-tube near the observer's hand. If the rod be pulled out to its full length, the reflector stands at its usual angle of 45°, and the field is *fully illuminated* by the lamp placed at the axis. By pushing the rod the reflector is made to stand more nearly at right angles to the tube, and less light is thrown down the tube, and by this means the light is *moderated*. Finally, when the reflector is at right angles to the tube, no light passes down it to the eye, but in this case the prism-application comes into play. Four right-angled glass prisms are placed symmetrically round the ring of the reflector, one of the sides of each receiving the rays from the axis-lamp perpendicularly. The light, reflected from their hypothenusal sides, and passing perpendicularly through their remaining sides, is made to proceed parallel to the sides of the tube. It is then finally received upon other four prisms placed properly in the plane of the wires of the telescope, so as to be transmitted entirely in that plane, and to illuminate perfectly both sides of the vertical wires, and the upper and under sides of the horizontal wires. This process has been used with perfect success for a considerable time for the illumination of the wires of the Transit Circle at Greenwich.

TRI'CLA'SITE. (Gr. τρεις, *three*, and κλαω, *I break*.) A mineral found in the talc and chlorite slate of Fahlum, regarded as a species of *Iolite*: it has a *three-fold* cleavage.

TRIPE. The stomachs of ruminants, when properly prepared, constitute *Tripe*. Dr. Thomson, in his *Domestic Management of the Sick Room*, says, "few things are more readily digested than tripe, when properly cooked." It should be slowly boiled, with an onion and some salt.

TRI'PLITE. (Lat. triplex, *three-fold*.) A mineral composed of phosphoric acid in combination with the oxides of iron and manganese, which occurs with beryl in the granite of Limoges, in France.

TRI'PTOTE. (Gr. τρεις, *three*, and πτωσις, *a case*.) In Grammar, a noun that has only three cases.

TRO'MBOLITE. Native phosphate of copper.

TU'BULAR BRIDGE. A bridge formed of a great tube or hollow beam, through the centre of which a roadway or railway passes. The most remarkable bridge of this kind is that designed by Mr. Robert Stephenson for carrying the Chester and Holyhead railway over the Menai Straits. This bridge consists of two rectangular tubes of wrought-iron plates riveted together; one tube being for the accommodation of the up line of rails, and the other for the accommodation of the down line of rails. A pier erected upon a rock in the middle of the straits divides each tube into two spans of 462 feet each, and there is also at each end a smaller tube of 230 feet span to serve as approaches to the bridge. These several tubes are joined together so as to form one long tube for each line of rails of the total length of 1524 feet.

The thickness of the central pier is 45 feet, of the side piers 32 feet each, and the tube projects 17 feet 6 inches over the masonry at each end. The bridge contains 9480 tons of wrought iron, 1988 tons of cast iron, and 1,500,000 cubic feet of masonry The total expense of its construction was 601,860*l.*, of which the iron work cost 443,160*l.* and the masonry 158,700*l.* It was commenced on the 10th of August, 1847, was finished on the 5th of March, 1850, and was opened for traffic on the 18th of March, 1850. A similar bridge of one length of tube and of a somewhat smaller span had been previously erected, under Mr. Stephenson's direction, over the river Conway on the same line of railway. This bridge was opened for traffic in 1848.

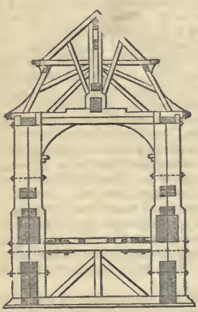
History of Tubular Bridges.— On the occasion of an entertainment given at the opening of the Conway bridge in 1848, Mr. Stephenson gave an account of the circumstances which had led to the conception of the plan of carrying a railway over a river or chasm by employing as a bridge a hollow beam or tunnel constructed of iron plates. About six or seven years before he had been called upon to construct a bridge on the Northern and Eastern Railway at Ware under certain limitations imposed by act of parliament which rendered bridges of the ordinary forms inapplicable; and he thereupon resolved to employ malleable iron beams, by the aid of which a cellular platform was made which answered the exigencies of the occasion. In this cellular platform however there does not appear to have been much novelty of conception, for it was merely an arrangement of beams of the ordinary form of railway girders, and the

(1.)

only peculiarity of these beams was that they were made of wrought iron instead of cast iron as had been the previous practice. They were proportioned moreover in the same manner as cast-iron beams, as will be seen by *fig.* 1., whereas malleable iron beams it is now known should have the top and bottom flanges of about the same dimensions. However, from the suggestions of this structure, the idea of a tubular bridge first arose in Mr. Stephenson's mind, and in his original conception he appears to have contemplated the use of elliptical or cylindrical tubes supported by chains. Mr. Stephenson's engagements did not permit him to work out this idea or to put it into such a practical form that he would have himself had confidence in carrying it into execution. He therefore called in the aid of Mr. Fairbairn to accomplish this task, and Mr. Fairbairn taking up the idea where Mr. Stephenson had left it, pursued the inquiry with great ardour and sagacity until he finally brought the idea into the form in which it was carried into practical effect.

Long before this time, however, a form of bridge much more nearly resembling that finally adopted for crossing the Menai Straits than Mr. Stephenson's cellular platform at Ware, or even than his subsequent conception of an oval or cylindrical tube supported by chains, had been successfully introduced in Switzerland; but the bridges which had been erected upon this plan, instead of being made of wrought iron, were constructed of timber. The first of these bridges appears to have been erected over the Rhine at Schaffhausen by Jean Ulrich Grubenmann in 1757. It consisted of two spans — the one of 170 feet, and the other of 193 feet. In 1778 another bridge of a similar construction was built by the same person over the Limmat at Wettingen. The span of this bridge was 390 feet. *Fig.* 2. is a section of this bridge at the ends, and

(2.)



(3.)

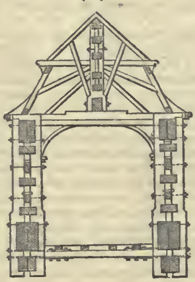


Fig. 3. is a section at the centre. It will be apparent from these figures that this bridge is composed of a platform for the roadway, two side frames of carpentry, and a roof, so that it in fact constitutes a great hollow timber beam of a nearly rectangular form. These bridges were both burnt by the French in 1799, after having remained in constant use, the one for forty-two years and the other for twenty-one years. Armies, artillery, and heavy weights, had passed over them in safety, and they appear to have perfectly fulfilled the purpose for which they were designed. Each of the side frames was raised into its place in a piece by means of powerful screw jacks resting on piles.

Subsequently to this time lattice bridges came into considerable use in America. These bridges consist of two or more great frames of carpentry formed of planks or timbers crossing one another diagonally and bolted at top and bottom to shelf pieces. The lower shelf piece carries a platform which forms the roadway, and in some cases the top is also covered with lattice work so as to convert the bridge into a hollow lattice beam. In a few cases these lattice bridges were formed of iron, and in Boston there is an elliptical tubular lattice bridge of iron of 120 feet span. This bridge had been in use a few years before the construction of that cellular platform at Ware which Mr. Stephenson says first suggested to his mind the idea of a tubular bridge. Lattice bridges formed of bars of iron have of late years come into use in this country. A singular phenomenon has been observed in some of these bridges. The centre of the bridge, instead of sinking, has actually risen up when the bridge has been put into its place.

In entering upon the consideration of the best mode of carrying out Mr. Stephenson's idea, it occurred to Mr. Fairbairn, upon whom this responsibility now devolved, that the most judicious course would be to institute a series of experiments to determine the breaking weight of beams or tubes of different forms, with the view of ascertaining what form of tube would reconcile the greatest amount of strength with the least quantity of material, and also what load a tube of a given form and of given dimensions could with safety sustain: these experiments were accordingly instituted, and they speedily furnished information of great practical importance. It was very soon found that oval and cylindrical tubes were not of so eligible a form as rectangular ones; and it was further found that in rectangular tubes the strength should be chiefly concentrated at the top and bottom, and in nearly equal proportions. It also occurred to Mr. Fairbairn that it would be advisable to make the top and bottom of the tube of a cellular form, which would obviate the necessity of using plates of such a thickness as could not be so securely riveted; and this construction, it was anticipated, would also impart greater stiffness to the structure, and render the top less liable to buckle up when a heavy strain was applied. The determination of the rectangular form of these bridges, the rejection of the chains, the introduction of the cellular structure of the top and bottom, and the settlement of all the details of the iron work, was unquestionably the work of Mr. Fairbairn; but it does not follow that Mr. Stephenson was unequal to the determination of these particulars, or that, if his other engagements had enabled him to perform the experiments which were judged necessary, instead of delegating them to other hands, a result equally satisfactory would not have been attained. However, the existing form of tubular bridge, as carried into execution for crossing the Conway river and the Menai Straits, is certainly quite as much Mr. Fairbairn's creation as it is Mr. Stephenson's, since Mr. Fairbairn settled the form, established the proportions, arranged all the details of construction, and set the first tube in its place.

Experiments to determine the best Form of Tube. — The first experiments were made upon cylindrical tubes formed of iron plates, riveted together like the chimney of a steamboat. The tube experimented upon was laid horizontally between two supports, and a small hole was cut in the centre of its lower side to enable a rod of iron to pass through; from this rod of iron the weights employed to ascertain the strength were suspended; around the hole a collar was riveted so as to impart as much strength to that part of the tube as before the perforation had been made, and a cushion of hard wood 8 inches square was fitted to the interior of the tube above the perforation. Through this piece of wood the rod which carried the weights ascended, and a cutter passing through the end of the rod rested on a square plate of iron superimposed upon the wood, so that from the wooden cushion the whole weights depended. Many of the tubes gave way by tearing at the riveting of the plates; but some also broke from the compression at the top. The more important results of these experiments are exhibited in the following tables: —

STRENGTH OF CYLINDRICAL TUBES USED AS BEAMS.

The thickness of the plates in these experiments was ascertained by cutting a portion of the plate into small pieces and screwing these pieces together in a vice. The collective thickness was then accurately measured, which divided by the number of pieces gave the thickness of each. It appears probable that the whole of the tubes would have been broken by compression, but for the weakening of the bottom caused by the rivet holes and which generally produced fracture by extension in that part.

The ends of the tubes where they rested upon the supports had to be kept in shape by circular pieces of wood inserted into them. When these pieces of wood were withdrawn, the ends were flattened horizontally. At the same time the centre of the tube was flattened vertically by the action of the weight hanging at the under side, and in looking endways at the tube the two sections made a species of cross; the ends forming the horizontal part of the cross, and the centre the vertical part.

The following are the results of the experiments made with elliptical tubes: —

Strength of Elliptical Tubes used as Beams.

(4.)

(5.)

Numbers 5. and 6. of the foregoing experiments were not made with simple elliptical tubes, but the tube employed in number 5. was an elliptical tube with a fin at the top (*fig.* 4.), and the tube employed in number 6. was more of a rectangular form with a fin at the top (*fig.* 5.). These top fins were not found to operate advantageously, as they were thrown into compression before the strain came on the top of the tube itself, and the strength was thus overcome in detail.

The most important of the experiments, however, are those upon rectangular tubes, the results of which are as follows: —

Strength of Rectangular Tubes used as Beams.

These experiments having been concluded and a few others of a similar character, which it would be needless to recapitulate, Mr. Fairbairn directed his attention to the determination of the proportions which it would be proper to adopt for the tubular bridges which it was proposed to construct. It was made very clear from the experiments, that the rectangular form was the best, and that the strength should be chiefly concentrated at the top and bottom of the tube, where the extending and compressing forces would act with greatest energy, and where they must be met. The proportion of the sectional area of the top to that of the bottom to give the maximum strength, was also found to be as 5 to 3 in the case of thin rectangular tubes. It was also made clear that the strength of a tubular beam would be increased if the buckling or crumpling up of the top side could be prevented, and it was known from previous experiments of Mr. Hodgkinson upon cast-iron pillars, that a given quantity of metal would better resist compression if disposed in a tubular form than if disposed in any other form. Hence it occurred to Mr. Fairbairn, that the compressing strain upon the top of the tube would be more effectually counteracted by disposing the metal in the form of longitudinal tubes than by disposing it in the form of a flat plate. The tube with the corrugated top, tested in the eighth experiment upon rectangular tubes, was made in pursuance of this idea, but eventually it was determined to form the top of the bridge of a series of parallel rectangular tubes or cells, chiefly because that form was more convenient in construction and better admitted of painting and repairs. The bottom of the tube it was considered advisable to make in the same fashion, and these points being settled, a model tube was constructed, which was nearly identical with one of the tubes of the intended bridge in every thing but size. The model tube was 78 feet long, and 75 feet between the supports; 4 feet 6¾ inches deep at the middle, and 4 feet 0¾ inches deep at the ends. It was 2 feet 8 inches wide in the body; but the cellular top was somewhat wider, being 2 feet 11½ inches wide, and the bottom, which was not cellular but consisted of a flat plate, was of the same width as the top. The cellular top was composed of six longitudinal channels formed by seven vertical plates 6½ inches deep running longitudinally from end to end of the tube and having a plate above and another below them extending through the whole length and breadth of the top. The thickness of the plate of the bottom of the model tube was ·156 inches, of the sides ·099 inches, and of the top ·147 inches. The sectional area of the top was 24·024 square inches, of the sides 9 square inches, and of the bottom 8·8 square inches. The weight of the tube was 4·86 tons. Its ultimate deflection was 4·375 inches, and its breaking weight 35½ tons. The tube gave way by tearing asunder at the bottom.

The top plates of the tube having been made a little thicker than was intended, two strips of plate 20 feet long, 6½ inches wide, $\frac{5}{16}$ths of an inch thick, and weighing about 4 cwt., were riveted along the bottom of the tube at the centre part. The ultimate deflection then became 4·11 inches, and the breaking weight 43·3 tons. In this experiment the tube got out of shape and collapsed. To obviate this evil for the future, vertical ribs of angle iron were riveted along the sides of the tubes internally at distances of 2 feet apart, and the tube having been repaired, was again subjected to experiment. The ultimate deflection was now found to be 5·68 inches, and the breaking weight 56·3 tons. As, however, in this experiment the fracture occurred, not at the centre of the tube, but at some distance to one side, where the plates were weak, a final experiment was made with the plates decreasing in thickness from the middle according to the proper law. The tube then broke by compression of the cellular top with a weight of 86¼ tons.

Mode of Determining the Dimensions proper for the Menai and Conway Bridges. — The strength of any beam larger or smaller than a beam of any given size, but which is increased or diminished proportionally, varies as the square of the alteration of its linear dimensions, or more nearly as the 1·9th power in the case of tubular beams, whereas the weight varies as the cube of any linear dimension. A beam, therefore, of twice the length, depth, and thickness of any given beam, will be about four times as strong and eight times as heavy. Taking the weight of the model tube upon which the

foregoing experiments were made at 6 tons, the distance between the supports at 75 feet, and the breaking weight of the tube at 60 tons, Mr. Fairbairn calculated that a tube of 400 span, such as was intended to carry the railway over the Conway river, would bear a load of 1704 tons exclusive of its own weight. For since the span of 400 feet is 5·33 times greater than that of the model tube, then $5{\cdot}33^2 \times 60 = 1704$ tons, and the weight of the tube will be $5{\cdot}33^3 \times 6 = 906$ tons. Now a given load distributed equally over a beam produces nearly the same strain upon it as half the load applied at its centre, or more correctly the ratio is as 5 to 8. Taking the half of 906 or 453 from 1704 we have 1251 tons as the actual load which Mr. Fairbairn considered that the tube would bear exclusive of its own weight.

Mode of Computation by Hodgkinson's Formula for Cast-iron Beams. — Some years before the formation of the Britannia and Conway bridges, Mr. Hodgkinson had ascertained the form of cast-iron beams which gave the greatest strength with the least material, and by the formula derived by Mr. Hodgkinson from these experiments, Mr. Fairbairn found that the model tube would bear about 20 tons if it were of cast-iron. But it actually bore 56·3 tons in one of the experiments of which the result was not the best, and introducing this correction into the formula, it appeared that a tube six times larger than the model tube, and therefore of 450 feet span, 27 feet deep, and with 460·8 square inches of sectional area of iron at the bottom, would bear 2018 tons exclusive of the weight of the tube itself. The results obtained by calculating the strengths as the squares and the weights as the cubes of the dimensions do not differ materially from the foregoing, and Mr. Fairbairn calculated that a tube of 462 feet span 31 feet deep and 460 square inches of area at the bottom would bear 2469 tons; and supposing the tube to weigh 1200 tons the breaking weight, when the load was applied at the middle, would be 1869 tons, exclusive of the weight of the tube itself. Now a tube which will carry 1869 tons at the centre, exclusive of its own weight, will he reckoned carry about twice this amount, or 3738 tons, equally distributed over it exclusive of its own weight; and taking the maximum load to which the bridge would be subjected at one ton per lineal foot, it followed that the bridge, when thus proportioned, would bear eight times the load that could ever be put upon it. One of the tubes of the Conway bridge when completed was tested in the same manner as the model tube by placing weights upon it and observing the deflections. The result was found to confirm the accuracy of the deductions derived from the experiments upon the model tube. The law followed by the deflections appeared to show that the tube would sustain a load of 2200 tons equally distributed over it, and exclusive of its own weight, before it broke, and that the ultimate deflection would be 30 inches.

Mr. Hodgkinson's Experiments. — Besides the experiments made by Mr. Fairbairn, a number of experiments upon tubular beams was made by Mr. Hodgkinson at Mr. Stephenson's desire, and from these experiments results were obtained of great interest in a scientific point of view. Mr. Hodgkinson found that the strength of tubes to resist compression varied greatly with the thickness of the metal of which they were composed. Thus, when the plates composing a tube, compressed in the manner of a pillar, were ·525, ·272, and ·124 inch, the resistances per square inch of section were 19·17, 14·47, and 7·47 tons respectively. Mr. Hodgkinson also found that the power of plates to resist compression varied as the cube, or, more nearly, as the 2·878 power of their thickness. He further found that long continued impact upon a tubular beam of small size, producing a deflection of less than one-fifth of what would be required to injure the tube by pressure, was completely destructive of the riveting. In large bridges, however, the inertia of the mass will, by resisting the effect of impact, prevent any such injurious effect from taking place. He also determined, experimentally, that the strength of similar tubular beams was as the 1·9th power of their linear dimensions. Mr. Hodgkinson further made a series of experiments to ascertain if the thickness of the plates of a tubular bridge might be diminished towards the ends, as indicated by theory, and he found that such was the case. The thickness of the plates of the top, bottom, and sides, at any point, was therefore made in the proportion of the rectangle of the segments into which the distance between the supports of the tube was divided at that point, the tube itself being of uniform dimensions throughout; but at and near the supports the thickness was half that of the middle. A further experiment was made to ascertain how far the effect would be advantageous to stiffen tubular beams with cast-iron applied at the top, and it was found that 10 square inches area of cross section of cast-iron at the top of the beam balanced 21 square inches of cross section of malleable iron at the bottom of the beam, proving that the cast-iron would resist compression more efficiently than the wrought. These investigations, howeve[r] though highly important, did not materially influen[ce] the configuration of the Conway and Menai bridges, th[e] proportions of which were mainly settled by Mr. Fai[r]bairn from his experiments upon the model tube alread[y] described. Experiments were also made both by M[r.] Fairbairn and Mr. Hodgkinson to determine the strengt[h] of tubular beams when laid upon their sides. The pu[r]pose of this investigation was to determine the later[al] strength to resist storms blowing on the side of the tub[e] and it was found that the proportions and strength proper for resisting the vertical strains would also give lateral strength more than sufficient to withstand an[y] storm to which the tube could be exposed.

Comparative Strains caused by Stationary and Movin[g] Loads.— In proportioning iron beams or girders to be[ar] any given load the prevailing practice among engineer[s] has heretofore been to give a strength adequate to carr[y] three times the load if the load be stationary, and twic[e] that strength, or a strength adequate to carry six time[s] the load, if the load be a moving one. At the time th[e] Conway and Menai bridges were constructed the precis[e] effect upon iron bridges of shifting pressures, vibration[s] and concussions consequent upon the passage of a rai[l]way train, was by no means accurately known; but sinc[e] that time those relations have been investigated by [a] commission appointed for the purpose, and it was one [of] their functions to ascertain what increase of the statica[l] pressure upon an iron beam or bridge would occasio[n] the same strain as a given velocity of the load. It [is] clear that this relation once determined the statical pres[]sure is all that has thenceforth to be considered, and th[e] question of the strength proper for all kinds of construc[]tions is consequently narrowed to the determination [of] the strength necessary to withstand a certain statica[l] strain, which is greater in an ascertained proportion tha[n] that due to the intended maximum load.

Effect of Momentum on the Deflection of a Beam.— If a load be placed upon any long or slender beam proppe[d] up in the middle, and the prop be suddenly withdraw[n] so as to allow deflection to take place, it is clear that th[e] deflection must be greater than if the load had bee[n] gradually applied. For the momentum of the weigh[t] and also of the beam itself, falling through the spac[e] through which it has been deflected, has necessarily t[o] be counteracted by the elasticity of the beam; and th[e] beam will therefore be bent momentarily to a greate[r] extent than what is due to the load, and after a few vi[]brations up and down it will finally settle at that poin[t] of deflection which the load properly occasions. It [is] obvious that such a beam must be strong enough no[t] merely to sustain the pressure due to the load, but als[o] that accession of pressure due to the counteracted mo[]mentum of the load, and of the beam itself; and this in[]creased strain is produced in the case of all beams t[o] which a deflecting weight is applied, but is most materia[l] in those in which a large and rapid deflection takes plac[e]. A rapid deflection increases the amount of the deflectio[n] as well as the amount of the strain, as is seen in th[e] cylinder cover of a Cornish pumping-engine, into whic[h] the steam is suddenly admitted, and in which the mo[]mentum of the particles of the metal put into motio[n] increases the deflection to an extent which the mer[e] pressure of the steam could not produce.

Effect of Deflection on the Amount and Position of th[e] Strain.— If a railway train moving at a high rate of spee[d] be made to descend a steep declivity, the pressure of th[e] wheels upon the rails will obviously be diminished; an[d] if the motion of the train be supposed to be very rapi[d] and the declivity very great, the wheels will leave th[e] rails altogether, and the train will advance after th[e] fashion of a projectile. In like manner, if a rapid trai[n] ascends a steep acclivity, the pressure of the wheels upo[n] the rails will be increased. Now a beam bent by a pass[]ing train forms both a falling and rising plane, and o[n] the first half of the beam the strain will be less tha[n] what is due to the load, and on the second half of th[e] beam the strain will be greater than what is due to th[e] load. The maximum strain therefore, and consequentl[y] the maximum deflection, will not be at the centre of th[e] beam, but at a point somewhere between the middle an[d] one end. In order to remedy this inconvenience th[e] beams of a railway bridge should be made with a sligh[t] rise in the centre, so as to form a straight line when de[]flected by a passing train.

Law of the increased Strain consequent upon Deflec[]tion.— The momentum of any moving body being pro[]portional to the square of its velocity, it follows that i[n] the case of a railway train deflected either sideways o[r] upwards by a curve or incline, the strain will be pro[]portioned to the square of the amount of motion in [a] new direction given in any specified time; or with an[y] given velocity of the train the strain will be proportiona[l] to the square of the amount of the deflection whic[h] takes place from a perpendicular or horizontal plane i[n] any given distance along the line.

Effect of the Inertia of Beams. — The mass of matte[r]

in a beam first resists deflection by its inertia, and then promotes deflection by its momentum; but whether in practical cases increased mass without reference to strength or weight will, upon the whole, increase or diminish deflection, will very much depend upon the magnitude of the mass, relatively with the magnitude of the deflecting pressure, and the rapidity with which that pressure is applied and removed. Thus, if a force or weight be very suddenly applied to the middle of a ponderous beam, and be as suddenly withdrawn, the inertia of the beam will, as in the case of a collision of bodies, tend to resist the force, and thus obviate deflection to a considerable extent; but if the pressure be so long continued as to produce the amount of deflection due to the force, the effect of the inertia in that case will be to increase the deflection. The mass must, under such circumstances, move through a space equal to the deflection, whereby a momentum will have been acquired that will afterwards expend itself in increasing the deflection. By far the severest strains, however, to which railway structures are habitually exposed arise from the jerks and concussions caused by the imperfect juncture of the rails at the ends, or other similar irregularities of surface, and a large amount of inertia in a beam will enable it to withstand such shocks much better than it could otherwise do. A large inertia compels the train to deviate from the horizontal plane to an extent answerable to the difference of weight of the striking and stricken bodies, so that if the bridge be heavy it will, under such circumstances, be less deflected, and consequently will suffer a less serious strain.

Law of the Elasticity of Iron Beams. — A bar of iron is usually regarded as a very stiff spiral spring, and it is supposed that it will be compressed or extended equally by equal increments of pressure. This law, however, though nearly true for malleable iron, is not true for cast-iron. The compressions and extensions of a bar of cast-iron one inch square, and of any length, were found by Mr. Hodgkinson to be represented by the following formulæ: —

For the extension, $w = 13934040\frac{e}{l} - 290743200\frac{e^2}{l}$.

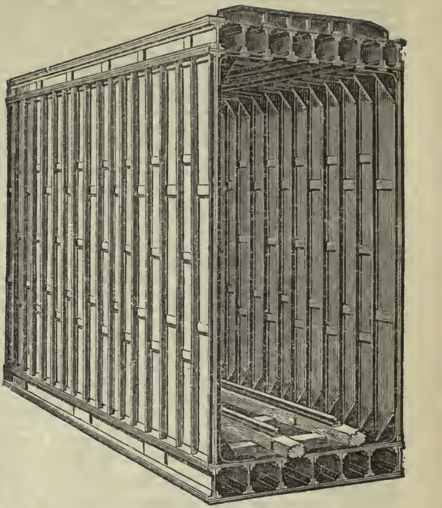
For the compression, $w = 12931560\frac{d}{l} - 522979200\frac{d^2}{l^2}$.

Here w is the weight in pounds acting upon the bar, e the extension, and d the compression in inches, and l the length of the bar in inches. Iron beams alternately deflected and released will be broken in time with a much less strain than that necessary to produce speedy fracture. Thus it has been found experimentally, that cast-iron beams deflected by a revolving cam to only half the extent due to their breaking weight will, in no case, withstand 4000 successive deflections; but 4000 successive deflections through one-third of the distance due to their breaking weight may be incurred without visible injury. Looking, however, to the various jolts, vibrations, and concussions to which railway structures are exposed, it does not appear that even a strength answering to six times the breaking weight gives an adequate margin for safety in the case of cast-iron beams.

Proportions to be observed in the Construction of Tubular Bridges. — The sectional area of the bottom of a tubular bridge of wrought iron plates should be to the sectional area of the top, as 11 to 12. The breaking weight is then found by multiplying the total area by the depth, by a constant (80), and dividing by the length. The depth of tubular beams of 150 feet span should be about $\frac{1}{13}$th of the span, and the depth of tubular beams of 300 feet span should be about $\frac{1}{15}$th of the span. These rules are empirical, but they are a near approximation to the most approved practice of the present time.

Description of the Britannia and Conway Tubular Bridges. — Having now indicated the manner in which the proportions and configuration of these bridges were arrived at, and having further pointed out the considerations which should influence the design of all railway bridges composed of iron beams, whatever be the subordinate features of their construction, it will be proper to describe briefly the more important features of the Britannia and Conway bridges as they at present stand. The annexed figure represents a portion of one of the tubes seen in perspective. There are two tubes in each bridge, one for the accommodation of the up line, and the other for the accommodation of the down-line. Each tube is rectangular, formed of plates of iron riveted together, and with ribs to support the sides, like the ribs of a ship. The most remarkable feature of the construction, however, is the cellular top and bottom. In all beams which have to be loaded in the centre, it is proper to concentrate the strength as much as possible upon the edges of the beam, or at the top and bottom; and in the case of these bridges this is done by building upon the top and bottom a number of square pipes or pillars joined laterally together, and running from end

(5.)



to end of the bridge. The upper pipes sustain a force of compression, the lower of extension; and the function of the sides of the tube is merely to keep these combinations for meeting compression and extension in their proper places. The sectional area of the top and bottom of the tubes may easily be computed by taking the width of each tube, which is 14 feet 8 inches, and the thickness of the plates; but in the model tube, which gave the best results, the sectional area of the top was to that of the bottom as 24 to 22, and this is the proportion commonly employed. There are eight cells or pipes composing the cellular top, each 1 foot 9 inches square. The plates composing the top of the Britannia bridge are, $\frac{12}{16}$ths at the middle of the bridge, and $\frac{10}{16}$ths at the ends of the bridge. The ends of the plates are carefully abutted together, and strips of iron are riveted over the joints. The bottom is composed of six cells or pipes, each 2 feet 4 inches by 1 foot 9 inches; and the upper and lower platforms, by the introduction of partitions between which the cells are constituted, consist each of a double thickness of plates so arranged that the end of each plate comes to the centre of the other, as shown in the accompanying figure. A small plate covers each joint, and as it was important not to weaken the bottom of the tube by the rivet holes running across it, the rivets are arranged in longitudinal rows, each a considerable distance from the other, and they act as cogs or steady-pins in keeping the plates together. By this expedient the longitudinal cohesion of the bottom is better maintained; and the strength of each tube approximates to what it would be if formed out of a solid piece of iron, instead of being built up of riveted plates. The thickness of the plates forming the upper and lower platforms of the bottom is $\frac{9}{16}$ths at the middle of the tube, and $\frac{7}{16}$ths at the ends. The vertical plates are, $\frac{9}{16}$ths at the middle, and $\frac{8}{16}$ths at the ends. The sides of the tube are, $\frac{8}{16}$ths at the middle of the bridge, increasing to $\frac{10}{16}$ths where the bridge rests upon the piers; for as the ends of the tube have to sustain the whole weight, they require to be made very strong and stiff to retain them in shape. To impart increased stiffness at the ends of the tubes strong cast-iron frames are introduced within them, and an arrangement of rollers is put beneath the ends of the tubes to enable the metal of the tubes to expand or contract with changes of temperature.

(6.)

The tubes of each bridge were built in the same manner as an iron ship, adjacent to the place where they had to be erected. A wooden platform or quay was erected upon the shore, upon which a tube was built, and stone supports were subsequently erected at the ends, upon which the tube when completed was made to rest. The

timber platform was then cleared away, so as to enable a number of boats or pontoons to be floated beneath the tube, and these rising with the tide lifted the tube. The floating mass was then drawn by ropes across the stream, and the ends of the tubes were rested in shelves left in the masonry of the piers, by which the tube had to be sustained. On the tops of the piers hydraulic presses were set, from which chains descended to the ends of the tube, and by putting these hydraulic presses into operation the tube was raised up a small distance, and so soon as it was raised sufficiently above the shelf the intervening space was built up. Another lift was then taken, and so on, the masonry following up the tube as it ascended, until it reached the level of the top of the piers. In the Britannia bridge there are four spans; and the tubes of each span are joined together at the ends, so as to form one long tube for each line of railway. The effect of thus joining the ends of the tubes is virtually to diminish the span, for the tube takes a contrary flexure where it passes over the piers, and if a line be drawn down the side of the tube where these contrary flexures meet, it will be found that the tube might be cut through that line without weakening it at all.

Chepstow Tubular Bridge.—A tubular bridge of a construction very different from that of the Conway and Britannia bridges has been designed by Mr. Brunel, for carrying the South Wales railway over the river Wye, at Chepstow. This bridge has a nearer resemblance to a suspension bridge than to a hollow beam; but instead of the heads of the towers being tied back by chains, as is usual in suspension bridges, they are kept asunder by cylindrical struts of wrought iron, and rods descend from the tops of the towers, which are also of iron, to support the platform of the bridge. The limits of this article, however, prevent any detailed description being given of this bridge and of other tubular bridges which have been constructed since the Conway and Menai bridges were projected. (For further information on the subject, see Mr. Fairbairn's *Account of the Construction of the Britannia and Conway Tubular Bridges*, and the *Report of the Commission appointed to inquire into the Application of Iron in Railway Structures*.)

TURGITE. A compact reddish brown mineral composed chiefly of oxide of iron, found in the Turginsk copper mines in the Ural.

TURNBULL'S BLUE. A modification of *Prussian Blue*. It is a *Ferridcyanide of Iron:* its ultimate components are 5 atoms of iron, 12 of carbon, and 6 of nitrogen.

TURNER'S CERATE. This is the *calamine ointment* of the Pharmacopœia. The modern zinc ointment prepared with oxide of zinc and hogs' lard is a good substitute for it; it is a mild drying ointment.

TURNER'S YELLOW. The fused oxichloride of lead, in fine powder: it is the basis of a good yellow oil colour formerly much used in coach-painting: it is also called *patent yellow*, and *Cassel yellow*.

TURPETH MINERAL. The yellow subsulphate of mercury, so called from its yellow colour, which resembles that of the root of the *Ipomœa* or *Convolvulus Turpethum*.

TYMPAN. (Lat.) A part of a printing-press on which the blank sheets are placed.

TY'ROLITE. A native arseniate of copper found at Falkenstein in the Tyrol.

TY'ROSINE. A crystalline substance obtained from cochineal.

U.

U'LLMANNITE. A sulphuret of nickel, antimony, and arsenic, from Siegen, analysed by Ullman.

UMBILI'CAL CORD. In Anatomy, the cordlike prolongation of the teguments of the abdomen, including the vessels which pass from the fœtus to the placenta in placental mammals; or to the allantois and vitellicle in implacental mammals, birds and reptiles; or to the vitellicle alone in plagiostomous fishes. In other fishes, in batrachians, and in most invertebrates, the vitellicle is sessile, and there is consequently no umbilical cord.

UMBILI'CAL VESICLE. The name given to the proportionately small vitellicle, or yolk bag, in man and most mammalia.

U'SNINE. A substance extracted from different lichens of the genus *Usnea*. It forms yellow and very difficultly soluble crystals, fusing like a resin. It has slightly acid characters, and forms crystallisable compounds with the alkalies: hence it has also been called *Usnic acid.* Its ultimate composition is represented by the formula C_{38} H_{17} O_{14}.

U'TERINE. (Lat. uterus.) In Anatomy, that which appertains to the womb, as the uterine arteries, veins, nerves, and the uterine portions of the placenta or cotyledon.

UTERUS. (Lat.) The womb, or the muscular and vascular part of the efferent canal or tract in the female viviparous or ovo-viviparous animal, in which the fœtus is developed. In the human subject and quadrumana it is single; in many quadrupeds it is bifid; in some, it is completely divided into two symmetrical uteri.

UTRI'CULUS. (Lat.) In Anatomy, the term is applied to the upper and larger of the two divisions of the vestibular portion of the membranous labyrinth of the internal organ of hearing.

UVIC ACID. (Lat. uva, *the grape*.) A synonym of the *Racemic* or *Paratartaric acid*, an acid isomeric with the tartaric, but differing from it in certain respects, more especially in its relations to polarised light.

V.

VACCI'NIC ACID. A name given by Lerch to a peculiar volatile acid which occasionally replaces the butyric and caproic acid in butter.

VALERIA'NIC, or VALE'RIC ACID. This acid constitutes the leading ingredient of the volatile oil obtained by distilling valerian root with water. It may also be obtained from the root of *Angelica*, so that it has been called *Angelicic acid;* and it is contained in the bark of the *Viburnum opulus*. Lastly, valerianic acid is artificially formed by the action of a mixture of quick lime and caustic potassa, on the oil of potato spirit, the *fusel oil* of the Germans, the *hydrated oxide of Amyle* of modern chemists. The formula of this acid is C_{10} H_9 O_3+HO. It is an oily colourless liquid, smelling intensely of valerian, and of a sour, pungent, and nauseous taste, leaving a sense of sweetness, and a white spot upon the tongue.

VALO'NIA. The cup of a large species of acorn imported from the Levant and the Morea, and largely used by tanners.

VAREC. The impure carbonate of soda, made in Brittany: it is also sometimes called *Blanquette:* it corresponds to our *Kelp*.

VASODE'NTINE. (Lat. vas, *a vessel*, dens, *a tooth.*) In Anatomy, that modification of dentine in which capillary tracts of the primitive vascular pulp remain uncalcified, and carry red blood into the substance of the tissue. They form the so-called vascular or medullary canals, and are usually more or less parallel in their course. A large proportion of the central part of the tooth of the sloth and megatherium consists of vasodentine, and a smaller proportion of the same part of the tusks of the elephant and of the scalpriform incisors of the rodents.

VAU'QUELINITE. The native double chromate of lead and copper: named in honour of Vauquelin, the late celebrated French chemist.

VEDETTE or VIDETTE. (Fr. from Lat. video, *I see.*) A sentry placed on an outpost or elevated point, so as to be able to observe advantageously the approach of an enemy, and to give early notice of his movements.

VE'GETAL. (Lat. vegeo, *to flourish;* vegetus, *lively.*) In Physiology, that class of vital phenomena common to plants and animals: viz. digestion and nutritive assimilation, growth, absorption, secretion, excretion, circulation, respiration, generation; as contradistinguished from a second class of vital phenomena, viz. sensation and volition, peculiar to animals: the first are called the "vegetal functions," the second "the animal functions;" and the powers or forces on which they depend have been termed respectively the "vegetal life" and the "animal life."

VE'NA PORTÆ. (Lat.) In Anatomy, the great trunk formed by the union of the veins from the abdominal organs of digestion, which trunk ramifies, after the manner of an artery, in the substance of the liver, and transmits its blood by capillaries to the hepatic veins.

VE'NICE WHITE. A pigment consisting of carbonate of lead mixed with sulphate of baryta. *Dutch White* and *Hamburgh White* are similar mixtures.

VE'NTRAL. (Lat. venter.) In Anatomy, the parts or the aspect of the region of the belly: the plates of the vertebral or serous layer of the embryo that are extended towards that region are called "the ventral laminæ."

VERA'NDAH. A term of Eastern origin applied to a light gallery external to a house, supported on pillars, and frequently inclosed in front with lattice work. In England verandahs are frequently met in villas and cottage residences attached to sitting rooms on the ground floor, where they afford a good substitute for a colonnade, and provide shelter against rain and sun.

VERA'TRIC ACID. An acid contained in the seeds

of *Veratrum sabadilla*, hence also called *sabadillic acid.* Its formula is $C_{18} H_9 O_7 + HO$.

VERGERS. Officers of the courts of law who carry white wands before the judges. There are also vergers attached to cathedrals and collegiate churches, who carry a small mace or rod tipped with silver before the clergy.

VERGE'TTE. In Heraldry, a pallet, or small pale. A shield divided by pallets is termed *Vergette.*

VERMICE'LLI. (Ital.) A paste of wheat flour in the form of wormlike cylinders of various diameters: the smallest or thread-like being termed *vermicelli*, and the larger *macaroni.* It is also cut into ribbands and other forms, and is then called *Italian paste.* It is made by forcing the paste through small apertures in an iron plate, which is done by a powerful screw press. The most glutinous varieties of wheat are those which yield the fittest flour for this manufacture.

VERMI'CULITE. (Lat. vermis, *a worm.*) A fine scaly talc composed of micaceous plates cemented together by a whitish matter; it is a hydrated bisilicate of magnesia, oxide of iron, and alumina. When heated to redness it projects out with a vermicular motion as if it were a mass of small worms. Hence the name.

VE'RMIFORM. (Lat. vermis, and forma, *shape.*) In Anatomy, certain parts that are convoluted and shaped like a worm are so called, as, *e.g.* a hollow process or prolongation of the intestinum cæcum; a part along the middle of the upper and under surfaces of the cerebellum.

VERST. A Russian measure of length containing 3500 feet; about three-fourths of an English mile.

VE'RTEBRA. (Lat. verto, *I turn.*) The term, restricted, in Anthropotomy, to certain moveable portions of the segments of the skeleton of the trunk, is now applied, in Anatomy, to the entire segment; which consists, in its typical state, of a "centrum," "two neurapophyses" and a "neural spine," two "hæmapophyses" and a "hæmal spine," and two "pleurapophyses." The principal processes of a vertebra, which are usually exogenous, are, the "parapophyses," the "metapophyses," the "hypapophyses," the "diapophyses," the "anapophyses," and the "zygapophyses." The endoskeleton of the vertebrate animals consists of a series of such segments or vertebræ, some of which may support a pair of "diverging appendages," and two pairs of such are usually developed into limbs.

VESICA'TORIN. *Cantharidin.* The blistering principle of *Cantharides*, *Lytta*, *Mylabris*, and other blistering beetles. *See* CANTHARIDES, in DICT.

VE'SPERS. (Lat. vesper.) Evening service in the Roman Catholic church.

VICTO'RIA. The name given to one of the small planets between the orbits of Mars and Jupiter. It was discovered by Mr. Hind, at Mr. Bishop's observatory, in the Regent's Park, on the evening of the 13th of September, 1850, in the constellation *Pegasus*, and is the twelfth of the group in the order of discovery. Its brightness is somewhat greater than that of some of the others, being equal to that of stars of the eighth magnitude. Mr. Hind selected as the symbol of the new planet a star and laurel leaf, emblematical of the Goddess of Victory. (*Monthly Notices of the Royal Astronomical Society*, vol. xi.) *See* PLANET.

VI'LLARSITE. A mineralogical name of one of the hydrated silicates of magnesia.

VILLI. (Lat. villus, *wool.*) In Anatomy, the name given to minute vascular processes covering, in the proportion of about twenty-five to every square line, the surface of the mucous membrane of the small intestine, and giving it a velvety or fleecy appearance. They promote the absorption of chyle from the completely digested food. Similar minute vascular processes of the chorion and other membranes are called "villi."

VI'OLINE. An emetic principle contained in the root of the *Viola odorata*, or common violet.

VIRGI'NEIC ACID. A name applied by Querenne to one of the acids contained in the rattlesnake root of America (*Polygala Senega*). It is a volatile fatty acid, of a strong disagreeable odour and taste.

VI'SCERA. (Lat. viscus, *a bowel.*) The contents of the three great cavities of the body: the brain, *e.g.* is the viscus of the cranium, the heart one of the viscera of the thorax, and the stomach one of the abdominal viscera. The term is usually restricted to the organs of the thorax and abdomen; for the myelon is as much entitled to be called a viscus of the spinal canal, as the encephalon a viscus of the cranium. The hæmal arches of the cranial vertebræ have been called "visceral" in the embryo, and their interspaces the "visceral clefts."

VITE'LLICLE. (Lat. vitellus, *yolk.*) The bag which is developed around the food-yolk, or that part of the yolk which has not been converted into the germ-mass and embryo: it is chiefly formed by a development of the inner layer of the germinal membrane; the constricted part at which it is continued into the wall of the intestinal canal is called the "vitelline duct." In man and mammalia the vitellicle is called the "umbilical vesicle."

VI'TTIE VAYR. The Tamool name under which perfumers sell the fibrous roots of the *Andropogon muricatum*: they contain an agreeable odorous oil. The *oil of lemon-grass*, and the *grass oil of Namur*, are obtained from other species of *Andropogon.*

VI'VIANITE. A native hydrated phosphate of iron which occurs in beautiful crystals at St. Agnes, in Cornwall.

VOL'TAITE. A species of *iron alum*, which occurs in black octaedral crystals in the Solfaterra of Puzzuoli. Named in honour of Volta.

VO'LTZITE. A native oxisulphuret of zinc, found at Rosiers, in the department of Puy de Dome: named after Voltz, the engineer of the mines.

VOMICI'NA. A name given by some pharmaceutical chemists to the alkaloid more usually termed *Brucia*, obtained from the bark and seeds of the *Nux vomica* and from *St. Ignatius' bean*; it is usually associated with *Strychnia.*

VO'RAULITE. A mineralogical name of the ferromagnesian phosphate of alumina, found near Vorau, in Styria. It appears to be a species of *blue-spar*, or *lazulite.*

VU'LCANITE. A mineralogical synonym of the pyroxene, or volcanic garnet.

VU'LGATE. (Lat. vulgatum, *made public.*) The Latin translation of the Old Testament, which is as highly reverenced in the Roman Catholic church as the original itself, and from which the texts and other portions of Scripture used in the liturgy are taken. The translation earliest in use was commonly called "Itala," and made from the Septuagint. Saint Jerome composed a new one from the original Hebrew. These two translations were, in after times, intermingled, and the Vulgate is composed partly of each: *e.g.* the Psalms are in the old or Italic translation. The Vulgate is declared authentic, and appropriated to the use of the church, by the Council of Trent.

W.

WAFERS. Adhesive discs for securing letters or sticking papers together. Common wafers are punched out of a paste made of very fine flour which is pressed between two heated plates of smooth iron. Transparent wafers are made of films of isinglass or gelatine, dried upon plate glass, and punched out of various forms and sizes. Wafers are coloured with various materials, but care should be taken that these are not, as is often the case, of a poisonous nature. The wafer makers are very unwilling to show the process.

WAGNERITE. The native fluo-phosphate of magnesia, from Herpen, in Salzburg.

WARD'S PASTE. A quack medicine, of which *pepper* is the active ingredient, and which has obtained some celebrity as a remedy for piles, and for fistulæ and abscesses about the rectum. Its efficacy is said to depend upon the gentle stimulus which it gives to the affected parts, and severe cases of piles are sometimes relieved by it. The *Confection of black pepper* of the *London Pharmacopœia*, which is a mixture of powdered black pepper, elecampane root, fennel seeds, honey, and sugar, is intended as a substitute for this remedy.

WART. A thickening and induration of the cuticle, which is elevated in different forms. They frequently wear away by abrasion, and may be removed by caustic applications, amongst which nitrate of silver, and acetic or nitric acid, are most commonly employed.

WASP. *See* VESPIDÆ in DICT.

WATERING OF STUFFS. This is a process to which silk and some other woven fabrics are subjected, with a view of giving a peculiar appearance to their surface, as seen by reflected light: it is generally done by passing the goods, in a damped state, between rollers, some of which are variously indented or engraved: sometimes the appearance depends upon the pressure of one fold of the stuff laid transversely or diagonally upon another, and powerfully pressed between plain revolving cylinders.

WATERPROOFING. The process by which textile fabrics are rendered impervious to water. This is most perfectly effected by means of caoutchouc, which is applied in various ways, but there are other substances, and among them some of the earthy soaps, which are more or less effective, such, for instance, as a mixed solution of soap and alum, to which some gelatinous material is occasionally added.

WE'BSTERITE. The native subsulphate of alumina, from Newhaven on the coast of Sussex: named in memory of Webster, the geologist.

WEN. A term commonly applied to fleshy and other tumours, more especially when they affect the face or neck.

WHOOPING COUGH. *Chincough*, or *Kincough*. A disease characterised by a convulsive cough, accompanied by a peculiar sonorous or whooping inspiration, and returning by paroxysms which are usually terminated by vomiting. It is infectious, and most commonly attacks children, seeming to depend upon a specific infectious or contagious matter, and affects the same individual once only. It usually comes on with slight febrile symptoms, hoarseness, and common cough, and in about a fortnight the spasmodic attacks ensue. The fit is terminated by expectoration of mucus, or vomiting of the contents of the stomach, after which the patient returns to his usual pursuits, and generally expresses a desire for food, except in very severe cases, where lassitude and fainting ensue, and often bleeding from the nose and headache. The disease is of very variable duration, but generally goes off gradually after having lasted for some weeks. The dangerous cases are those in which the head is much affected, or which are accompanied by bronchitis. The treatment consists in obviating irritation, keeping bowels open, giving nauseating medicines, and perhaps an occasional emetic, and in full habits blisters and leeches may be resorted to. Sedatives or narcotics, carefully administered, are often of the utmost service, especially hemlock, henbane, or even opium, in conjunction with squills and ipecacuanha. Opiate and stimulating liniments applied to the chest and to the region of the spine are also frequently resorted to. A mixture of cochineal and carbonate of potash has by some been considered as almost a specific in the treatment of this disorder. The relics of the cough, which are often very tedious and obstinate, are best removed by change of air.

WI'LLIAMSITE. A mineralogical synonym of the native silicate of zinc.

WI'NCING MACHINE. The reel by which the dyer winds various articles through the dyeing vat or copper.

WINTER-GREEN. The *Chimophila umbellata*. This plant, under the name of *Pipsisseiva*, was first used medicinally by the aborigines of America. The infusion of the dried leaves is tonic and diuretic. It has been found useful in some chronic affections of the urinary organs.

WINTER'S BARK. The bark of the *Drimys Winteri*, or *Wintera aromatica*, a large forest tree growing in Chili, Peru, and New Granada, and which was first brought to England by Captain Winter, who accompanied Sir Francis Drake, in 1578, to the Straits of Magellan, where he obtained his specimens. It is found in the market in large quills or rolled pieces of a dull yellowish grey colour, an aromatic odour, and warm pungent flavour. It was at first confounded with *Canella bark*, which it much resembles in appearance and flavour, but its inner surface is reddish brown, whereas that of canella is much paler, and solution of sulphate of iron gives a precipitate in its infusion, but not in that of canella. Canella is the bark of the *Canella alba*, a large tree growing in the West Indies and America.

WITCH MEAL. A popular name given to the pollen or powder sold in the shops under the name of *Lycopodium*, procured from the *Lycopodium clavatum*, or *Club moss*. It contains a large quantity of oily inflammable matter, and when thrown into the flame of a candle produces a sudden flash or blaze, whence it is theatrically used for imitating lightning. It has also, from its yellow colour, been called *Vegetable sulphur*. In pharmacy it is used for enveloping pills to prevent their adhesion, and for which, being tasteless and inert, it answers well, and better than magnesia, which is usually employed for that purpose.

WI'THAMITE. A mineral discovered by Witham in minute red crystals in the porphyry of Glencoe. It appears to be a ferro-silicate of alumina.

WOAD. The *Isatis tinctoria*, or *Woad plant*, yields by the fermentation of its leaves a blue colouring matter resembling indigo. It is the *Pastel* of the French.

WO'HLERITE. A crystallised mineral containing tantalic acid, zirconia, and silica, found embedded in the zircon-sienite, near Brevig, in Norway. Analysed by Scherer, and named in honour of Wöhler, the eminent chemist.

WO'LCHITE. An arsenio-sulphuret of lead, copper, and antimony found in rhombic crystals in the iron mines at Wölch, in the Lavant valley, in Carinthia.

WO'LFSBANE. The popular name of the *Aconite*, called also *Monkshood* from the shape of its flowers. In sufficient doses it is virulently poisonous, its most characteristic effects being the production of tingling and numbness, vomiting, contracted pupil, failure of the circulation, and occasional convulsion. The root has sometimes been mistaken for horseradish, and has led to fatal results. It has been medicinally used with great success in some obstinate cases of *tic doloureux*, or *neuralgia*. Its powers are ascribed to the presence of the alkaloid *Aconita*.

WORM BARK. The bark of the *Andita inermis*, or *Cabbage bark tree*, of the West Indies. It is cathartic, emetic, and narcotic, in doses of from 20 to 30 grains. It is usually given in the form of decoction.

WORMSEED. The substance sold under this name consists of broken peduncles, mixed with the calyx and flower buds of some species of Artemisia, and is not the seed of *Artemisia Santonica*, as usually represented. Wormseed is imported from the Levant, and used as a vermifuge in doses of from 10 to 30 grains.

WORM TEA. A preparation kept in the shops of the United States, and much used: it consists of spigelia root, savine, senna, and manna.

WORMWOOD. The *Artemisia Absynthium*. It contains a peculiar, bitter principle, to which its medica virtues may be ascribed, called *Absynthine*. Its infusion was formerly a favourite popular remedy for worms, but it is now in disuse.

WOUND BALSAM. The compound tincture of *Benzoin* of the Pharmacopœia, known also as *Friars balsam*.

WOURARA or WOURALI. *Ourari*. A powerful poison used in Guiana: it is obtained from a species of *Strychnos*. *See Waterton's Essays on Natural History*.

WRY'NECK. A permanent inclination of the head towards one of the shoulders, not connected with distorted vertebræ, and arising often from a contraction of the integuments from burns, or other causes, or from a contraction of the fibres of the sterno-mastoid muscle.

WU'LFENITE. A mineralogical synonym of the native molybdate of lead.

WY'VERN. In Heraldry, an imaginary animal resembling a flying serpent.

X.

XA'NTHINE. (Gr. ξανθος, *yellow*.) The yellow colouring principle of madder.

XA'NTHITE. (Gr. ξανθος.) A mineral found in small grains and crystals of a yellow colour, at Amity, Orange county, New York: its principal constituents are silicate of lime and silicate of alumina.

XANTHOPHYLLINE. (Gr. ξανθος, *yellow*; φυλλον, *a leaf*.) The yellow colouring matter formed in autumnal leaves.

XA'NTHOPHY'LLITE. (See above.) A yellow foliated crystalline mineral, found in the talc slate in the Ural: it is a ferrosilicate of alumina, lime, and magnesia.

XA'NTHOPI'CRITE. (Gr. ξανθος, and πικρος, *bitter*.) A crystalline bitter principle contained in the bark of the *Xanthoxylum Caribæum*, which is used in the Antiles as a febrifuge.

XA'NTHOPRO'TEINE. (Gr. ξανθος, and πρωτειον, *the chief rank*.) A yellow acid substance formed by the action of nitric acid upon fibrine.

XA'NTHORHA'MNINE. (Gr. ξανθος, and ῥαμνος, *a kind of shrub*.) A yellow substance extracted from the berries of *Rhamnus tinctoria*, the *Persian berries* of commerce.

XE'NOLITE. (Gr. ξενος, *foreign*, and λιθος, *a stone*.) A silicate of alumina, from Peterhoff, in Finland: it appears to be a species of cyanite.

XESTA. (Gr.) An Athenian measure of capacity, answering to the Roman sextarius.

XY'LITE. (Gr. ξυλον, *wood*.) A ligniform asbestus, from the Ural.

XY'LOIDINE. (Gr. ξυλον, *wood*.) A white granular substance, formed by the action of nitric acid upon starch, and upon certain modifications of lignine: it is related to Schönbein's *Gun cotton*.

XYLO'RETINE. (ξυλον, *wood*, and ῥητινη, *resin*.) A crystalline resinous substance found in certain varieties of turf.

Y.

YELLOW EARTH. A mixture of hydrated silicate of alumina and peroxide of iron, found in Scotland, Bavaria, the Harz, and elsewhere: it is sometimes used as a coarse yellow pigment.

Z.

ZEA MAYS. See MAIZE, in DICT.

ZEDOARY ROOT. The sliced tuber of *Curcuma Zedoaria*, a warm aromatic bitter. *Zerumbet root* is a similar product.

ZEIL'ANITE. A species of spinel or corundum from Ceylon. It has also been called *Candite*.

ZEUXITE. (Gr. ζεῦξις, *connection*, because found in the *United Mines*, Cornwall.) A mineral, composed of fibrous crystalline aggregates of a greenish brown colour, and having the appearance of asbestous actinolite. It is a hydrated ferro-silicate of alumina.

ZIE'GA, or SERAI. After rennet has ceased to produce the coagulation of milk, the addition of acetic acid occasions a further separation of curd, to which the above names are applied.

ZI'NCITE. Native ferriferous oxide of zinc, found with Francklinite and calcareous spar, at Franklin and Stirling, in New Jersey.

ZI'NCKENITE. A native sulphuret of antimony and lead, found near Stolberg, in the Harz, named after its discoverer Zinken.

ZOLLVEREIN. (Germ. *Customs Union*.) A name given to the German Commercial Union, of which Prussia is the head, by which it was determined that there should be perfect freedom of commerce between all the states that joined it: that the duties on importation, exportation, and transit, should be identical in all such states: that these duties should be charged along the frontier of the dominions of the contracting parties, and that each should participate in the produce of such duties in proportion to its population. The basis of this league was first laid in 1818: since which period it has been gradually joined by nearly every German state, except Austria; and there is reason to believe that this last power will soon be included in its arrangements. (See *Com. Dict.* art. PRUSSIAN COMMERCIAL UNION.)

ZOMIDINE. (Gr. ζωμος, *broth*.) The aqueous extract of flesh: one of the substances giving the odour to meat-broth, and probably the same as OSMAZOME.

ZONA PELLUCIDA. (Lat.) In Embryology, the external investment of the ovarian ovum in mammalia, which consists of a thick transparent membrane, and appears, under the microscope, as a bright zone or ring.

ZWIE'SELITE. A fluophosphate of iron and manganese, found at Zwiesel, in Bavaria.

ZYGA'NTRUM. (Gr. ζυγον, *a yoke*.) The articular cavity at the back part of the neural arch of the vertebræ of serpents and some lizards which receives the zygosphene.

ZY'GAPOPHY'SIS. (Gr. ζυγον, *a yoke; αποφυσις, a process*). The articular or oblique process of the vertebra, by which it is connected to the adjoining vertebræ.

ZY'GOSPHENE. (Gr. ζυγον, and σφην, *a wedge*.) The wedge-shaped process from the fore part of the neural arch of the vertebræ of serpents and some lizards, superadded to the ordinary anterior zygapophyses, and articulated to a cavity in the antecedent vertebra.

ZYMO'TIC. (Gr. ζυμη, *leaven*.) In Medicine, diseases caused apparently by the reception into the system of a virus or poison, which is diffused through the frame, and operates upon it like a ferment or leaven. In the Registrar-general's Report, the following diseases are grouped together as "zymotic:" — small pox, measles, scarlatina, hooping cough, croup, thrush, diarrhœa, dysentery, cholera, influenza, purpura and scurvy, ague, remittent fever, infantile fever, typhus, metria or puerperal fever, rheumatic fever, erysipelas, syphilis, noma or canker, hydrophobia.

THE END.

LONDON:
SPOTTISWOODES and SHAW,
New-street-Square.
